So far as the Government part of this is concerned the Government doesn't need to, and shouldn't, take any hand in the development of the power, and there isn't a man in the United States who recognizes more fully than I do, the importance of power development or who is more earnestly, in season and out of season, every day of the year, for water power development.

Let me say one word more about this question of water power. Many people say to you that water power will pay the entire cost of the improvement of the St. Lawrence. Well I say to you that as a matter of law, it can't do that and as a matter of justice and fairness it shouldn't do that. This water power will be developed under the General Water Power Bill and I had the honor personally to make the fight which kept boundary streams in the General Water Power Bill. You have the legislation ready and all you have to do is to give private capital the opportunity to develop the power.

The General Water Power Bill provides this,—and it is not going to be changed because it is a just and fair bill,—it provides that when the state where the water power is developed has a Public Service Commission, that that Public Service Commission shall regulate the charges. On what principles are they regulated? They regulate them on this basis, they allow the companies to prove what it costs per horse power to develop the power which they are selling. They allow them a reasonable sum for depreciation and amortization and then they allow them a reasonable profit. Now how are they going to allow for something that hasn't anything to do with water power? Because navigation has no connection with water power, navigation is an entirely separate and distinct thing. How can they allow those who develop the water power to charge the consumers of the power for the development of navigation in the St. Lawrence? It can't and shouldn't be done and we shouldn't, for one moment, delude ourselves with any dream that we are going to pay the entire cost of improvement of navigation out of the development of the water power. Why, this country needs the improvement of its transportation facilities. All along the Atlantic Coast, starting in from Boston and Portland, including every southern port, Baltimore, Savannah, Charlestown, Mobile, Galveston, New Orleans, every port is growing from day to day and year to year in its commerce, and most of these ports are growing rapidly in the export of wheat.

Do you realize,—and it seems impossible for those who haven't examined it to realize it,—do you realize that on the Houston Ship Canal they are carrying 10,000,000 tons of freight a year? Of what kind? They are carrying that material which is just as useful as water power,—oil. And it is increasing in quantity from month to month and they have found down there that it is not economical to have a 25 foot water-way, on that little stream leading up from the ocean, only about 50 or 60 miles long. They have found that 20 to 22 ft. depth wouldn't do. They have 25 feet and they are before Congress at this session to get it increased to 30 feet and the Committee, of which I have the honor to be Chairman, has reported a bill to give them their 30 feet depth. There isn't anything any more important to the development and the progress of this nation than the use of oil and its various products. There isn't anything that is multiplying in its use from day to day, with anything like the rapidity of oil, and there is no place where it is being shipped as it is down in those gulf ports. And there is one of the things that you have to do. We haven't any money in this Bill for deepening these harbors. We are simply going to

adopt the project and then trust to Providence that we can persuade Congress that it is necessary to let this oil come to us just as cheaply as it can, let the cost of gasoline go down five cents, if it is possible to do so take it out of the transportation costs. Isn't that a real problem to be weighed against the St. Lawrence route? Isn't it as important to us as developing a waterway in the foreign country? And that is only one of our pressing needs. Here is the Ohio River. Congress over 26 years ago adopted the project of improving the Ohio River by locks and dams. In 1910, after seven of the 54 locks and dams were completed, we provided that we should complete that improvement within 12 years. Twenty-six years have passed. We have improved 500 miles of it, about half, and the rest remains to be done.

The Ohio runs between coal mines and forests, rich fields waving with grain and all the products of the soil and, in its upper portion, through a beehive of manufacturing plants which have caused that section to be called "The Workshop of the World;" and cheap transportation can be had to carry all these products from Pittsburg, Cincinnati, St. Paul, St. Louis, New Orleans and intermediate points; and all of those great American cities which we love just as much as we do Montreal and Toronto, which are just as near our hearts; yet how are we going to get the money to complete this great transportation project if we spend hundreds of millions of dollars upon one foreign waterway, when it is hard to wring thirty millions of dollars out of an unwilling Congress for all the waterways of this great country of ours.

And then the Mississippi flows down dividing our whole empire of states, with great grain fields on both sides of it, furnishing to the vast territory tributary to it a far shorter route to the sea than the St. Lawrence route, and the southwest pass needs to be improved, and it will take millions to complete the work. Where are we to find the money if we spend all our income on the St. Lawrence? We never have provided that the nation should deepen the harbors on the Mississippi and they are all filled and silted and haven't the requisite depth. Don't we need the money to do that? Shouldn't we provide it? Don't we love all those cities down there just as much as we do Canada? And isn't it just as important to the life and the prosperity of this nation as a whole, that that great river be improved?

And so you could go over the various waterways of the United States, taking them one by one, pointing to their use in the national system of transportation. Why, as I think of this St. Lawrence route, I think of something that is in the mind of this nation because the President has recently brought it to the attention of Congress. I think of the fact that during the war, at an enormous expense, at the expense of billions we built up a great Merchant Marine only to find that the effort to operate it lost us a million dollars a day for the 365 days of the year. And finally we threw up our hands in despair and said that we couldn't stand the losses and that we had demonstrated that the Government couldn't operate ships, and the President came to Congress and said that we must sell these merchant-ships, these hundreds of thousands of tons that we had built at this enormous expense, let them pass into private hands, but under the American flag. But he said it was demonstrated with equal clearness that owing to our high cost of labor it was impossible for private parties even with efficiency, with energy, with capacity, with all that goes to make business successful, it would be impossible for them to operate those ships successfully in competition with the cheaper paid labor of Europe and with the experienced seamanship of those countries, and so he proposed that we should subsidize the American Merchant Marine, pay them 30 to 50 millions of dollars a year in order to enable them to operate upon the ocean, as Congress is going to do it, in my judgment.

If it is impossible for an American Merchant Marine to operate upon the free ocean, the Atlantic and the Pacific, with all the advantages they offer, how I ask you, when you can only bring up the St. Lawrence a boat with 4000 tons capacity, which is uneconomical even on the ocean itself where they require at least 7500 to 10,000 tons to be economical, how are you going to induce private enterprise to enter upon any such business venture as navigating ocean ships of that capacity on the St. Lawrence route? Deepen and widen the St. Lawrence, spend your hundreds of millions of dollars, starve your own waterways in the United States, do this for a third of the life of one generation, ten years, and when you have the waterway there ready, to the depth and of the draft that the Joint Commission recommends, what are you going to do with it when you can't operate ships upon the ocean of proper tonnage to be economical, when you can't operate them without a subsidy, how are you going to get any one to operate them upon the St. Lawrence route?

And are you going to come then and ask for a subsidy for this route for a thousand miles up to Montreal from the ocean and then on to Duluth? And do you think that the nation is in condition to grant the subsidy or that they will believe in the enterprise when they have examined it sufficiently to subsidize the boats that would navigate the channel? I am thoroughly convinced that this is a vision.

The Two-Stage Current Transformer

Chief Engineer, Sangamo Electric Co.

This paper presents a brief discussion of the current transformer as used with measuring and controlling apparatus with special reference to the degree of accuracy which can be attained in the ratio and phase angle. A new type of current transformer is then described, in which it is possible to secure much higher accuracy with a given amount of iron and copper in the transformer. In this new device the transformation is effected in two stages, the first yielding in the usual way a secondary current which is approximately correct in magnitude and phase, and the second yielding an auxiliary corrective current which, when combined with the first secondary current, gives a resultant current which very closely approximates to the secondary current which would be furnished by an ideal current transformer having no errors. The two currents may easily be combined by having two like windings in the devices operated, one for the main and one for the auxiliary secondary current.

The mathematical theory of the two-stage current transformer is developed and applied. Experimental curves are given to compare the performance of the new transformer with that of an ordinary simple current transformer of good average performance. The effect of mutual inductance between the external secondary circuits is discussed, and some of the special advantages of the new transformer are given.

The Simple Current Transformer

The term "current transformer" as ordinarily used refers to a transformer used to deliver to electrical measuring and controlling devices a definite fraction of the line current. It consists essentially of a core of magnetic material on which are wound two coils, one of which, usually of a few turns of large wire, is connected in series with the high-voltage circuit, while the other coil (usually of a greater number of turns of smaller wire) supplies a secondary induced current which operates the measuring and controlling devices in the secondary circuit. The impedance of the external secondary circuit is properly referred to as the secondary burden.

In order that a secondary current may be induced, a certain component of the primary current must be used to produce the necessary magnetization, and to supply the core loss. The core being of iron it is readily appreciated that this component of current varies with (1) secondary burden, (2) frequency, (3) magnitude of the secondary current. Because this component does not vary directly with the secondary current, the ratio of the two currents varies with any changes in the above three factors occurring either separately or jointly. Also, the electrical phase difference between the primary current and the secondary current, which would be exactly 180 deg. in an ideal transformer, departs from 180 deg. by a small angle, the "phase angle," which varies with each of the three causes mentioned as affecting the ratio of currents. For the accurate operation of electrical measuring apparatus, especially wattmeters and watt-hour meters, it is necessary that the ratio of primary current to secondary current should always be constant in a fixed ratio and that the departure from the 180 deg. phase relation should be negligible. This should be true for all ordinary conditions of secondary burden, primary current and frequency. Changes in ratio affect the readings of instruments at all power factors while phase angles cause errors which greatly increase as the power factor is lowered. For example, in using a polyphase watt-hour meter for measuring the energy delivered over a three-phase system, a variation of 1 per cent in the ratio causes an error of 1 per cent in the registration, irrespective of the power factor. When the system is at 86.6 per cent or 50 per cent power factor, a phase angle of 20 minutes will cause errors of 0.3 per cent and 1.0 per cent respectively in the registration of the meter. While such errors in ratio and phase are known to exist, their effect upon the accuracy of the instruments to which they are connected is not always appreciated. In the past and even at the present day, many central-station men consider a current transformer as of absolute ratio and zero phase angle.

Besides the conditions already spoken of as affecting the ratio and phase angle of the ordinary current transformer, there is the question as to the magnetization of the core brought about during moments of opening and closing of the primary circuit or accidental opening of the secondary under load.

Voltage ("potential") transformers are inherently capable of a very much better performance than current transformers, especially as regards phase angle. The induction watt-hour meter has also been brought to a high state of development, and its performance on inductive and non-inductive loads is readily controlled by the user through the three standard adjustments (light-load, full-load, phase). The current transformer has lagged in development behind the other two essential elements of metering equipment. The only way to improve it radically, with the methods of construction commonly employed, is to use iron of magnetic qualities much superior to anything now commercially available. It is the purpose of this paper to show how the transformation of current for metering purposes can be brought up to an accuracy at least as high as that of the other component functions, by means of a device which we have called a "two-stage" current transformer.

Presented at the A. I. E. E. Annual Convention, Niagara Falls, Ontario, June 26-30, 1922.

The two-stage current transformer (shown diagrammatically as two distinct transformers in Fig. 1) inherently and automatically effects a correction of current ratio and phase angle between primary and secondary currents to a high degree of accuracy and within wide limits of secondary burden. This is effected in a manner which may be called a "multi-

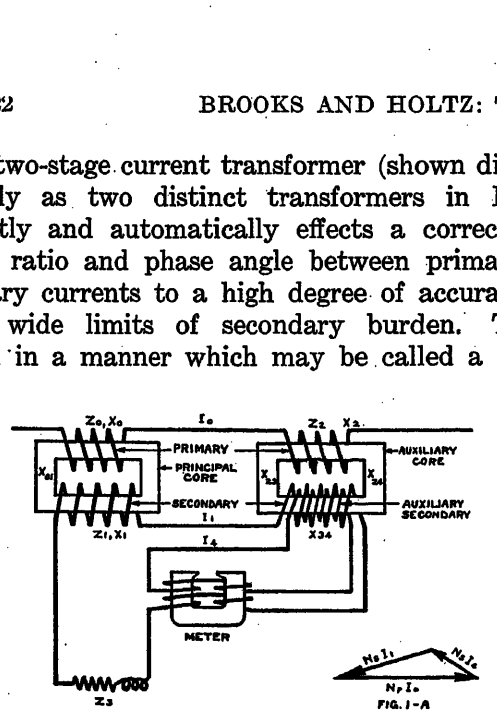

Fig. 1—Elementary Diagram of Electric and Magnetic Circuits of Two-Stage Current Transformer shown as Two Separate Transformers

stage" transformation in which one transformer (the one at the left in Fig. 1) is used to effect the transformation in the ordinary way, yielding a current which is approximately correct as to magnitude and phase. The primary current and this secondary current are then passed through two windings of the second current transformer in which the ratio of secondary turns to primary turns is equal to the desired ratio of primary current to secondary current, the two currents being sent through their respective windings in such a way that their magnetizing effects upon the core (in ampere-turns) tend to oppose each other. (This exact ratio of turns is in contrast to the fact that in ordinary current transformers as now constructed, in order to secure approximately the desired ratio, one or more turns of the secondary winding must be omitted from the number which would be required by an ideal transformer). This second current transformer is provided with another winding called the auxiliary secondary, having very approximately the same number of turns as the principal secondary winding.

It will be evident that if the first transformer is operating under conditions such that the secondary current happens to be exactly correct in magnitude and phase, the ampere-turns of the two windings of the second transformer will annul each other at every moment, and will produce no resultant magnetization in the core of the second transformer and as a result no current will flow in the auxiliary secondary winding.

If, however, as is usually the case in practise, the secondary current produced by the first transformer deviates from the desired ideal value in magnitude or phase angle, or in both, this current and the primary current flowing in opposite directions around the core of the second transformer produce a resultant magnetizing force which acts upon this core. If the auxiliary secondary be now connected to an external circuit, a current will flow which will tend to reduce the flux in the auxiliary core to zero. Under suitable conditions this auxiliary secondary current closely approximates in magnitude and phase to the current which must be vectorially added to the principal secondary current to produce a current such as would be given by an ideal transformer of exact ratio and zero phase angle.

The relations involved may be seen from the vector diagrams of Fig. 2, in which (a) is a simplified diagram of the action of an ordinary current transformer. $O\,F$ represents the direction of the flux in the core, $O\,E_1$ that of the induced secondary e. m. f.; their magnitudes are immaterial for the present discussion. With the usual case of a secondary circuit having resistance and inductance, the secondary current $O\,I_1$ will lag behind $O\,E_1$, and if the secondary coil has one turn, $O\,I_1$ may also represent the secondary ampere-turns. $O\,A$ is drawn of length equal to $O\,I_1$ and 180 deg. away from it, and represents the component of the primary ampere-turns which balances the secondary ampere-turns. To produce the flux and supply the core losses a magnetizing current I_m must flow through the one-turn primary, and I_m shows the magnitude and direction of this current and its magnetizing ampere-turns. Combining $O\,A$ and $O\,I_m$, we get the vector $O\,I_0$, which represents the primary current and its ampere-turns. It may be seen that since $O\,A$ is shorter than $O\,I_0$, I_1 is smaller than the desired value. (In practise, this is usually corrected, for any given set of conditions, by

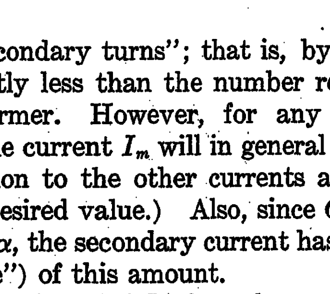

Fig. 2—Vector Relations of the Two-Stage Current Transformer

"dropping secondary turns"; that is, by making their number slightly less than the number required by an ideal transformer. However, for any other set of conditions, the current I_m will in general not change in such proportion to the other currents as to keep the ratio at the desired value.) Also, since $O\,A$ leads $O\,I_0$ by the angle α, the secondary current has a phase error ("phase angle") of this amount.

If we pass $O\,I_0$ and $O\,I_1$ through one-turn windings surrounding another core in such a way that their magnetizing effects are substantially in opposition, their resultant magnetizing force will be equal to $O\,I_m$. These two opposing windings may thus be regarded as equivalent to a one-turn primary winding traversed

by the current I_m. Then in a third one-turn closed-circuit winding around this core (see Fig. 2 (b)) the current I_4 will be induced. It is evident that if this

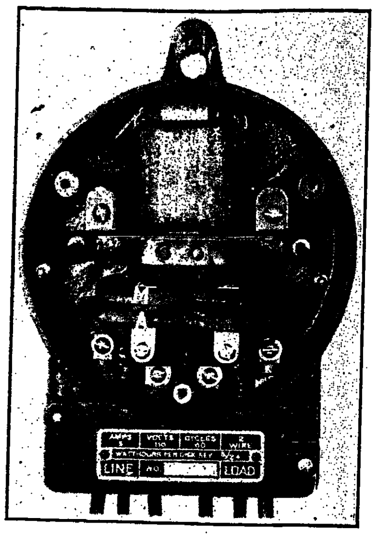

Fig. 3—Motor Element of Watt-Hour Meter, Showing the Two Current Windings Required for Use with the Two-Stage Current Transformer

current be vectorially added to $O\,A$ of Fig. 2 (a) the resulting current will be very much closer to $O\,I_0$ in magnitude and phase than is $O\,A$.

The current from the auxiliary secondary may be readily utilized by providing the meter (or other de-

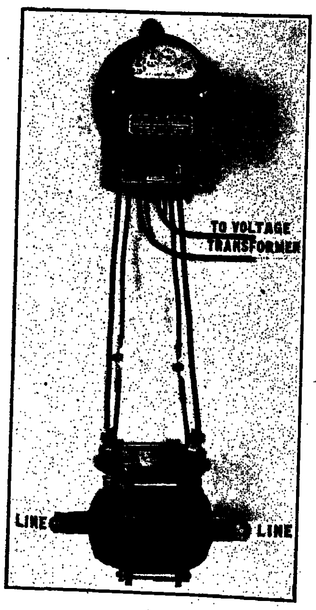

Fig. 4—Two-Stage Current Transformer Connected to Watt-Hour Meter

vices) with two identical current windings connected respectively to the main and auxiliary secondary circuits, as shown in Figs. 1 and 3. Under such conditions the total ampere-turns in the windings of each instrument so connected to the transformer system will be for all practical purposes exactly equal to the ampere-turns derived from an ideal transformer. The mathematical treatment of the electric and magnetic network involved is given in the appendix to this paper.

Instead of the two physically distinct transformers shown diagrammatically in Fig. 1, it is more convenient to use a single primary winding and a single secondary winding encircling both cores, with the auxiliary secondary winding and a few turns of the main secondary winding surrounding the auxiliary core only.[1] This method of construction produces a two-stage transformer which is physically a single compact unit (see Fig. 4), which shows such a transformer connected to a watt-hour meter. The method of linking the electric and magnetic circuits is shown diagrammatically in Fig. 5, in which the numbers 1, 2, 3 represent the primary winding, the main secondary winding, and the auxiliary secondary winding respectively.

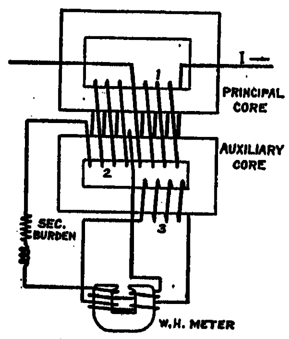

Fig. 5—Electric and Magnetic Circuits of Two-Stage Current Transformer Made as a Structural Unit

Comparative Performance

Without going into details concerning the causes limiting the accuracy of current transformers having simple secondary windings, it is sufficient to recognize that a higher degree of accuracy in current transformers is desirable in order to bring up the accuracy of the readings of the meters and indication of the instruments which they operate. Let us consider the effect of such errors when the secondary is connected to a watt-hour meter which, for the purpose of this discussion, is assumed to be correct for all loads and power factors within the limits considered. If the meter were connected directly to the line the speed would be proportional to

$$S = E\,I\cos\theta$$

and if we assume next that a current transformer of nominal 1:1 ratio is interposed we would have the speed proportional to

$$S' = \frac{E\,I}{R}\cos(\theta - \alpha)$$

where R is the value, as taken from the calibration curve of the transformer, of the quotient, true ratio divided

1. This construction was suggested by Dr. F. B. Silsbee.

by marked ratio, and α is the small angle (the "phase angle") by which the reversed secondary current leads the primary current.

When operating at unity power factor the term cos $(\theta - \alpha)$ is almost exactly equal to unity, so that the per cent registration of the meter will be almost inversely proportional to R.

As the power factor decreases the effect of α is felt more and more. Since for inductive loads the value of θ is positive there will be a tendency for the meter to run faster as the power factor is lowered. As the load is lowered the values of both R and α increase and in

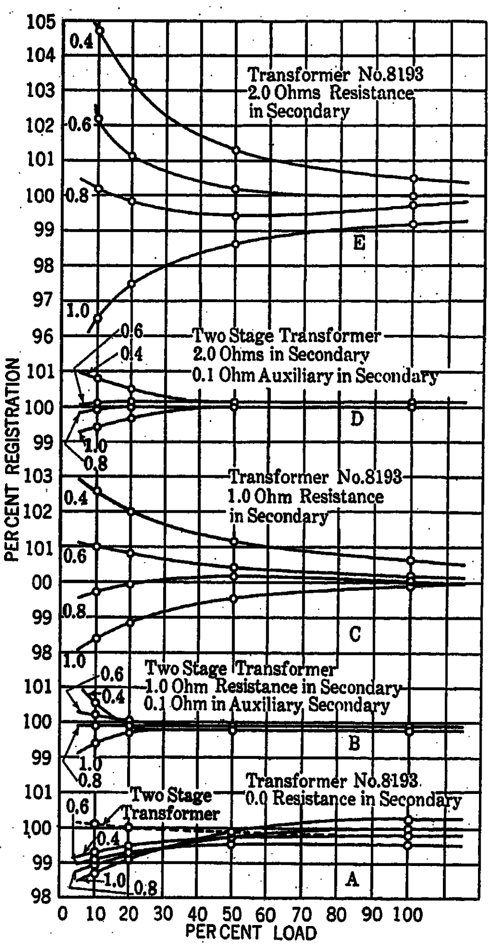

FIG. 6—COMPARATIVE PERFORMANCE OF SIMPLE CURRENT TRANSFORMER AND TWO-STAGE CURRENT TRANSFORMER

general there is a slight tendency for one to compensate the other, yet in most cases the meter will actually exhibit an increased per cent registration on inductive loads. For leading power factors the opposite is true and as the power factor is lowered the meter becomes slower and slower.

Fig. 6C shows this characteristic on inductive loads very clearly. The data as plotted show the degree to which the accuracy of a meter is affected when connected to a line through a modern simple current transformer. This transformer exhibits a good average performance. Transformers of considerably lower accuracy are in service and some of heavier modern designs show a higher accuracy. The curves show the per cent registration of the meter for various loads and at power factors as indicated. Without the transformer the per cent registration would in each case have been 100. The data were taken by direct measurement rather than by computation from ratio and phase-angle curves. In the case cited the secondary burden was 1 ohm resistance plus the resistance of the meter. This particular transformer had about 1200 ampere-turns at full load in the primary. A two-stage transformer was built having about the same amount of iron in its structure but using only one-half the number of ampere-turns. Data were taken on this transformer when connected to a meter and with various values of secondary burden. For zero secondary burden there was practically no deviation from 100 per cent registra-

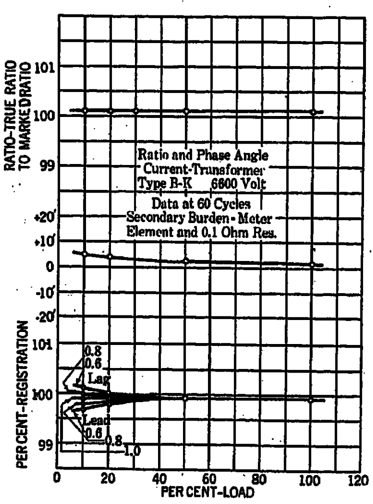

FIG. 7—RATIO, PHASE-ANGLE AND PERFORMANCE CURVES OF TWO-STAGE CURRENT TRANSFORMER

tion for all loads and power factors. Figs. 6B and 6D show the results using secondary burdens of one ohm and two ohms respectively and in both cases there is practically no deviation from 100 per cent registration for all loads above 20 per cent. Figs. 6C and 6E show results which do not even compare favorably with A, B and D, although the secondary burden in case C was very favorable to high accuracy. Fig. 6A shows in full lines the performance of the ordinary current transformer when the secondary burden is only a meter element and 0.1 ohm lead resistance. The dotted line shows the performance of the two-stage transformer under the same conditions. For the latter the curves for the various power factors were so nearly coincident that they are shown as one line.

Fig. 7 shows the conventional ratio and phase-angle curves for the two-stage current transformer with a secondary burden consisting of a watt-hour meter and 0.1 ohm resistance. The lower set of curves, like those of Fig. 6, shows the performance as a function of both ratio and phase-angle.

The above data show the great utility of the two-stage transformer in obtaining the highest degree of

accuracy in electric metering when the use of a current transformer becomes necessary. When used on switchboards the auxiliary secondary need be connected only to the wattmeters and watt-hour meters, since in general an error of 1 to 2 per cent in the indications of ammeters is of no serious consequence.

Watt-hour meters operated from two-stage current transformers need not be calibrated to compensate for inaccuracies in the transformers themselves, since the main secondary and the auxiliary secondary together provide an effective current which is at all times in the proper phase with and ratio to the primary current. This condition is practically independent of any change of secondary burden, frequency, or aging effects in the main core, and should the main secondary become open-circuited the auxiliary secondary will still provide current in approximately the proper ratio.

Effect of External Mutual Inductance

In general the introduction of the auxiliary corrective current into any device means that the main secondary and auxiliary secondary circuits are magnetically coupled outside the transformer. This condition results in the introduction of e. m. fs. into the auxiliary secondary circuit in addition to those generated within the auxiliary secondary coil itself. Such e. m. fs. may become harmful to the successful operation of the transformer if they become sufficiently large. In order to show this effect an experiment was made on a two-stage transformer, as follows: The burden in both main secondary and auxiliary secondary circuits was approximately 0.25 ohm, and 0.79 mh. inductance. The constants of the transformer were first determined with the above secondary burdens and the test repeated using a mutual inductance of 0.21 mh. to couple magnetically the secondary and auxiliary secondary outside the transformer. The tests were made at 60 cycles.

The following table shows the change in constants for the condition with and without mutual inductance:

Without Mutual Inductance					
Per Cent Load....	10	20	40	60	100
Ratio............	1.0017	1.0012	1.0010	1.0010	1.0010
Phase Angle......	5.5′	3.5′	1.5′	0.7′	−0.7′
With Mutual Inductance					
Ratio............	1.016	1.014	1.011	1.010	1.007
Phase Angle......	5.2′	2.0′	0.0′	−3.5′	−5.6′

The above figures show that the introduction of mutual inductance between the main secondary and auxiliary secondary circuits outside the transformer is at least harmful to the ratio of the transformer. It should be noted, however, that the mutual inductance used in the above experiment was about four times as great as that between the two current windings of a watt-hour meter. Furthermore, it is a simple matter to provide an external corrective mutual inductance of equal numerical value but of opposite sign, thus canceling the mutual induction taking place in the meter. This device would be a small laminated core with two windings.

The usual practise of keeping the secondary burden as low as possible should be adhered to in the case of the auxiliary secondary, and the corrective current should be applied only to apparatus where it is required from the standpoint of accuracy.

Some Features of Design

From a practical standpoint it is desirable to make the mutual reactances between primary and auxiliary secondary and between main secondary and auxiliary secondary the same and to arrange the coils so that both of these reactances will vary in the same ratio. This will not always be an easy matter when designing current transformers of high-voltage type, but in a laboratory standard transformer where the insulation between primary and secondary can be reduced to a minimum the problem is less difficult. By breaking up the primary and secondary into a number of sections and interleaving the sections on the core some very remarkable characteristics can be obtained. For example, a two-stage transformer of this type was built which had the primary and secondary built in two sections each and placed on the core in the following order: *P- S- P- S*; ampere-turns at full load, about 900.

The following table shows the characteristics of this transformer for 0.1 ohm resistance in the main secondary and auxiliary secondary circuits.

Per Cent Load....	10	20	30	60	100
Ratio............	1.0005	1.0005	1.0002	1.0002	1.0001
Phase Angle......	2.0′	1.0′	0.5′	0.0′	0.0′

For the commercial testing of instrument transformers such a transformer could be considered as having a fixed ratio and negligible phase angle.

Testing Two-Stage Current Transformers

Almost any of the methods now in use for determining the constants of current transformers can, with slight modification, be applied to the two-stage current transformer.

The Agnew watt-hour meter method[2] will be of particular interest to the laboratory of limited facilities, since it gives results which are sufficiently accurate for all commercial purposes and requires no instruments or apparatus of precision except a current transformer whose constants are known. When testing a transformer of one-to-one ratio even this special transformer is not necessary. The ratio and phase angle as determined by any one of these methods will be termed the "effective" ratio and phase angle since they are determined from the vector sum of two currents.

Fig. 8 shows the arrangement for testing a one-to-one ratio two-stage current transformer. Two watt-hour

2. Agnew, Watt-hour Meter Method of Testing Instrument Transformers, Scientific Paper of the Bureau of Standards No 233, 1914; Craighead and Weller, *General Electric Review* Vol. 24, p. 642, 1921.

meters a and b are each equipped with two sets of series coils having the same number of turns as a standard five-ampere coil. Each disk is marked in hundredths of a revolution. The potential coils are connected in parallel to a source of e. m. f. of the same frequency as that which supplies current to the primary of the current transformer and arrangements should be made whereby the phase relations between the main

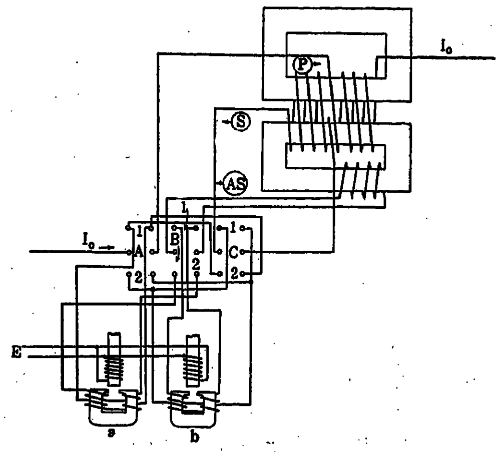

FIG. 8—DIAGRAM OF CONNECTIONS FOR AGNEW TWO-WATT-HOUR-METER METHOD OF TESTING A 1:1 RATIO TWO-STAGE CURRENT TRANSFORMER

current I_0 and applied e. m. f. E can be altered. It is not necessary that either of the watt-hour meters be in correct adjustment on unity power factor since it is shown that the constants of the two watt-hour meters do not enter into the computations. In many cases, however, the computations are somewhat lessened if the two meters are kept in rather close agreement as regards their constants.

When taking readings at low power factors in order to determine the phase angle it is desirable that the meters be in agreement as regards the angle by which the shunt-field flux lags behind the voltage. It is not necessary that the flux from each potential pole be exactly 90 deg. behind the voltage, but it is desirable that the angle be the same in both. For this reason it has been found desirable to adjust the meters to agreement at unity and at some low power factor; say 20 per cent.

Three double-pole double-throw switches are provided as shown. By throwing the switches first in the position $A_1 B_1 C_1$ meter a is in the primary of the transformer with one of the series coils disconnected while meter b has its windings connected to the secondary and auxiliary secondary respectively of the two-stage transformer. By throwing the switches into the position $A_2 B_2 C_2$ the relative position of the meters is interchanged.

If when the switches are in the position $A_1 B_1 C_1$ we designate by a_1 and b_2 the revolutions recorded on the meters a and b in a given time, and by a_2 and b_1 the revolutions recorded for the two meters a and b when the switches are in the position $A_2 B_2 C_2$, we have the ratio of the transformer

$$R = \sqrt{\frac{a_1 b_1}{a_2 b_2}} \tag{1}$$

if the applied e. m. f. E is in phase with the current I_0.

If the applied e. m. f. is not in phase with the current the quantity under the radical may be termed R', the *apparent ratio* of the transformer, since it is dependent not only upon the effective ratio of the currents but upon the phase angle as well.

From the standpoint of computations it is desirable to make b_1 and b_2 the same, in which case, neglecting terms of second and higher orders, we have

$$R = \sqrt{a_1/a_2} = 1 + \frac{a_1 - a_2}{2\,a_2} \tag{2}$$

When taken at power factors other than unity $1/R' \times 100$ would be the per cent registration which a meter would exhibit when placed in the secondary circuit of the current transformer if it were correct when placed in the primary circuit. Such data would be of particular interest to the practical meterman who desires to know the effect of both ratio and phase angle upon the accuracy of the meter. The curves shown in Fig. 6 are plotted on this basis.

Phase angles are determined by taking readings at both unity and low power factor for the same volt-

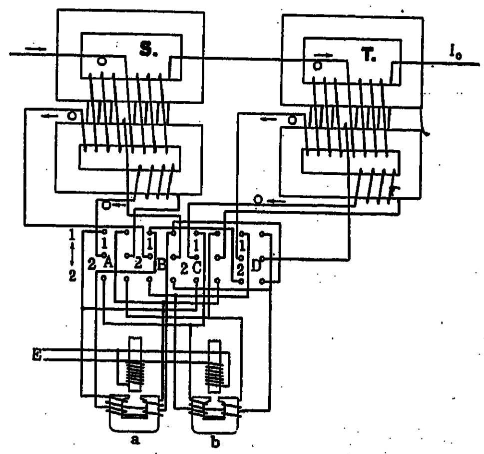

FIG. 9—DIAGRAM OF CONNECTIONS FOR AGNEW TWO-WATT-HOUR-METER METHOD OF TESTING TWO-STAGE CURRENT TRANSFORMERS OF RATIO OTHER THAN UNITY

ampere load, using a wattmeter, voltmeter and ammeter to determine the power factor as regards the primary current and applied voltage E. For this case we denote by a_1', a_2', b_1', b_2', the readings corresponding to a_1, a_2, b_1, b_2 in the test at unity power factor. Upon making $b_2' = b_1'$ we have the phase angle

$$\alpha = \tan^{-1}\left[\frac{1}{\tan\theta}\,(1 - R/R')\right] \tag{3}$$

where $R' = \sqrt{a_1'/a_2'}$ is the apparent ratio at the low

power factor and R is the ratio at unity power factor while θ is the angle between E and I_0.

This formula gives the phase angle in radians. For practical purposes, since the angle is small, we may take the angle as equal to the tangent. Doing this and multiplying by 3438 to reduce to minutes, we have

$$\alpha = \frac{3438}{\tan\theta}\,(1 - R/R')\ \text{(minutes)} \qquad (4)$$

Fig. 9 shows the arrangement for testing a two-stage current transformer whose nominal ratio is different from unity. The transformer S is used as the standard and may be of either the two-stage or simple type. If of the simple type there will be no auxiliary secondary connections from this transformer to the switch as shown. If we let

R_1 = ratio of the standard transformer S
α_1 = phase angle of the standard transformer S
R_2 = ratio of the two-stage transformer B
α_2 = phase angle of the two-stage transformer B

then with the same meaning attached to the a and b symbols as before

$$R_2 = R_1\sqrt{a_1/a_2} = R_1\left(1 + \frac{a_1 - a_2}{2\,a_2}\right) \qquad (5)$$

$$\alpha_2 = \tan^{-1}\left[\frac{1}{\tan\theta}\left(1 - \frac{R_2}{R_1 R_2'}\right)\right] + \alpha_1 \qquad (6)$$

where $R_1 R_2' = R_1\sqrt{a_1'/a_2'}$ is the apparent ratio at the low power factor and $b_1' = b_2'$ as before.

From this we may derive the practical formula

$$\alpha_2 = \frac{3438}{\tan\theta}\left(1 - \frac{R_2}{R_1 R_2'}\right) + \alpha_1\ \text{(minutes)} \qquad (7)$$

Advantages of the Two-Stage Transformer

In conclusion it may be well to point out some additional advantages of the two-stage transformer.

From an engineering standpoint it is possible greatly to reduce the amount of copper and iron required to give results which are at least as good or better than now attained in the highest grade transformers produced. It is not necessary to have an accurate knowledge of the magnetic properties of the iron used. With reasonable amounts of materials used the inaccuracy of metering due to the presence of current transformers can be reduced to a negligible quantity. This is in contrast to the average simple current transformer whose accuracy under service conditions often leaves much to be desired. Even with a given secondary burden it cannot be compensated for all loads and power factors, as the curves clearly show.

The results of a questionnaire sent out recently to the large electric power companies by the Meter Committee of the National Electric Light Association[3] showed that, "The installation of separate current transformers was reported in practically all cases for watt-hour meters, while indicating instruments and other devices, including relays, are combined on the same transformer." The use of one two-stage transformer would give as good or better metering accuracy, and would save the cost of the extra transformer and the space occupied by it.

3. Report of N. E. L. A. Meter Committee, June 1921, p. 9, 44th Convention.

Current transformers of very large range, beyond the maker's facilities for precision testing, can be made with the assurance that by having approximately the correct number of turns in primary and principal secondary and the exact ratio of turns in primary and auxiliary secondary the ratio will be accurately correct and the phase angle negligible.

Transformers of ordinary construction of small number of secondary turns cannot be brought to exact ratio because it is not feasible to drop a fraction of a turn. This difficulty is absent in the two-stage transformer.

Since watt-hour meters operated from two-stage transformers do not need to be adjusted specially to offset transformer ratio and phase-angle errors, the work of testing such meters will be simplified and the cost of testing reduced.

An important possible application of the two-stage transformer is in the measurement of the output of a-c. generators on acceptance tests. In the case of large machines it is customary to stipulate a large penalty for each per cent by which the efficiency falls below the contract figure, and conversely a large bonus for an efficiency superior to that specified. It is therefore highly desirable to use current transformers which have a constant ratio and do not require troublesome corrections for phase-angle errors. The auxiliary winding can be applied to indicating wattmeters as well as to watt-hour meters.

Particularly on high-voltage circuits where accurate metering is so desirable the simple current transformers of best design show very poor characteristics. This is due to the separation of primary and secondary windings necessitated by the insulation requirements. This is particularly true of the Nicholson air-insulated transformer and the bushing type having low ampere-turns and long mean path of flux in the iron. In these cases the two-stage transformer will make possible a step well in advance of present-day methods of metering high-voltage systems.

Appendix

In the following discussion the mathematical relations underlying the action of the two-stage current transformer are established, and a comparison is made with the corresponding relations for the simple current transformer. In this connection the authors wish to acknowledge valuable assistance rendered by Dr. F. B. Silsbee.

The following symbols will be used:

I_0, I_1 and I_4 = primary, main secondary, and auxiliary secondary currents respectively

$X_0, X_1 \ldots X_4$ reactances of the several coils as indicated by the subscript and on Fig. 1
Z_3 = impedance of main burden plus resistance of coils 1 and 3
Z_4 = impedance of auxiliary burden plus resistance of coil 4
X_{01}, X_{23}, etc. = mutual reactances between coils indicated by the subscripts
$N_0, N_1 \ldots N_4$ = number of turns in coils 0, 1 . . . 4
μ_1, μ_4 = permeability of iron in main and auxiliary cores respectively
a_1, a_4 = cross-section of iron in respective cores
l_1, l_4 = length of magnetic circuit in respective cores
ω = 2π times frequency
j = $\sqrt{-1}$
D_1, D_4 = leakage factors (approx. equal to 1)
$\delta_{01}, \delta_{23}, \ldots$ etc. = leakage differences
c = $\dfrac{a_4 \mu_4 D_4 l_1}{a_1 \mu_1 D_1 l_4}$
z_3, z_4 = Z_3/X_1 and Z_4/X_1 respectively
$\eta_{34} \ldots$ etc. = $\delta_{34} \mu_4$ . . . .
ζ = Z_4/X_4

Throughout the development, the currents, impedances, and permeabilities will be regarded as plane vectors and the final ratio will be obtained as a complex number whose modulus is the true ratio and whose argument is the phase angle.

Applying Kirchoff's laws to the two secondary circuits shown in Fig. 1 we obtain

$$I_1 [Z_3 + j (X_1 + X_3)] + I_4 j X_{34} = - I_0 j (X_{01} + X_{23}) \tag{8}$$

$$I_1 j X_{34} + I_4 (Z_4 + j X_4) = - I_0 j X_{24} \tag{9}$$

Solving these two simultaneous equations gives

$$I_1 = - I_0 \frac{j (X_{01} + X_{23}) (Z_4 + j X_4) + X_{34} X_{24}}{(Z_4 + j X_4) [Z_3 + j (X_1 + X_3)] + X_{34}^2} \tag{10}$$

$$I_4 = - I_0 \frac{j X_{24} [Z_3 + j (X_1 + X_3)] + X_{34} (X_{01} + X_{23})}{(Z_4 + j X_4) [Z_3 + j (X_1 + X_3)] + X_{34}^2} \tag{11}$$

Now each of the reactances (X_{mn}) may be split up into a number of factors so that

$$\left.\begin{aligned}
X_1 &= \omega \frac{4\pi}{10} \frac{a_1}{l_1} \mu_1 N_1^2 D_1 \\
X_3 &= \omega \frac{4\pi}{10} \frac{a_4}{l_4} \mu_4 N_3^2 D_4 (1 - \delta_3) \\
X_4 &= \omega \frac{4\pi}{10} \frac{a_4}{l_4} \mu_4 N_4^2 D_4 \\
X_{01} &= \omega \frac{4\pi}{10} \frac{a_1}{l_1} \mu_1 N_0 N_1 D_1 (1 - \delta_{01}) \\
X_{23} &= \omega \frac{4\pi}{10} \frac{a_4}{l_4} \mu_4 N_2 N_3 D_4 (1 - \delta_{23}) \\
X_{24} &= \omega \frac{4\pi}{10} \frac{a_4}{l_4} \mu_4 N_2 N_4 D_4 (1 - \delta_{24}) \\
X_{34} &= \omega \frac{4\pi}{10} \frac{a_4}{l_4} \mu_4 N_3 N_4 D_4 (1 - \delta_{34})
\end{aligned}\right\} \tag{12}$$

In these expressions the leakage factors D_1 and D_4 are those by which the inductances of coils 1 and 4 respectively differ from those computed from the well-known simple formula for uniformly and closely wound ring coils. In the case of the other reactances the corresponding differences are allowed for by introducing the quantities δ which are in practical cases small compared with 1.

If we now limit ourselves to the practical case where $N_3 = N_4$ and $N_0 = N_2$, and for abbreviation let

$$c = \frac{a_4 \mu_4 D_4 l_1}{a_1 \mu_1 D_1 l_4} \tag{13}$$

and also let $Z_3/X_1 = z_3, \quad Z_4/X_1 = z_4$ (14)

we get, on making the various substitutions, the two equations:

$$I_1 = - I_0 \times$$

$$\frac{\dfrac{N_2}{N_1} \left\{ 1 - \delta_{01} + \dfrac{N_3}{N_1} c \left(- \delta_{23} + \delta_{34} + \delta_{24} - \delta_{34} \delta_{24} \right) - j \left[z_4 \left(\dfrac{N_1^2}{N_3^2 c} + \dfrac{N_1}{N_3} \right) - z_4 \left(\dfrac{\delta_{01} N_1^2}{N_3^2 c} - \dfrac{\delta_{23} N_1}{N_3} \right) \right] \right\}}{1 - \dfrac{N_3^2}{N_1^2} c \left(- \delta_3 + 2 \delta_{34} - \delta_{34}^2 \right) - j \left[z_3 + z_4 \left(1 - \delta_3 + \dfrac{N_1^2}{N_3^2 c} \right) \right]} \tag{15}$$

and

$$I_4 = - I_0 \times$$

$$\frac{\dfrac{N_2}{N_1} \left[\dfrac{N_1 - N_3}{N_3} - \dfrac{N_1}{N_3} \delta_{24} + \delta_{01} + \delta_{34} + \dfrac{N_3}{N_1} c \left(- \delta_3 - \delta_{24} + \delta_{23} + \delta_{34} - \delta_{23}\delta_{24} + \delta_3\delta_{24} \right) - j z_3 \dfrac{N_1}{N_3} (1 - \delta_{24}) \right]}{1 - \dfrac{N_3^2}{N_1^2} c \left(- \delta_3 + 2\delta_{34} - \delta_{34}^2 \right) - j [z_3 + z_4 (1 - \delta_3 + \dfrac{N_1^2}{N_3^2 c})]} \tag{16}$$

While these separately are very complicated functions of the leakage factors and burdens it will be noted that the δ's and z's are in practise small compared to 1 and hence we may neglect the higher powers and products of these quantities entirely. If this is done the division of numerator by denominator may be carried out explicitly and we obtain

$$I_1 = -I_0 \frac{N_2}{N_1}\Big[1 - \delta_{01} + \frac{N_3}{N_1} c\,(-\delta_{23} + \delta_{34} + \delta_{21}) - \frac{N_3^2}{N_1^2} c\,(2\,\delta_{34} - \delta_3) + \ldots + j\left(z_3 + z_4 \frac{N_3 - N_1}{N_3} + \ldots\right)\Big] \tag{17}$$

$$I_4 = -I_0 \frac{N_2}{N_1}\Big\{\frac{N_1 - N_3}{N_3} + \delta_{01} - \frac{N_1}{N_3}\delta_{24} + \delta_{34} + \frac{N_3}{N_1} c\,(\delta_{23} - \delta_{34} - \delta_{24}) + \frac{N_3^2}{N_1^2} c\,(2\,\delta_{34} - \delta_3) + \ldots - j\Big[z_3 - z_4\Big(1 + \frac{N_1^2}{N_3^2 c}\Big)\Big]\Big\} \tag{18}$$

It will be seen that most of the terms (e. g., δ_{01}) of (18) are equal in magnitude and opposite in sign to the corresponding terms in (17), which is of course the mathematical expression for the physical fact that I_4 has very nearly the correct value to compensate for the departure of I_1 from its ideal value of $-I_0 N_2/N_1$.

If therefore we compute the effective ratio in the usual form we get, after a rearrangement of terms

$$\text{Ratio} = \frac{I_0}{I_1 + I_4} = -\frac{N_3}{N_2}\Big\{1 - \frac{N_3}{N_1}\delta_{34} + \delta_{24} + \ldots + j\Big[z_4 \frac{(N_1 - N_3)\,N_1}{c\,N_3^2} + \ldots\Big]\Big\} \tag{19}$$

The corresponding expression for a single-stage transformer of the usual type is

$$\text{Ratio} = \frac{I_0}{I_1} = -\frac{N_1}{N_0}\,[1 + \delta_{01} + \ldots - j\,(z_3 + \ldots)] \tag{20}$$

A comparison of equations (19) and (20) shows at once the advantages of two-stage transformation. If N_1 is made equal to N_3 then the ratio in (19) becomes independent of the secondary burdens, and if in addition $\delta_{34} = \delta_{24}$ (*i. e.* if coils 3 and 2 have equal mutual inductances on coil 4) then the ratio becomes constant and equal to N_3/N_2.

To see in more detail the effect of various conditions on the operation of the apparatus we may make some further algebraic transformations and must introduce some physical assumptions. It is evident from (20) that if δ_{01} and z_3 were constants, ordinary current transformers would have a constant ratio and phase angle at any given frequency and burden. Consequently the entire variation of transformer ratio with current and the main part of its variation with frequency and burden are due to the fact that the permeability is not constant and the core loss does not vary in proportion to the square of the flux density. In the group of equations (12) no explicit mention was made of core loss but this may readily be taken care of by considering μ to be a complex quantity having a real component proportional to that component of the induced voltage in quadrature with the magnetizing current and an imaginary component proportional to the core-loss component of the induced voltage. The leakage differences δ are roughly a measure of the ratio of the air leakage flux peculiar to one coil to the total flux which is mainly in the iron. Consequently these quantities, roughly at least, will be inversely proportional to the permeability of the iron. Also the quantities z_3 and z_4 involving, as they do, X_1 or X_4 in the denominator will be inversely proportional to μ. We may therefore at least approximately set

$$\left.\begin{aligned} \delta_{34} &= \eta_{34}/\mu_4 \\ \delta_{24} &= \eta_{24}/\mu_4 \\ z_3 &= \zeta_3/\mu_4 \\ \frac{N_1^2\, z_4}{N_3^2\, c} &= \frac{\zeta_4}{\mu_4}, \quad \text{or} \quad \zeta_4 = \frac{Z_4}{X_4}\,\mu_4 \end{aligned}\right\} \tag{21}$$

Inserting these relations in (13) and (14) gives
Ratio (two-stage) =

$$-\frac{N_3}{N_2}\Big[1 + \Big(\eta_{24} - \frac{N_3}{N_1}\,\eta_{34} + j\,\zeta_4 \frac{N_1 - N_3}{N_1}\Big)\frac{1}{\mu_4}\Big] \tag{22}$$

and

$$\text{Ratio (single-stage)} = -\frac{N_1}{N_0}\,[1 + (\eta_{01} - j\,\zeta_3)\frac{1}{\mu_1}] \tag{23}$$

The equations cannot be profitably pushed farther than this unless the permeability can be expressed as a definite function of the flux density. It may be noted, however, that the flux density at which a core works is proportional to the net induced voltage per turn and varies inversely as the frequency. Consequently for high frequencies or small currents and burdens μ_1 will be small but fairly constant while with higher flux densities corresponding to lower frequency or larger current and burden μ will be larger but will vary more rapidly with current. Since the auxiliary core has to circulate only the very small auxiliary current through the very moderate auxiliary burden, the flux density in it is low and μ_4 in equation (22) is fairly constant, though small. In the single-stage transformer, however, the flux must be sufficient to circulate the entire secondary current and μ_1 in equation (23) will vary rather rapidly with current.

The principal gain from two-stage transformation, however, is seen by the coefficient of $1/\mu_4$ in equation

(**22**), which involves only the *difference* of two nearly equal leakage factors instead of a single factor. Moreover, the main secondary burden does not enter at all into the first order terms in equation (**22**) for the two-stage transformer, and the auxiliary burden is multiplied by the factor

$$\frac{N_1 - N_3}{N_1}$$

which is always small and may be made zero if desired. To make $N_1 = N_3$ however in general will make I_4 larger than if N_1 is slightly less than N_3. The consequent increase in auxiliary flux density and in the variability of μ_4 and in second order terms may more than neutralize the improvement in the ζ_4 term.

Equation (**22**) shows very clearly the effect of external mutual inductance between the main and auxiliary secondary circuits, since such an effect is equivalent to increasing η_{34} and will directly destroy the balance between δ_{34} and δ_{24}. This effect is referred to at some length in the present paper.

On the whole it is seen that the errors of the single-stage transformer have been reduced to one order of magnitude smaller by the use of the two-stage transformation. This is confirmed by the experimental results which show that a transformer which operating single-stage has errors of several per cent will on two-stage operation show errors of only a tenth of this amount, or less.

Discussion

James R. Craighead: There are in addition to those outlined in this paper, several other methods of making phase angle correction in current transformers. The simplest is the use of a non-inductive shunt placed across the primary winding or across the secondary winding, which subtracts a certain amount of current either from the primary or the secondary side of the transformer. This current is in a phase position which is such that it tends to restore the remainder of the secondary current to the phase position of the primary current, and by so doing can diminish to some extent the usual leading (or positive) phase angle of the current transformer. Inductive reactance may be substituted for the non-inductive shunt where the phase angle is negative.

An extension of this method is the use of a separate winding on the core of the current transformer, which gives an opportunity of using other voltages than the voltage generated at the secondary terminals. This allows the use of condensance, reactance and resistance; and by using these three the sub-division of the current can be made so that the net current going through the meter for any given point can be brought more exactly into phase apposition. Both these methods produce a correct phase angle under only one condition, and change in current, frequency or secondary burden is usually accompanied by change in phase angle.

Consequently, this form also does not give a continuous or complete correction.

A third method requires the use of two current transformers. A main current transformer has the standard connection, with its primary in the primary line, and its secondary connected to the meter or other burden. An auxiliary current transformer is placed with its primary either in the primary line or the secondary line, and it has a ratio very different from the ratio of the first transformer.

This second transformer produces a very small current, roughly sufficient to produce a corrective result if applied either across the primary terminals of the main current transformer, or across the terminals of the burden. A combination can be made

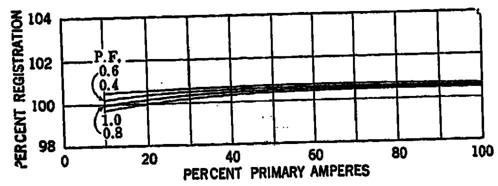

Fig. 1—Current Transformer for Metering Service—Accuracy at 60 Cycles
Burden of 1.8 ohms resistance (45 voltamperes)

to produce a result which is somewhat better than a simple point correction, by selecting main and auxiliary transformer so that their characteristics tend to offset errors through same range. As the auxiliary transformer has a comparatively large number of turns, more accurate correction of ratio may be made than with a transformer of standard type. Full correction can be obtained under only one condition, as in the preceding method.

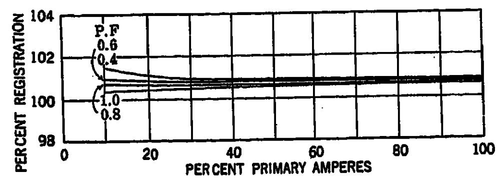

Fig. 2—Current Transformer for Metering Service—Accuracy at 60 Cycles
Burden of one watthour meter and leads (0.15 ohm resistance, 3.75 voltamperes)

The method proposed by Mr. Brooks, while resembling the previous method in the use of two transformers, is distinctly different in principle. If the auxiliary secondary, which I prefer to call the tertiary is disconnected, the transformer consists of a core subdivided into two parts, with a common primary and secondary on both parts, the secondary being connected to an external burden. If then we connect the tertiary to a burden of

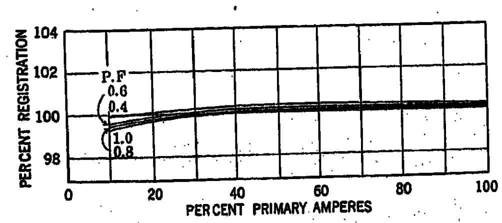

Fig. 3—Current Transformer for Metering Service—Accuracy at 60 Cycles
Burden of 0.97 ohm resistance, 4.03 milli henries inductance (45 voltamperes at 0.54 power factor at 5 amperes 60 cycles)

low impedance, the corrective current drawn reduces the flux in the auxiliary core. This increases the impedance of the secondary circuit and increases the voltage developed in the secondary by the main core, and consequently the flux in the main core and its exciting current. The error in the total secondary circuit is therefore increased, and we get a subdivision into two circuits, one whose accuracy has been largely increased

by the redistribution of the flux, and the other whose accuracy has been decreased by the same cause. The auxiliary core is really excited by the difference between the primary and secondary currents as a true primary current, and the tertiary winding tends to deliver a proportionate current. Since this difference is the error in transformation of the main transformer, the corrective current changes in proportion to the need for correction.

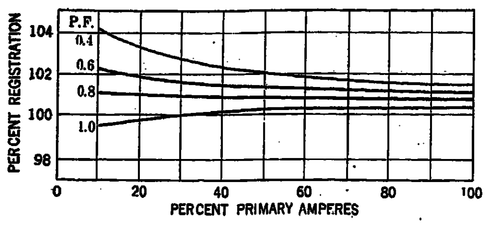

FIG. 4—CURRENT TRANSFORMER FOR METERING SERVICE—ACCURACY AT 25 CYCLES

Burden of 1.8 ohms resistance (45 voltamperes)

Consequently moderate changes in frequency, secondary burden or primary current make only very small changes in accuracy. From this the Brooks plan is evidently applicable where it s desirable to obtain high accuracy over a very small portion ofi the secondary burden, as a watthour meter. Where the purpose is to obtain better general accuracy on a large burden, such as curve drawing instruments, balanced relays, etc., the method is not applicable.

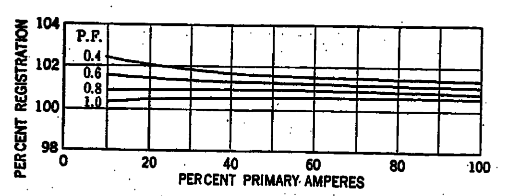

FIG. 5—CURRENT TRANSFORMER FOR METERING SERVICE—ACCURACY AT 25 CYCLES

Burden of one watthour meter and leads (0.15 ohm resistance 3.75 voltamperes)

Mr. Brooks has furnished curves showing the performance of an ordinary commercial type of transformer for comparison with his device. These results are not as good as may be obtained with the better grade of commercial transformers.

Figs. 1 to 6 show the accuracy of a meter (neglecting its internal error) operated from a current transformer of good standard type at power factors from unity to 0.4 lagging, with various secondary burdens and frequency.

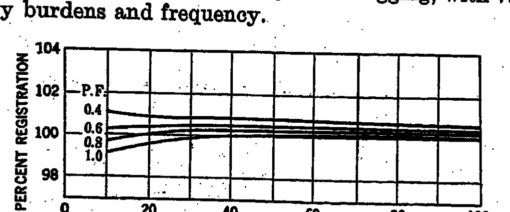

FIG. 6—CURRENT TRANSFORMER FOR METERING SERVICE—ACCURACY AT 25 CYCLES

Burden of 0.97 ohms resistance, 4.03 milli henries inductance, (45 volt-amperes at 0.54 power factor at 5 amperes 60 cycles)

The first three show operation at 60 cycles, with burdens of (Fig. 1) 1.8 ohms non-inductive resistance, or 45 volt-amperes, at 5 amperes and 60 cycles; (Fig. 2) 0.15 ohms resistance or 3.75 volt-amperes (practically a watthour meter with its leads); and (Fig. 3) 0.97 ohms resistance with 4.03 milli-henries inductance or about 45 volt-amperes at 0.45 power factor. This last is the highest burden recommended for use with the transformer when a watthour-meter is included. The results show errors due to the transformer of less than 1 per cent, as compared with much larger errors shown by the transformer used as a comparison by the authors of the paper.

The next three figures show similar data for the same transformer and burdens at 25 cycles. In Fig. 4 is shown the effect of a non-inductive burden of 1.8 ohms—which is rare in metering practise—on the accuracy for comparison with Fig. 1. Fig. 5 shows the accuracy with burden of watthour meter and leads corresponding to Fig. 2, and Fig. 6 the accuracy with the full-rated burden for this service, corresponding to Fig. 3.

With the last condition, the maximum error is again reduced to close to one per cent, while the more severe condition shown in Fig. 4 causes a maximum error of over 4 per cent, approaching the amount shown in Mr. Brooks' example at 60 cycles. This, however, is a burden greater than is recommended for watthour meters to work with the transformer.

A study of the 25-cycle results shows that the average error through the ranges selected is in each case in the same direction. It may therefore be partly offset by adjustment of the potential transformer burden or of the watthour meter itself.

Perry A. Borden: In developing the two-stage current transformer, Mr. Brooks has eliminated what has been probably the worst feature in a-c. metering. Heretofore, about the only comfort we had lay in the possibility of the current transformer errors being to some degree compensated for by those of the voltage transformers. But this, even if true for one condition of the load could not be universally so.

While the two-stage principle, as applied to transformers of an inherently compact design and of high ampere-turns means a close approach to perfection, it would seem that its greatest application would lie in the field of air-insulated transformers for high-voltage work, and for bushing type transformers where the primary is, of necessity, limited to a single turn.

A limiting factor in the use of the two-stage transformer would appear to be introduced by the necessity of duplicating the secondary wiring both internally and externally to the meter. On large systems, where each installation is subject to the supervision of a trained meter-man, this would mean little difficulty; but on small utilities where the metering installations are made by a wireman with no court of appeal but the manufacturer's blueprint, the probability of error in the meter wiring would be double what it is now; and I think those who have had experience with meters installed by non-technical help, will agree that this is no small factor.

I should like to ask Mr. Brooks if he has made any studies or carried on experiments in the use of this transformer without the refinement of the extra winding in the meter. It would seem that the commendable features of the principle would be sacrificed but little by paralleling the secondary and the auxiliary windings in the meter, or even at the terminals of the transformer. If this could be done, the only objection to the device,—that of duplicate current circuits—would be at once removed.

F. C. Holtz: In reply to Mr. Craighead's remarks we might add that it was not our intention to show in this paper the characteristics of the best transformers to be had. We did, however, choose a transformer of good average characteristics—a type which represents a fair average of those in service today.

I should also like to inquire of Mr. Craighead the weight of the transformer whose characteristics were shown on the screen.

J. R. Craighead: It varies from 20 pounds up to about 1500. It is an average curve of the total amount of transformer.

F. C. Holtz: The two-stage current transformer can be made extremely light in weight. For example, we have made transformers of 200 amperes capacity with one turn, weighing approximately 13 pounds. This being the total weight of a transformer for 13,200-volt circuits.

The two-stage principle becomes particularly applicable for high voltages where it is necessary to obtain great separation between primary and secondary, and where the simple transformer cannot maintain the high standards of metering accuracy.

In reply to Mr. Borden's discussion, I should like to bring in an endorsement of his suggestion that an important application is that of the one-turn-primary current transformer. Where metering is done close to the generator bus, it is often found that the multiple turn transformer cannot withstand the effect of short circuits and a compromise is reached between the operating and meter departments through the installation of single-turn-primary current transformers. While such transformers do readily withstand the effects of short circuits, they very often fail to give satisfactory results in metering. This is particularly true of transformers of 200 amperes capacity and lower. Such transformers often show over 5 per cent variation in ratio from 10 per cent load to 100 per cent and have phase angles as high as 6. degrees on light loads. It is possible through the application of the two stage principle to build current transformers of the one turn primary type, which in addition to possessing the feature of indestructibility, have good electrical characteristics at low secondary burdens, such as for example, a meter element and .1 ohm resistance. Transformers of this type have been constructed which maintain correct ratio to within .3 per cent from 10 per cent to 100 per cent load, and whose phase angle is less than 10 minutes over the same range of load.

H. B. Brooks: Referring to Mr. Craighead's statement that the two-stage transformer is applicable only where it is desirable to obtain high accuracy over a very small portion of the secondary burden, we consider that it is only a question of design to obtain high accuracy over a large burden. In general, it is not necessary to do this, except in the case of watthour meters, for errors of even several per cent are not serious where the object is to obtain data as a guide in operating the plant. Of course, if the large burden introduces a relatively large mutual inductance between the main and auxiliary secondary circuits, corrective measures may have to be employed. The simplest is the use of an external mutual inductance of equal magnitude and opposite sign, by which the error in question may be reduced to zero.

Tests by Mr. Holtz show that in two-stage transformers having at least 800 ampere-turns the effective ratio and phase angle are not impaired by the introduction into the auxiliary secondary of burdens approximately equal to that of a graphic wattmeter and only to a slight extent by introducing a graphic ammeter or relay. He has made tests of an 800-ampere-turn two-stage current transformer and has found that a considerable burden can be introduced into the auxiliary secondary circuit without greatly affecting either ratio or phase angle, and that even at 25 cycles the results are quite satisfactory and superior to those obtainable in ordinary current transformers of the highest performance commercially obtainable.

While the use of duplicate current circuits is a drawback as Mr. Borden suggests, it is not nearly so serious as might at first appear. If the principal secondary circuit of a two-stage current transformer be opened under load, the auxiliary secondary winding will supply a current nearly equal to the desired total secondary current. This fact gives a means by which even an unskilled man may check the correctness of the connections of the auxiliary secondary coil, as follows. Assume that a three-phase watthour meter is to be operated by two two-stage current transformers. First the auxiliary secondary coils are disregarded, and it is immaterial whether their terminals are open or short-circuited. The principal secondary terminals are then connected to the current coils of the meter, and the correctness of the connections checked by diagram and polarity marks, or any other suitable method, just as if the current transformers were of the ordinary type. This done, the voltage is removed from one element, and the direction and approximate speed of rotation of the disk are noted. The auxiliary secondary terminals of the current transformer which is driving the meter are then connected to the meter terminals, and as a check, the principal secondary circuit is opened. If the auxiliary coil has been properly connected, the meter disk will continue to rotate in the same direction and at practically the same speed as before. If the auxiliary coil was connected backwards, the disk will run about the same speed as before, but in the opposite direction.

The fact above cited simply means that the auxiliary winding is a corrective device capable of functioning not merely over a limited range of error in the principal secondary current, but even in the extreme case of the absolute failure of the principal secondary current the meter will be kept running at nearly the correct speed.

It is obvious that other means may be used for facilitating correct connections, such as a cable of secondary wires of different colors, with corresponding markings on the meter terminals. In any case, the method of checking just outlined is simple and easily applied.

Answering Mr. Borden's question about the elimination of the extra winding in the meter, we would say that a considerable amount of work was spent on this point. By proper precautions, very accurate results may be obtained, but it is necessary for the best results to use a rather large burden in the principal (non-precision) secondary circuit, and furthermore, to have means for checking the accuracy. With the use of duplicate windings on the meter, low burdens may be used in the principal secondary circuit if desired, and if the transformer has been properly made and checked at the factory, no means of checking the accuracy are required, save only to see that the connections are properly made as above outlined.

Three Thousand Tests on the Dielectric Strength of Oil

BY J. L. R. HAYDEN and W. N. EDDY
Member, A. I. E. E.
Both of the General Electric Company, Schenectady, N. Y.

Review of the Subject.—*Three thousand successive disruptive strength tests are herewith shown. These were made in six groups with 500 tests in each group under constant conditions of test. Three groups of tests were taken of standard insulating oil with three different shapes of the electrostatic field; small sphere gap, large sphere gap, and sphere-needle gap. One group of tests was made with commercial and another with chemically pure benzol. The last group was made with air as a dielectric. A brief review of results and conclusions follows.*

In measuring the voltage by a single sphere gap, set in air with reasonable care, the maximum error of test does not exceed 4 per cent and the average error is 1 per cent. In the average of six successive tests the maximum error decreases from 4 per cent to 2.9 per cent and the average error decreases from 1 per cent to 0.6 of 1 per cent.

In contrast to air, the behavior of oil is very erratic. Successive observations of its disruptive voltage, made under most carefully controlled conditions, differed by a percentage many times greater than the accuracy of the test,—the minimum value was as low as 49 per cent of the maximum. This inconstancy of the disruptive strength of oil appears inherent to the material. Little of the variation is dependent on the shape and size of the electrostatic field. Much of the variation is due probably to the complex chemical and physical nature of the oil.

Benzol gives far more consistent values of disruptive strength than oil, the more so the purer it is, but nevertheless benzol is much more erratic than air.

Under successive tests oil, first slowly and then more rapidly, deteriorates by carbonization due to the disruption. Benzol deteriorates very rapidly at first, and then becomes fairly constant. Filtration restores the initial disruptive strength, but the filtered material seems to deteriorate more rapidly than new material. This information indicates that there is either an intermediate chemical state of the disintegrated product or an absorption.

THE difficulty of obtaining consistent data on the behavior of insulating oil under disruptive dielectric stress is well known. It has been found that, because of this erratic behavior of oil, most available data on liquid insulation are so incomplete as to be of limited value.

To study this phenomenon of the erratic behavior of oil and its possible cause and explanation, 1500 successive breakdown tests were made on oil, 500 on one sample each (I) with a short sphere gap, which were described in a recent paper by the same authors,[1] (II) with a long sphere gap and larger spheres at higher voltage, (III) with a point-sphere gap, to see what effect the size or shape of the electrostatic field had.

Then 1000 successive tests were made with benzol, (IV) 500 with commercial benzol and (V) 500 with chemically pure benzol, to see whether the erratic behavior was specific to oil or shared by other liquid insulators.

Finally 500 successive tests were made in air at atmospheric pressure, to determine the possible accuracy of disruptive tests.

As Peek, Ryan and Whitehead have shown that the dielectric strength of air is uniform within errors of observation, comparison of this set of tests with the other five should show how much of their non-uniformity is due to the methods of testing, errors of observation etc.

Each sample was tested successively 500 times at the same gap length by gradually applying voltage to the electrodes (submerged in the sample) until the gap between them was broken down. All possible precautions were taken to prevent the presence of foreign particles, dust, etc. in the samples of liquid insulation, and to insure that each test was made in exactly the same manner. The rate of applying the voltage, which is all important in testing insulation, was made exactly the same for each test by using a motor operated rheostat. All 3000 breakdowns were taken in exactly the same manner as the first 500. Further details as to preparation of the sample, method of testing, development of curves, etc. will be found in the former paper. (loc cit.)

The data taken on each sample is shown graphically in two ways: (1) (*a*) The actual breakdown voltage in succession, (*b*) the average breakdown voltage, and (*c*) the per cent variation from the mean are plotted as ordinates against the number of the breakdowns as abscissas. (2) The per cent of the total number of breakdowns is plotted as ordinate against the per cent variation from the mean as abscissa. Each graph of this second group is a probability curve and was calculated from the data by the $\Sigma\,\Delta$ method[2]. The condition of the six groups of tests follow:

I. Five hundred breakdowns in oil between two one-cm. diameter spheres two mm. apart.

II. Five hundred breakdowns in oil between two 2.54-cm. diameter spheres 27 mm. apart.

III. Five hundred breakdowns in oil between a needle and 2.54-cm. diameter spheres 2 mm. apart.

IV. Five hundred breakdowns in commercial benzol between two one-cm. diameter spheres 2 mm. apart.

V. Five hundred breakdowns in pure benzol between two one-cm. diameter spheres 2-mm. apart.

VI. Five hundred breakdowns in air between two 2.54-cm. diameter spheres one cm. apart.

Figs. 1 to 3 show that the disruptive strength of oil is not constant and uniform, but varies in successive tests under identically the same conditions, over a wide range and in an entirely erratic manner. Comparison with Fig. 6, the air curve, shows that the variations

1. *Five Hundred Tests on the Dielectric Breakdown of Oil*, Hayden and Eddy, JOURNAL, A. I. E. E., February, 1922.

2. Engineering Mathematics. C. P. Steinmetz.

The points on the zigzag curve show the low-tension voltage (transformer ratio 580:1) at each of 500 successive breakdown tests made under constant conditions. Each of the ten points on the dotted line is the mean of the adjacent 50 breakdowns (25 on each side). Each of the ten points on the lower solid line shows the average variation of the adjacent 50 breakdowns (25 on each side) from their mean.

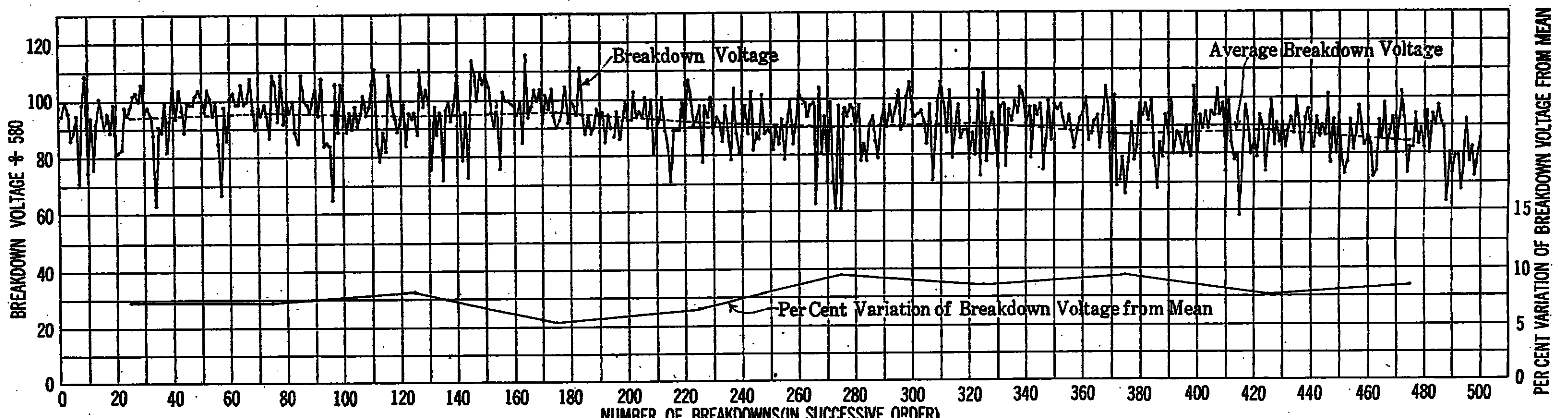

FIG. 1—FIVE HUNDRED BREAKDOWNS ON OIL BETWEEN TWO 1-CM. DIAMETER SPHERES 2 MM. APART

The points on the zigzag curve show the low-tension voltage (voltmeter coil ratio 2000:1) at each of 500 successive breakdown tests made under constant conditions.

Each of the ten points on the dotted line is the mean of the adjacent 50 breakdowns (25 on each side).

Each of the ten points on the lower solid line shows the average variation of the adjacent 50 breakdowns (25 on each side) from their mean.

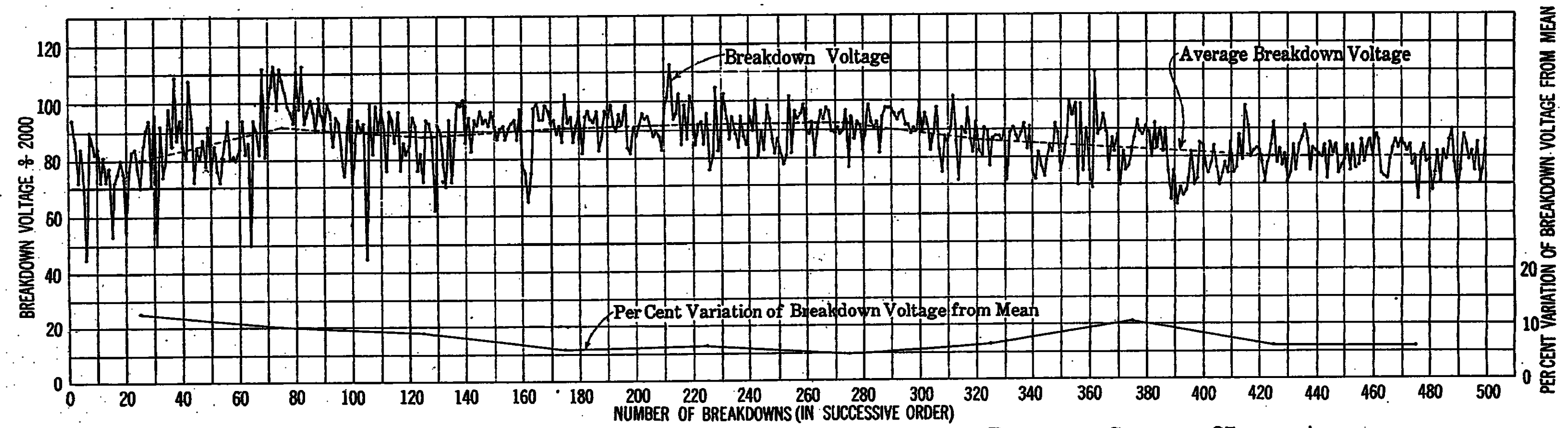

FIG. 2—FIVE HUNDRED BREAKDOWNS ON OIL BETWEEN TWO 2.54-CM. DIAMETER SPHERES 27 MM. APART

The points on the zigzag curve show the low-tension voltage (transformer ratio 120:1) at each of 500 successive breakdown tests made under constant conditions.

Each of the ten points on the dotted line is the mean of the adjacent 50 breakdowns (25 on each side).

Each of the ten points on the lower solid line shows the average variation of the adjacent 50 breakdowns (25 on each side) from their mean.

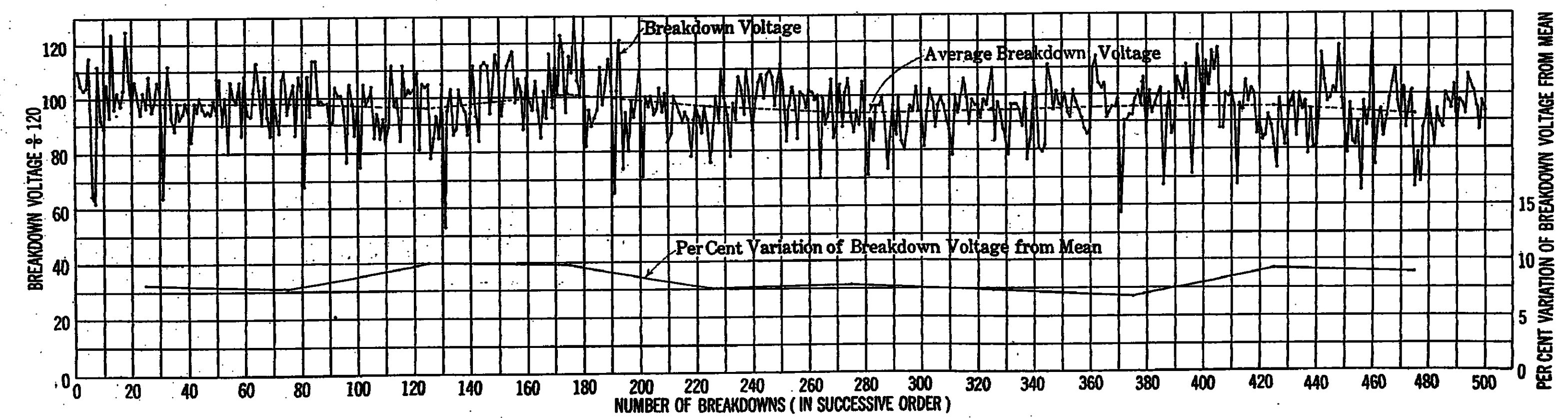

FIG. 3—FIVE HUNDRED BREAKDOWNS ON OIL BETWEEN 2.5-CM. DIAMETER SPHERE AND NEEDLE 2 MM. APART

The points on the zigzag curve show the low-tension voltage (transformer ratio 340:1) at each of 500 successive breakdown tests made under constant conditions.

Each of the ten points on the dotted line is the mean of the adjacent 50 breakdowns (25 on each side).

Each of the ten points on the lower solid line shows the average variation of the adjacent 50 breakdowns (25 on each side) from their mean.

After 300 breakdowns the benzol was removed from the container, refiltered, returned to the container and the tests continued.

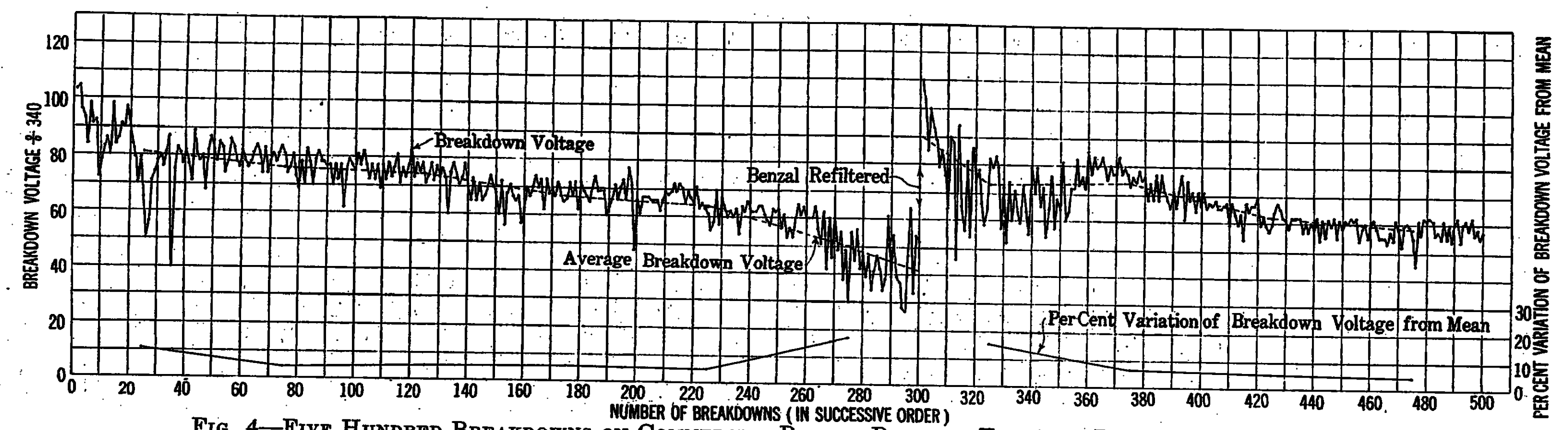

FIG. 4—FIVE HUNDRED BREAKDOWNS ON COMMERCIAL BENZOL BETWEEN TWO 1-CM. DIAMETER SPHERES 2 MM. APART

The points on the zigzag curve show the low-tension voltage (transformer ratio 340:1) at each of 500 successive breakdown tests made under constant conditions.

Of the 14 points on the dotted curve, each of the first 5 (at the left) is the mean of the adjacent 10 breakdowns (5 on each side). Each of the remaining 9 points is the mean of the adjacent 50 breakdowns (25 on each side).

The 14 points on the lower solid curve are distributed similarly. Each of the first 5 is the average variation of the adjacent breakdowns (5 on each side) and each of the remaining 9 is the average variation of the adjacent 50 (25 on each side) from their mean.

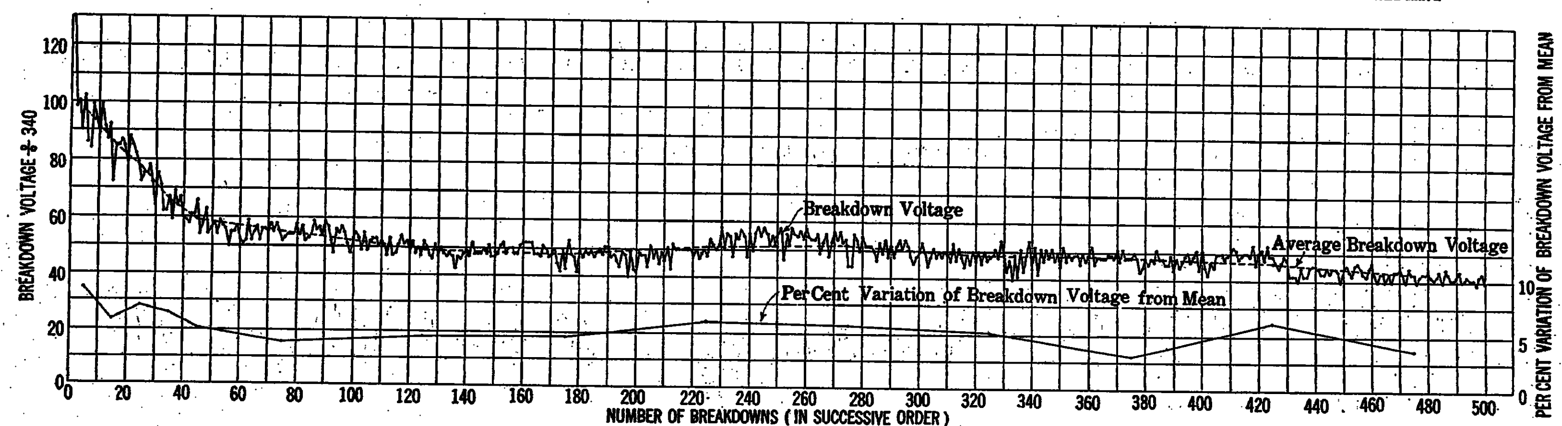

FIG. 5—FIVE HUNDRED BREAKDOWNS ON PURE BENZOL BETWEEN TWO 1-CM. DIAMETER SPHERES 27 MM. APART

The points on the zigzag curve show the low-tension voltage (transformer ratio 300:1) at each of 500 successive breakdown tests made under constant conditions.

Each of the ten points on the lower solid curve is the average variation of the adjacent 50-breakdown voltages (25 on each side) from their mean.

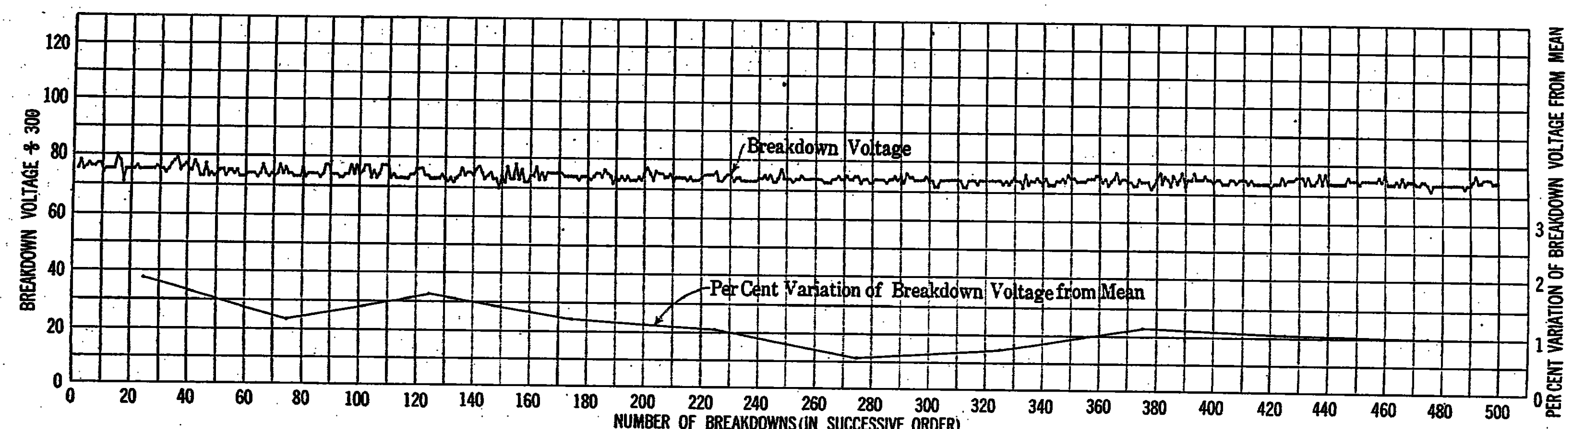

FIG. 6—FIVE HUNDRED BREAKDOWNS ON AIR BETWEEN TWO 2.54-CM. DIAMETER SPHERES 1MM. APART

between successive tests in oil are many times greater than the possible accuracy of breakdown tests in air, and that the cause of the variation therefore must be inherent to the material, the oil.

Comparison of the three oil curves in Figs. 1, 2, 3 and 7 shows that there is little difference between them. In other words, the erratic behavior of oil is not the result of the particular shape or size of the electrostatic field. The per cent variation between successive tests is a little less in a large sphere gap, and a little greater in a sphere and needle gap, than in a small sphere gap, but the difference is small compared with the difference between oil and air gap. In our former paper the point was made that with spheres in oil the actual breakdowns at the higher voltage fell below the breakdowns to be expected by the law of probability, possibly due to the approach to a true dielectric strength of the oil. The large sphere gap showed the same characteristics, while the sphere and needle gap gave a curve which was symmetrical on both sides of the mean, that is, apparently did not show this effect.

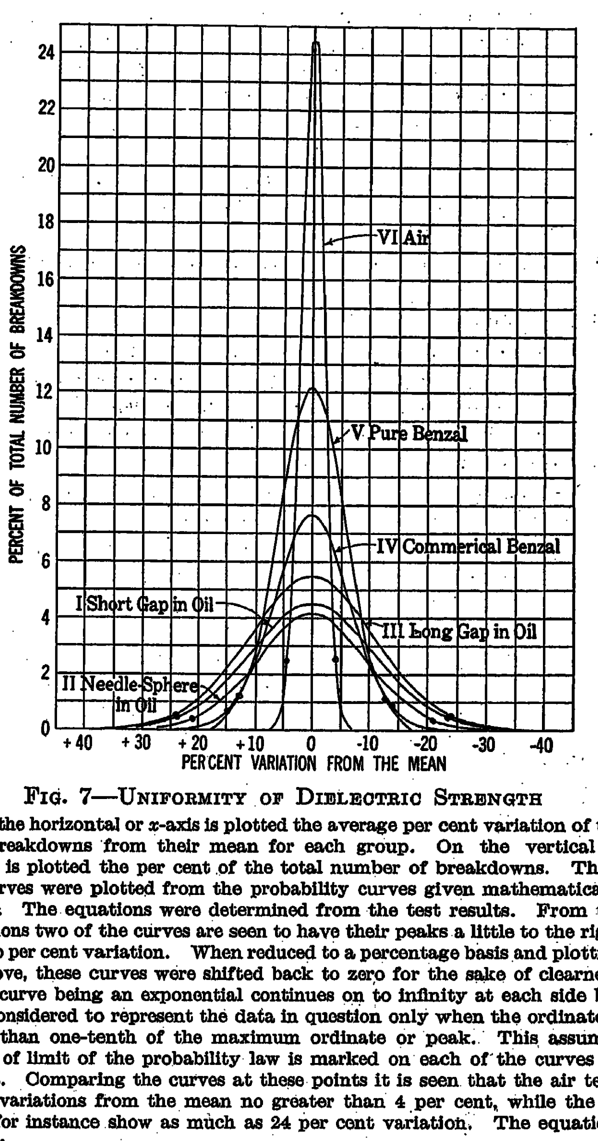

FIG. 7—UNIFORMITY OF DIELECTRIC STRENGTH

On the horizontal or x-axis is plotted the average per cent variation of the 500 breakdowns from their mean for each group. On the vertical or y axis is plotted the per cent of the total number of breakdowns. These six curves were plotted from the probability curves given mathematically below. The equations were determined from the test results. From the equations two of the curves are seen to have their peaks a little to the right of zero per cent variation. When reduced to a percentage basis and plotting as above, these curves were shifted back to zero for the sake of clearness. Each curve being an exponential continues on to infinity at each side but it is considered to represent the data in question only when the ordinate is more than one-tenth of the maximum ordinate or peak. This assumed range of limit of the probability law is marked on each of the curves by circles. Comparing the curves at these points it is seen that the air tests show variations from the mean no greater than 4 per cent, while the oil tests for instance show as much as 24 per cent variation. The equations follow:

Graph I —$y = 22.4\ \epsilon^{-.0051\,(x-3)^2}$
" II —$y = 20.7\ \epsilon^{-0.006\,x^2}$
" III —$y = 27.2\ \epsilon^{-0.0055\,(x-4)^2}$
" IV —$y = 45.8\ \epsilon^{-0.0251\,x^2}$
" V —$y = 60.8\ \epsilon^{-0.0536\,x^2}$
" VI —$y = 123\ \epsilon^{-0.232\,x^2}$

Examination of the two benzol curves, in Figs. 4, 5 and 7, shows that the variation between successive breakdown tests in benzol are materially less than in oil, especially so with chemically pure benzol, but nevertheless are still much greater than with air. Benzol therefore is intermediate in the uniformity of disruptive tests, between air and oil. Possibly this is due to the more uniform chemical constitution of benzol compared with oil.

Comparison of the two benzol curves shows that the uniformity of breakdown is greatly increased by the increased purity of the material. This suggests that the erratic behavior of oil may be due to the complexity of its chemical and physical structure.

The benzol curves were found to follow the law of probability both above and below the mean breakdown without showing any of the unsymmetry given by spheres in oil. With the same amount of energy back of the discharge the benzol seemed to carbonize much more rapidly than transil oil. Before testing, the benzol was, of course, transparent and colorless. After only 20 breakdowns it was opaque and black. Fig. 5 shows that during the first 50 breakdowns the dielectric strength decreased very greatly due to carbonization, and fell to less than half the initial value. After this however, additional carbonization of the benzol caused only gradual deterioration, no more than that of oil and the dielectric strength of the benzol containing colloidal carbon had become approximately constant. Fig. 4 shows that after refiltering, the benzol seemed to deteriorate slightly faster than at the beginning of the test.

The 500 breakdowns in air are seen to be much more consistent than even the benzol tests. As air itself is considered to have a definite and uniform dielectric strength these tests prove that the erratic behavior of the oil and even of the benzol greatly exceeds that which might be caused by the methods of testing, errors of observation, etc. That is, the comparative non-uniformity of the oil and benzol must be due to some inherent characteristics of the materials themselves.

On the probability curves of Fig. 7, the points where the probability has dropped to one-tenth its maximum value, have been marked by circles. While of course each probability curve as exponential extends to infinity most of the observed breakdown values are contained within the range of voltage between the maximum probability and the one-tenth value, and the width of the probability curve between the two circles of one tenth value thus offers the means of characterizing and comparing the different curves, with regards to their scattering of the breakdown values. Thus we get the

following table, showing the range of the voltages over which the breakdown tests are scattered, in per cent of the mean value:

TABLE I

Percentage range of breakdown voltage, from mean:

Air	± 4 per cent
Chemically pure benzol	± 12 per cent
Commercial benzol	± 14 per cent
Oil	± 24 per cent

Table II shows a tabulation of the average per cent error that might be expected for (1) a single test, (2) three tests, or (3) six tests on oil if the mean of 500 successive breakdowns is taken as the correct dielectric strength and any variation from that as the error.

TABLE II

	Air	Long sphere gap in oil	Short sphere gap in oil	Needle sphere gap in oil
Single Breakdown Test		per cent	per cent	per cent
Average error	1.1	7.8	7.8	8.4
Maximum error	6.7	48.5	34.1	44.8
Maximum error except 3 readings	4.0	33.0	31.8	35.0
Three Breakdown Tests				
Average error	0.8	5.2	4.9	4.9
Maximum error	4.0	22.4	19.7	19.1
Six Breakdown Tests				
Average error	0.6	2.7	3.5	4.1
Maximum error	2.9	17.5	15.0	14.3

It is seen that sphere-gap tests in air give an accuracy sufficient for their use for voltage determinations, especially when using the average of several observations, but that to get consistent results in the commercial testing of oil a gap should be so designed as to inherently average as many breakdowns as possible.

Discussion

W. A. Del Mar: I would like to ask the author why the successive tests were made on the same sample of oil. We have done a good deal of oil testing, and have always taken the precaution to pick out fresh clear samples for the tests. I am wondering whether more uniform results would be obtained if a fresh sample of oil were used for each test, than if you used the same sample five hundred times? It would seem that the matter of the chemical decomposition of the oil would enter into the problem, and that has not been mentioned in the paper.

E. D. Clarke: We have gone into the program of the testing of the variation and the breakdown of samples of oil, which seemed to be good oil. Quite an extensive investigation of the subject, which began some time ago and I would like to know how to eliminate some of the variation.

In this process we have raised the temperature of the quantity of oil to about 150 deg. fahr. gradually, and we have found that the oil then behaves quite uniformly.

Another thing is if the sample of oil be turned other side up, a few times, the values come out closely.

As to the point Mr. Del Mar brought up in this discussion, we have made a test with different samples from the same cup, and there was a very considerable variation.

John B. Whitehead: I think that these curves show a very encouraging uniformity, notwithstanding the large value that may be given to the extremes of variation; the authors have rendered a very material service in taking this large number of observations. It brings us to a point where it is possible, to specify the properties of oil in terms of a definite figure, and a maximum permissible deviation.

I think there will be little dissent from the conclusions of the authors that the irregularities are inherent in the structure of the material itself. When Mr. Hayden presented his last paper on the breakdown of oil, I ventured to ask a question, I believe he has not answered. It was whether he had tried corona as it appears on a round conductor as an indication of the dielectric strength of oil. It seems to me that the use of corona in such a connection might possibly automatically smooth out some of the variations that appear in these curves. I believe that using corona, individual breakdowns pertaining to local irregularities in the oil, might tend to extend themselves so as to produce an average condition for the whole of the conductor and so result in a smoother curve.

W. D. A. Peaslee: In Fig. 5 is the spacing of the spheres 2 or 20 mm.?

Mr. Hayden: Two mm.

Mr. Peaslee: In the table it reads two. I was wondering which one is correct, because giving the figures for both in millimeters is a startling comparison as to dielectric strength between commercial and pure benzol. It must be two.

Mr. Hayden: Two is right.

Mr. Peaslee: Were any experiments made with the heavier oil, not filtered during the process, as to whether any different result was shown than in the benzol curves. In the commercial benzol, after a considerable period of tests, the benzol was filtered, and the impurities precipitated by the disruptive discharge removed.

If that were tried, I believe, with Dr. Whitehead that this investigation is better than it looks, and that the extreme variations are not of such moment. This testing of oil is one of the most important things we have before us today in cable insulation and all other kinds of insulation. It seems to me that some of the results were tied up with the mobility of the three factors in the solution.

I would like to see some further work done on the filtering of the oil at different periods, to see if there is a section at which the rate of depreciation approaches the pure benzol curve, and in that case you will find, after the first 100 breakdowns, you are producing a constancy equal to that of air.

O. D. Wood: Designers have long realized the possibility of considerable variation in free oil spaces. For this reason, it has been the practise for years in transformers to break up with insulating barriers the oil ducts separating energized parts.

Solid insulation is not good when used alone, but oil separated by solid insulation in proper proportion gives the best cooling and breaks continuous paths, which may exist with free oil ducts or solid insulation.

The proper breaking up of the oil ducts with barriers tends to neutralize any unstable conditions that may exist in the oil. This is borne out by actual tests, an example of such tests made with oil spaces properly separated by barriers may be of interest. Free oil was separated by one, two and three insulating barriers. Tests were made with the barriers adjacent to each other, and alternating with oil spaces. The results obtained indicated a maximum variation of less than 10 per cent above and below the average value.

It is of interest to point out here, that although under certain conditions the dielectric strength of oil may vary over a very great range, in practise it has been made the most useful and reliable insulating material that is available.

J. E. Shrader: In air electrical discharges take place much more uniformly than in oil. The reason for this, no doubt, is the greater homogeneity in air than in oil. Then in studying the breakdown in oils one should examine it for non-homogeneity. I think that the most of us who have studied oils for their electrical properties recognize the fact that most of the non-homogeneity in oils is due to moisture. One speaker has stated that at elevated temperatures uniformity of breakdown is much greater. This is due to the fact that upon heating, moisture is removed and the oil becomes more homogeneous and not only is there greater uniformity of breakdown but breakdown occurs at higher voltages. Another cause of non-homogeneity is the presence of foreign materials such as lint and dust particles. The presence of these materials is deleterious the more because they take up moisture which may thus be concentrated in the strongest part of the electrical field, thus lowering the breakdown voltage. Barriers in electrical apparatus are of benefit because they prevent the lining up of these moisture laden particles.

In making successive tests upon a sample of oil the character of the sample is altered. By each breakdown moisture and impurities are removed so that at each successive breakdown we have a different set of conditions. Hence to get any real comparison of breakdown voltages each shot should be made upon a new sample of the original oil.

F. W. Peek, Jr.: The investigation of Messrs. Hayden and Eddy is very interesting in that a great number of consecutive points were taken and that all points were recorded. In a theoretical investigation of this nature it is desirable to use electrodes for which the stresses can be calculated. For this reason the sphere gap was used. With the electrodes and spacings used in practise the variation is decidedly less. However, the interesting fact is not the extent of the variation but that there is a variation and that it follows the probability curve.

It means that from time to time a chance variation occurs in the oil between the gaps which affects the dielectric strength. This variation, whether it is due to gas, or to the lining up of particles, has a considerable range. These tests, therefore, confirm, theoretically, the long established practise of using barriers.

C. P. Steinmetz: I had the advantage of seeing these results before their publication, and also of seeing a large number of other results which have not yet been published, and which, to my mind, seem to answer several of the questions raised.

To begin with the question whether new samples should have been taken. I have seen a large number of tests made by using new samples for from 25 to 50 tests, and from the results, I have to agree with Mr. Hayden that it is impracticable to do so, because the successive samples of oil from the same supply vary so much that constant or consistent results can be derived by using one sample only, but such a very large sample, several thousand cubic centimeters, that the individual breakdowns do not appreciably affect the oil. In these tests given here in the paper, I understand, Mr. Hayden took averages at every 50 successive breakdowns. These showed that for the first two hundred or three hundred tests there is no appreciable deterioration, but the breakdown voltage remains the same and only after that number of tests does the oil deteriorate.

Now, as to the different kinds of oil: I have seen tests of different kinds of oil, heavy oil and light oil, and water-white oil, but there was no appreciable difference in the nature of the tests.

The first thing that presents itself as possible cause of the erratic performance of oil, naturally, is occluded moisture. I have seen a number of tests made to find whether the moisture has anything to do with it. For instance, a sample of oil was taken and heated several times and the oil was then filtered by passing it through a large number of layers of hot filter paper, and then it was atomized into a high vacuum, and allowed to settle there, where certainly all occluded air and moisture was evaporated, and then allowed to settle under the exclusion of air for several weeks, and then it was tested again in the same way as oil taken straight from the barrel, but it did not show any materially higher nor more constant breakdown voltage.

A very curious result is shown by the curve of pure benzol. If you notice, there is a quite rapid deterioration during the first readings, and then it comes almost to a stand still, and the deterioration is less rapid. Now, benzol deteriorates very much more rapidly than oil, and while it started perfectly transparent, after fifty tests, it was entirely opaque, but it had become more constant, and a very highly carbonized black benzol was more uniform than the pure benzol. The curve of commercial benzol shows the same. After it was filtered, and a few hundred readings had been taken, the first part showed greater variability than after it became black. It is rather curious, and seems to show after you get it deteriorated and blackened, it becomes more constant again.

F. B. Silsbee: Some time ago I had occasion to participate in some tests of transformer oil for the American Society for Testing Materials[1] in which some 2000 breakdowns were involved. These were, however, distributed over a number of different conditions and consequently do not closely parallel the present work. It is interesting to note that the average deviation of 1 shot from the mean of a group of 50, as estimated from this A. S. T. M. data, comes out as 9 per cent which is in fair agreement with the present results. The earlier data also indicated, though much less emphatically, the astonishingly slight effect of the carbon formation on the breakdown voltage of oil.

One feature of interest in the present paper is the fact that in Figs. 1 to 4 inclusive there appear occasional very low points while there is an absence of corresponding occasional high points. This would presumably cause the frequency curves of Fig. 7 to be somewhat skewed as shown in the earlier paper by the same authors. It is is to be regretted that the experimental points are not shown on the curves of Fig. 7. Is it not probable that these low points are the result of a lining up of bits of impurity so as to make abnormally long weak spots in the dielectric much as suggested by Hirobe, Ogawa and Kubo?[2] These low points are strikingly absent in the case of pure benzol and air.

W. B. Buchanan: In his preliminary paper Mr. Hayden says that the discharge current was limited by the use of resistance in the low-tension circuit so that carbonization would be reduced to a minimum. Another important point is the length of time the arc is allowed to persist after each breakdown and as the method of controlling this is not stated, the system used in the Laboratories of the Hydroelectric Power Commission may be of value.

Our regular testing equipment is provided with an overload relay in the primary circuit thus opening the circuit much more quickly than can be done by hand. The relay does not operate on incipient sparking such as occurs when fine dust, etc. is present but can be depended on to open the circuit promptly as soon as actual break down value of the oil itself is reached. The voltage control is obtained from a motor-driven potentiometer rheostat, one coil closing the circuit automatically at zero voltage, another opening it on puncture of the oil. With this equipment we believe our oil test results are more reliable than is normally obtained by hand control and from a mental summary of the results obtained the writer would say that good oil which has been in service for some time and well taken care of may show a peak on the probability curve of the test results which would be comparable with that shown by Mr. Hayden for air. On the other hand new oil is nearly always more erratic and quite frequently the breakdown value as shown by the meter does not tell the complete story. Deductions may be made sometimes by noting the behavior of the oil itself under stress

1. Report of Committee D-9, A. S. T. M. on Electric Insulating Material—June 1921.

2. Hirobe, T., Ogawa, W., and Kubo, S. Report No. 25, Electrotechnical Lab., Tokyo, Japan.

previous to breakdown as to whether the possibility of improving the oil by further filtration is promising or otherwise.

W. S. Flight:

1. *General:*

This investigation has shown (a) That provided reasonable precautions are taken in determining the breakdown voltage of air fairly consistent results may be obtained. (b) When determining the breakdown voltage of certain liquid dielectrics it is impossible to obtain anything like as consistent results as with air.

It would appear that from Hayden and Eddy's investigations and also from other published data[3], that the mechanism of breakdown of liquid dielectrics (particularly that of oil of commercial purity) is different from that of gaseous dielectrics.

2. *Theory of Breakdown of Oil:*

From an examination of the present available data relating to the electric strength of oil it would appear that oil of commercial purity may breakdown in two different ways. (a) *When Tested between Point Electrodes*: by actual puncture through the dielectric in a similar manner to gaseous dielectrics: the action of the electric field being rather to repel than to attract any impurity into the gap. (b) *When Tested between Sphere Electrodes*: by the lining up of impurities which either shorten or entirely bridge across the gap. (c) *When tested between Disk Electrodes*: by a combination of methods (a) and (b).

(3) *Experimental Evidence in Support of the above Theory:*

(a) *Breakdown of Oil between Point Electrodes:* (i) *Results reported by the Electrical Research Assn.* The data given in Table I below have been abstracted from Table I on page 702 of the "*Electrician*" for December 2, 1921.

TABLE I

Investigator	½ in. sphere gap 15 mils apart	Point gap 15 mils apart
Digby & Mellis	11.5 kv.	17.5 kv.
Everest	20.0 "	22.0 "
Peek	64.0 "	22.0 "
Hirobe	92.0 "	15.0 "

These tests on oils containing different quantities of impurities as well indicated by the sphere gap tests, showed that the results obtained with point gaps were practically uninfluenced by the impurities in the oil. (ii) *Results reported by Dr. Hirobe*: In report No. 25 of the Third Section of the Electrotechnical Laboratory of Tokyo, Dr. T. Hirobe gives a curve showing the relationship between the moisture content and the breakdown voltage of fibre-free oil tested between point and disk. During these tests it was found that for a considerable range the breakdown voltage *increased* with increase in the moisture content. An indication of the numerical value of this increase can be obtained from the result given in Table II below.

TABLE II

Effect of Moisture Content of Oil on the B. D. V. of Fibre-Free Oil, when tested in a 300-mil gap between a point and a disk

Percentage of moisture in oil	B. D. V. at air temperature	Percentage *increase in* B. D. V. over that of moisture free oil
Nil	21 kv.	Nil
0.004	25 "	19
0.008	37 "	76
0.012	45 "	114
0.020	52 "	149
0.028	52 "	149

The increase in B. D. V. with increase in moisture content is explained by Dr. Hirobe to be probably due to the following: (a) That with pointed electrodes the electric field is not uniform and consequently the moisture cannot line up between the electrodes and form conducting chains. (b) That particles of water collect around the electrodes and by changing the shape or area of the point so reduce the maximum voltage gradient between the electrodes.

(b) *Breakdown of Oil between Sphere Electrodes:* (i) *Results Reported by Dr. Hirobe*: In the same reference as given in (a), (ii), Dr. Hirobe shows a corresponding curve obtained with the same oil but with ½ in. sphere electrodes and a gap of 150 mils. Both with fibre-free oil and oil containing fibres the electric strength was found to *decrease* with increase in moisture as shown in Table III.

TABLE III

Effect of Moisture Content of Oil on the B. D. V. of Fibre-Free Oil and Oil Containing Fibres, when Tested in a 150-mil gap between ½ in. diameter spheres.

Percentage of moisture in oil	B. D. V. at air Temp.		Percentage *decrease* in B. D. V. over that of moisture free oil	
	No fibres	With fibres	No fibres	With fibres
Nil	90 kv.	35 kv.	Nil	Nil
0.004	71 "	20 "	21.0	43.0
0.008	66 "	16.5 "	26.6	53.0
0.012	64 "	16 "	29.0	54.0
0.020	62 "	15.5 "	31.0	55.8
0.028	61 "	15.5 "	32.4	55.8

The fact that the presence of fibres causes, with a definite moisture content, a greater falling off of electric strength than when the fibres are not present, is attributed by Dr. Hirobe to the following: With sphere electrodes and a comparatively short gap the electric field is fairly uniform, and when fibres were present in the oil these were observed to line up across the gap, and if of lower electric strength than the oil itself, breakdown took place at a lower voltage. When water was introduced into the oil a small percentage was apparently dissolved in the oil and caused a certain decrease in the electric strength. The greater part of the moisture however, was held in suspension in the form of minute spheres, which, due to their high surface tension, were not distorted by the electric field and so could not of themselves form conducting chains across the gap. When fibres were present in the gap, the water was absorbed by the fibres, which on bridging across the gap thereby produced a greater falling off of the breakdown voltage.

4. *Tests on Oil of Lower Purity.*

In attempting to apply the theories outlined in Section 2 above to explain the results reported by Messrs. Hayden & Eddy, it must be remembered that as these investigators' oil was first rendered as free as possible from moisture and other impurities the electric strength was considerably higher than oil of commercial purity. For example the average breakdown voltage of the oil when tested between 1-cm. spheres and with a 2-mm. gap was 55 kv. whilst the American practise in industrial work is to accept oils which have a breakdown voltage of 22 kv. when tested between 1 in. diameter disks and a 0.10-in. gap, and the British practise is to accept oils having a breakdown voltage of 22 kv. when tested between ½ in. diameter spheres and a 0.15-in. gap. It is probable that with oils of commercial purity distinctly different results may be obtained, and it would appear well worth while to extend this investigation to cover oils of lower purity.

With the latter it is probable that considerably more erratic results would be obtained when the electrodes consist of a sphere,

3. See the following:
(a) Electrical Insulating Properties of Transformer Oil, by Dr. T. Hirobe. Report No. 25 of Elec. Tech. Laboratories Tokyo, Japan.
(b) Effect of fibre on the electric strength of insulating oil, by T. A. McLaughlin, Electrician.
(c) Research on Insulating Oils by the Electrical Research Association, *Electrician*, December 2nd, 1921.

and more uniform results when the electrodes consist of a point and a sphere.

It is interesting to note that even with the comparatively pure oil employed by Hayden and Eddy it was observed that the point electrodes gave the most consistent results, and also that with the point electrodes the curves between the percentage variation from the mean and the percentage of the total number of breakdowns was symmetrical on both sides of the mean.

5. *Effect of Viscosity*:

If, during the determination of the electric strength of liquid dielectrics the conditions are such that breakdown takes place due to lining up of impurities, the freedom with which these impurities can move about in the oil should have an effect upon the breakdown voltage.

Reducing the viscosity of a liquid dielectric may affect the breakdown voltage by (a) Increasing the ease with which the impurities can line up. (b) Increasing the velocity of the circulating currents in the oil which are set up by the electrostatic stress on the liquid adjacent to the electrodes.

The writer has shown elsewhere[4] that decrease in viscosity may under certain conditions cause an increase and under other conditions a decrease in the breakdown voltage of a liquid dielectric. It is possible that the more consistent results obtained with benzol may be due to the fact that this liquid had a lower viscosity than the oil employed. To study the effect which viscosity may have in this connection, it would be interesting to have similar data to that obtained by Hayden and Eddy on transil oil at, say 90 deg. cent.

W. N. Eddy: A large majority of the questions brought up in the discussions is very well answered in the discussion of Dr. Steinmetz.

We understand Mr. Buchanan to say he has obtained breakdown data on oil that are no more erratic than our data on air. We must admit that we are inclined to question the testing methods giving such radical results. After examining the rather brief description of his testing methods we believe we at one time tried out a similar scheme and discarded it as being too insensitive.

Mr. Flight suggests that the difference shown between oil and benzol might be due to the difference in viscosity, and that this could be brought out by taking similar data on oil at 90 deg. cent. We have taken several similar sets of data on both the same and much lighter oil at 100 deg. cent. and the results while possibly a trifle more consistent than our published oil data were in no way comparable with those on benzol.

J. L. R. Hayden: Answering some of the questions which have not yet been answered, we wish to say:

We have made tests of oil at different temperatures, up to 110 deg. cent. but have found no material difference in the lack of uniformity of successive tests. Neither did we find any material increase of uniformity by removing the moisture by heat and high vacuum.

We have made a number of successive tests on oil without previous filtering, and after filtering; we have made tests on the oil carbonized by a large number of disruptive tests, and on the latter oil after filtering off the carbon, but have found no material difference in the erratic variation of successive tests, though the average value of the breakdown strength was increased by filtering, and lowered by carbonization by previous tests. It therefore seems that the lack of uniformity is inherent in the oil as such.

We have not yet made any extensive tests on corona effects in oil, but our experience thus far is that there is no real corona formation in oil, but the appearance of visual corona is coincident with dissociation and gas formation, and what corona appears, is in the gas bubbles, but not in the oil. When this occurs, the results become still more erratic, as may be expected from the formation of gas in the discharge gap.

As regards to the lengthy discussion by Mr. W. S. Flight, while we do not agree with all his conclusions on the mechanism of breakdown, we came to the conclusion that the breakdown of oil between needle points is different from that between spheres. But this conclusion is not new but had been reached by Mr. A. B. Hendricks of Pittsfield, in an extended investigation on oil made some years ago, which led to the development of the present disk gap, standardized now for commercial oil testing. Mr. Hendricks found that the indications of the quality of oil by the point or edge gap do not parallel those of the sphere gap, but sometimes the point gap shows variations in quality better, sometimes the sphere gap. Neither gap therefore is most satisfactory for all conditions. This has led him to the development of the present disk gap for commercial testing, as a combination of a uniform field, between the flat disks, analogous to the sphere gap, and a point or rather edge gap, between the edges of the disks, showing the character of the point gap.

Control of Gaseous Conduction

BY V. BUSH and C. G. SMITH
Member, A. I. E. E. Associate, A. I. E. E.
Research Dept., American Radio and Research Corporation

Review of the Subject.—*In electric circuits of all sorts, power is transmitted principally by metallic conductors. In order to control the flow of power, or to convert it from one form to another, the constants of the circuits are varied. The connections of the metallic conductors may be altered for this purpose; but on high potentials this operation is attended with difficulty. The rapidity and ease of control are also limited.*

For this reason there has been a tendency, in recent years, toward the increased use of control devices employing non-metallic conduction and these are now being rapidly brought to the fore. As examples we have the very versatile thermionic tube and the mercury arc rectifier. The former has received particular attention of late.

Devices employing conduction by gaseous ions have been handicapped in this general evolution by three main disabilities: the first being the difficulty of placing the discharge where wanted, the second, the tendency of the working gas to disappear, and the third, decidedly erratic action. These disabilities have recently been to a large extent removed by the advent of a principle called the "short path principle", by which discharge can be prevented except where wanted. This has also led to long life, for by placing the discharge in proximity only to certain porous materials, gaseous clean-up and disintegration are both prevented. With this change, uniformity of action also appears.

By utilizing this principle, gaseous conduction devices may be designed, for example, as rectifiers. Two examples are described, the first obtaining unilateral characteristics by the use of a magnetic field, and the second by the use of a space charge.

The present models, as described are capable of handling only small amounts of power; but there is no inherent limitation in this direction. The usual conditions of cost, reliability, life and so on will determine development for higher powers.

It is impossible to predict at present the particular portions of the electrical field in which this device in its various forms will find a use. The authors believe, however, that engineers will find its possibilities of interest.

CONTENTS

I. Classification

THERE is a very noticeable tendency in present-day electrical engineering toward the use of control devices which may be generally specified by stating that they involve non-metallic conduction. It is difficult to control the flow of current in a wire by any control device which does not actually separate the metallic circuit. A small amount of control can be obtained by magnetic fields, but this is entirely inadequate for most power purposes. On the other hand, the flow of current through devices which involve other types of conduction may be much more readily controlled by external means. This gives rise to a host of devices, for the control of current makes possible the construction of rectifiers, amplifiers, and the like.

In present-day power engineering there is great need for better rectifiers for railway work and so forth, and for better control devices for handling in reasonable space the large voltages and currents necessary in extensive power systems. Undoubtedly the next few years will see a rapid development of devices for these purposes. The probability is that much of this development will occur along the lines of non-metallic control.

Devices which utilize non-metallic conduction may be readily classified according to the nature of the carriers of electricity which are employed.

1. Devices employing ions in a liquid or semi-solid: Insulators which become conducting because of high temperature and electrolytes in general involve this type of conduction. Such conduction is always accompanied by chemical action. No devices involving this type of conduction have become commercially important as rectifiers or the like. The aluminum lightning arrester is an example of a protective device operating on this basis.

2. The simplest type from a theoretical standpoint is that in which electrons only are used. The device then consists of a container exhausted to a hard vacuum, with two or more electrodes, one of which is a source of electrons. Such a device is the thermionic tube, the most important single piece of apparatus which has appeared in electrical engineering in twenty years. In addition to the thermionic tube, various other similar arrangements have been suggested in which the supply of electrons is obtained without utilizing an incandescent member, as for instance by the use of the photo-electric effect. None of these latter are at present commercial.

Devices under this classification are characterized by somewhat severe current limitations. The internal drop is very variable, and is determined by space charge effects. They are capable of operating at very high potentials.

3. Devices employing electrons, and gaseous ions:

(a) Under this heading we have first the device which employs a hot filament in a gas-filled receptacle. Such for instance is the Tungar rectifier. This device conducts relatively large currents, for it employs gaseous conduction as well as conduction by means of the primary electrons evaporated from the filament.

Presented at the Annual Convention of the A. I. E. E., Niagara Falls, Ont., June 26-30, 1922.

It is, however, unable to withstand large reverse potentials.

(b) Under this heading there have been second many devices in which the supply of electrons is obtained in other ways than by heating a filament. The principal way is to remove them from a cold metal electrode by positive ion bombardment. The old "Geissler" tube operates in this manner. So also does the gaseous X-ray tube. Such devices offer great possibilities, but have not heretofore become important commercially as control devices on account of difficulties which will be treated below. Under this heading comes the device which is the subject of the present paper, and this class will be further analyzed.

4. There are also devices in which the carriers are electrons, gaseous ions and charged metallic vapor. This includes all sorts of arcs. The mercury arc rectifier comes under this heading; and as an example of its use as a control device, the Vreeland oscillator.

This type of conduction is accompanied by rapid vaporization of the electrodes. The part played by the vapor in the conduction is still a matter of doubt. The material of the electrodes is transferred and lost, so that it must be continually replaced. In mercury arc devices this replacement is made automatic. Devices of this type are characterized by low internal drop, and the current capacity limited only by the cooling means employed. In voltage they are limited to that potential which will cause ionization of the working gas and conduction from the cold electrode.

II. Analysis of Type 3 (b)

The type of device employing electrons and gaseous ions in which the electrons are obtained by bombardment, has many desirable features. First, the current which can be passed through such a device is limited only by the capacity of the cooling means employed to dissipate heat. For short intervals there is hence practically no upper limit to the amount of current which can be passed between the electrodes. This is in contrast to the thermionic device, in which the upper limit of current is dependent upon the number of electrons which can be evaporated from a filament. In this respect the gaseous conduction device and the arc are similar.

Second, there is not necessarily involved any part at very high temperature. This greatly simplifies design and removes one limitation to the life of the device.

There is no inherent reason that disintegration of electrodes should accompany gaseous conduction proper. Where disintegration enters in such a device it is incidental and avoidable; for the operation does not depend upon and is not necessarily accompanied by disintegration. This feature is in direct contrast to both the thermionic tube and the arc. In the former the filament, in order to emit electrons copiously must unavoidably operate at such temperature that molecules of the material of the filament also evaporate to some extent. The filament life is thus directly connected with the quantity of electricity passed through the tube. In the arc the wasting of the electrodes is also intimately involved in the mechanism of conduction, and is here much more rapid; although it can be avoided in the mercury arc, and to a lesser extent in other arc devices, by provision for replacement.

On the other hand, gaseous conduction devices have always in the past been subject to very decided limitations.

First, the voltage which could be employed has been limited by the gas pressure used. In this respect there has been for this type of unit, in common with the arc a serious disadvantage as compared to the thermionic tube. The disadvantages ordinarily present in this class of device in general, and this disadvantage in particular, are treated in detail in this paper.

Second, the internal drop is in general of necessity higher than in the arc. A comparison of internal drop with that of the thermionic tube is hardly possible, for the gas tube involves a drop nearly independent of the current, while the exact opposite is true of the thermionic device.

Third, gaseous conduction devices have been uniformly erratic in action. The reason for this will be brought out below. On this account, knowledge of the theory of gaseous conduction has been delayed, and experimenters have been repelled from this field. The limitation is not inherent, but has always been present.

Fourth, this class of apparatus has been liable to short life on account of a change in the nature or pressure of the gas employed, or due to a variation in the electrode surface. This last disadvantage is decidedly avoidable, but it has been the principal obstacle in the past to development along these lines.

This paper is devoted to the brief exposition of a development by which the disadvantages of this type of device have been largely overcome. By removing the difficulties, the way has been prepared for a number of applications of the principles of gaseous conduction. One of these applications is described sufficiently to render the use of the principles apparent.

III. The Short Path Idea

The first limitation was in the working voltage (or the back voltage in a rectifier) which could be employed. In the ordinary gas tube this is limited to that voltage which will cause ionization of the gas and release of electrons from the electrodes by bombardment at times when the device should really be insulating. There has been recently developed a principle which allows of the use with the gas conduction tube of voltages far in excess of this limit.

This principle is properly called the "short path principle". It is the outgrowth and extension of an observation which has long been noted by physicists. It allows of the use of high back-voltages by not giving them opportunity to produce ionization.

It has long been known that if two electrodes are situated in a gas of a pressure such that their distance apart is comparable with the mean free path of an electron in the gas, a discharge will pass between them by long paths in preference to shorter ones. If two electrodes are spaced close together in a large bulb in a properly attenuated gas, the discharge between them will prefer the long path from the back of one electrode clear around to the back of the other, the short direct path remaining dark. It has not been generally recognized how strong is this preference, or that it could be utilized to advantage. The short path idea extends this principle by suppressing the long path entirely. If we so construct the device that *all* paths between the electrodes available for discharge are short, the device will stand large voltages and carry practically no current. All paths may be rendered short, as above defined, either by placing the electrodes close together or by placing obstructions in the way of the discharge. The diagram of Fig. 1 will show one manner in which this can be accomplished. It will be noted in this diagram that, if the electrostatic field between the electrodes be mapped out, all lines of electrostatic force are either short or are interrupted by the glass of the containing tube in such manner that the path available for discharge is short. When a potential is applied to such a device, there is no conduction even far above the potential at which the device would break down if the electrodes were widely separated, or the gas pressure high. As an illustration of this statement, a device constructed as above with clean electrodes and pure gas, with a spacing of one millimeter and a pressure of two millimeters of helium, will withstand continuously 10,000 volts and pass an amount of current which is hardly measurable. With the electrodes several centimeters apart, this same tube would have broken down at perhaps 300 volts, and at 500 volts applied would have carried several hundred amperes, if the external circuit would allow, and would probably have been destroyed. It should be noted carefully, however, that in order to render the unit thus insulating, under conditions where widely spaced electrodes would break down, it is necessary that *all* paths available for conduction be short.

By properly utilizing this principle, the voltage limitation of the gaseous discharge type of conduction is largely removed.

IV. First Application of the Short Path Idea

The short path idea also removed the third limitation. It can render a gaseous conduction device stable and reproduceable instead of erratic in action.

Gaseous conduction devices have in the past almost always been constructed in glass tubes and with the diffuse discharge intimately in contact with the glass. Such construction is sure to lead to erratic behavior. Due to the ionization, the glass is bound to accumulate charge, which will vary rapidly with the nature of the discharge, the temperature of the glass and a number of other factors. These charges vary the electrostatic fields present, and modify the conduction in a sudden and arbitrary manner. Due to this factor alone, such devices have gained an undesirable reputation as regards unreliability of action. It is evident that in order to remove difficulty in this regard, the discharge must be confined to a part of the device remote from any insulator.

This can now be accomplished. By the short path idea, ionization is prevented everywhere in the device except in one region where the paths are left long or are rendered so. This region is located far from any insulators. Charges therefore cannot accumulate. The resulting discharge is steady.

One means of arranging matters is shown in Fig. 2. The tube here shown is similar to the insulating tube of Fig. 1, except that one of the electrodes is made hollow and a central opening to this hollow space is provided. Between the electrodes in the center there are hence long paths. So when a potential is applied,

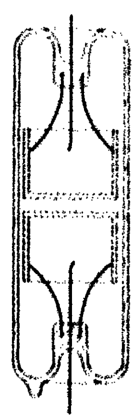

Fig. 1

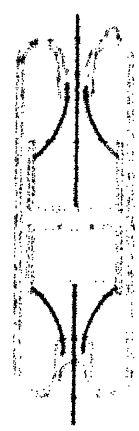

Fig. 2

a discharge can occur in this central region and nowhere else. Such a discharge is remote from the glass of the tube or from any other insulator. It is thus not affected by parasitic charges, and is steady in accordance with the circuit conditions.

As an example of this steadiness may be mentioned a tube carefully constructed along the lines shown in Fig. 2. A current of about ten milliamperes was passed through this tube from a storage battery source. A pair of high-resistance telephones placed in series with the tube gave no sound. In fact the variations in current were amplified by a two-stage thermionic amplifier before becoming barely audible. This is in decided contrast to the result which would have been obtained had the electrodes been widely separated and the discharge in proximity to the glass walls.

Nearly all of the study which has been made of the laws governing gaseous discharge has utilized glass-walled tubes with the discharge in proximity to the glass. To this fact may be attributed much of the present lack of complete knowledge of these laws.

V. The Maintenance of Gas Pressure

The same control of the discharge which is used to render it stable may at the same time be used to avoid

the last disadvantage mentioned in the analysis. This limitation involved the disappearance of the working gas.

The variation in pressure which occurs in the usual gaseous conduction apparatus has long been a source of difficulty. It was one of the principal drawbacks of the gaseous X-ray tube; and it has to a large extent prevented the rapid development of gaseous discharge illumination.

When a discharge is passed through the ordinary gaseous discharge tube, the nature and pressure of the gas continually change. Of course when the working gas is chemically active, the disappearance is readily accounted for. Even when using an inactive gas, such for instance as helium, a variation in pressure will occur. There will, for one thing, be a variable amount of gas occluded on the walls of the container, but the change in pressure from this cause is small when any fair-sized amount of gas is present. In addition, however, there is a continual and really serious disappearance of the gas due to another phenomenon entirely. In order to make a gaseous device of long life, this effect must be avoided. This disappearance is not due to chemical action, as it continues even when the working gas is chemically inactive.

A study, made possible by short path control, has determined the action of this second cause of disappearance and has found a remedy.

The action of clean-up of a working gas which is chemically inactive is usually accompanied by disintegration. In any case the presence of disintegration greatly increases the rapidity with which the working gas disappears. The amount of gas which can be removed from a vessel in this manner is truly surprising. By passing a discharge between aluminum electrodes in a half-liter vessel, for example, the gas pressure of helium has been reduced from seven millimeters to practically zero in a few hours' time. In fact, quite a hard vacuum may with care be produced in this manner.

Apparently gaseous discharge is accompanied by a penetration of the impacting positive ions into the cathode. The distance to which they can penetrate in this manner must be extremely small, under ordinary conditions of the order of magnitude of one-ten-thousandth of an inch. Yet very large volumes of gas may thus disappear. If we compute the gas pressure produced in this manner at the surface layer of the electrode material, it is found to be enormous. This possibly forces gas further into the interior of the metal progressively. It also results in minute explosions which project small particles of the metal from the electrode at high velocity. This is at least part of the mechanism of electrode disintegration. This disintegration is accompanied by gas disappearance.

One or two observations will tend to throw light on the above statements. First, the gas which disappears in this manner can be in great part recovered by heating the electrode material to near its fusing point, thus apparently offering the imprisoned gas opportunity to escape. The temperature necessary for recovery therefore depends upon the material of the electrodes. This has been accomplished with several different materials.

Another observation is more striking. A tube was constructed as shown in Fig. 3. In one electrode was located a small volume of pure tin. In fact the lower electrode, of iron, was coated all over inside with the tin. The discharge is confined by reason of the short path principle to such space that one electrode is in effect entirely of tin. The device was also constructed so that during discharge the surface of the tin could be observed by means of a low-power microscope. The tube was then operated at a current such that the electrodes became sufficiently warm to render the tin molten. Under these conditions a very interesting phenomenon was observed. Small bubbles appeared on the surface of the tin, gradually increased in size and finally burst. The bursting was accompanied by the projection of a small amount of metallic tin at fairly good velocity. Some of these bubbles were large enough to be observed with the naked eye, although their size depended naturally on the temperature and hence the viscosity of the tin. Moreover, it was observed that with the discharge thus confined to tin electrodes in this molten state, there was no change of the pressure of the working gas over long intervals of time of discharge. Intervals were studied of several thousand hours and with 100 or 200 milliamperes flowing. It thus becomes very apparent that disintegration and gaseous clean-up go together. Also that by proper construction, difficulties of this nature can be entirely avoided.

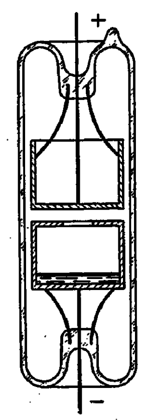

Fig 3

As an additional method of attack, it has been noted that a discharge maintained in proximity to carbon, and to nothing else, will not result in a disappearance of the working gas, provided the carbon is of proper grade and the working gas is chemically inactive. This is also true of some other materials under definite limitation as to allowable voltage drop and so on. The use of carbon, however, will serve as an excellent example. Apparently carbon does not disintegrate appreciably under a discharge of reasonable voltage drop, for tubes with carbon electrodes operated over periods of several thousand hours showed no measureable change in the carbon surface. This is due undoubtedly to the porosity of the carbon, which prevents a gas pressure from accumulating. Carbon will not hold the working gas imprisoned.

There is still room for a great deal of investigation

on the subject of gaseous clean-up. The above procedure will enable us, though, to construct devices of this nature in which any limitation of life due to disintegration, or loss of working gas, is entirely avoided as far as can be determined from tests extending over more than 6000 hours on two of the specific constructions outlined.

VI. Magnetically Controlled Tubes

By utilizing the above principles, we now have available a type of gaseous discharge device which is capable of withstanding a high voltage, which is stable in operation and which is of long life. There is immediately a large number of ways in which such a device may be controlled and utilized. One of these and its application will be described in the present

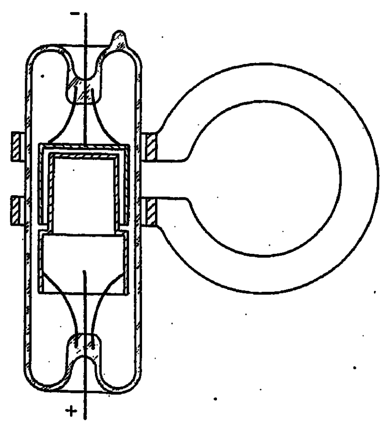

Fig. 4

paper. In a previous paper[1] has been described a different form, which need here only be mentioned.

In the form of device described in the previous paper a construction is utilized such as is shown in Fig. 4. The electrodes consist of two concentric cylinders. The gas pressure employed is such that the distance apart of the cylinders is short compared to the mean free path of an electron in the gas. *All* paths between the electrodes are rendered short by the construction shown. Under these conditions the device insulates for a fairly high potential applied in either direction.

Provision is made, however, for the introduction of a magnetic field which is nearly axial in the space between the electrodes. This is accomplished by means of a permanent magnet and pole pieces, as shown, whereby the field is conducted to the space where it is desired. Without the presence of the field, the flight of electrons between the cylinders is radial. By the action of the field, these paths are curved. A curved path between the cylinders is long compared to the direct radial path. Accordingly the device may be so arranged that, with the field present, the electron paths are long enough to cause cumulative ionization and consequent conduction, whereas without the field we have complete insulation.

1. *Proceedings* of Inst. of Radio Engineers, February, 1922.

Under these conditions the strength of field necessary for conduction with the inner cylinder negative is greater than that for conduction with the outer cylinder

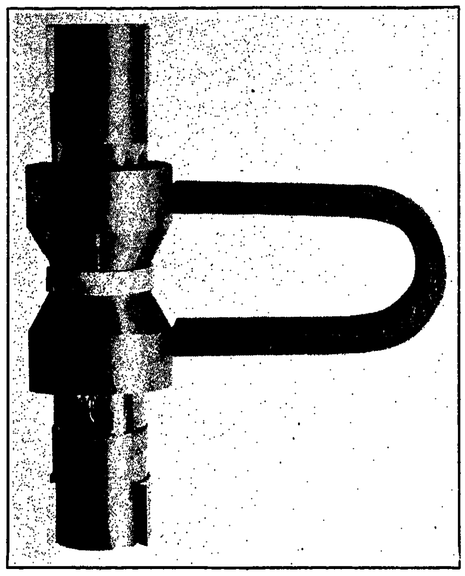

Fig. 5

negative. In fact, the ratio of the two critical fields is the same as the ratio of the cylinder diameters. This relation, which was first derived from the mathematics of the electron paths, has been checked by experiment. Accordingly, by utilizing a field strength intermediate between these two values, a device may be produced

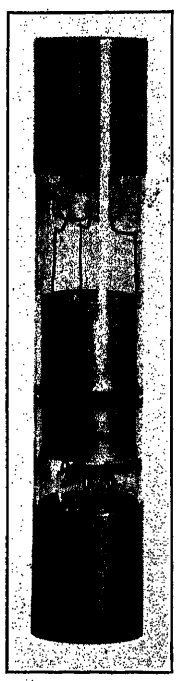

Fig. 6

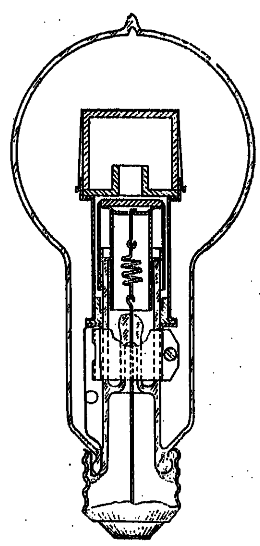

Fig. 7

which will conduct in one direction only; that is, a rectifier.

Illustrations of a tube of this type are shown in Fig.

5 and Fig. 6. The magnet and pole pieces are removed in Fig. 6 in order to show the construction. It will be noted that the tube is made cartridge type, with ferrules to be inserted in clips similar to fuse clips.

Certain quite important benefits as regards allowable voltage range and allowable variation of field strength may be obtained by arranging the magnetic field to be somewhat curved and of non-uniform strength. These matters need not be entered into at the present time.

The above method of control, by means of a magnetic field may, of course, be used for other purposes than that of producing rectifiers. By utilizing a tube in which the design is adjusted to render it critical to field strength, an amplifier may be produced. Also, by any of the usual schemes of "coupling back," such an amplifier may be made to act as an oscillator.

The magnetic type of tube is thus capable of a variety of uses. As a rectifier constructed with carbon electrodes of special composition and with one of the inactive gases, it has an internal drop of about 150 to 200 volts. The efficiency is therefore high on rectification of voltages of a few thousand. The current which can be passed through such a tube is limited only by the amount of heat which can be dissipated from the surface of the tube. Hence its power output is limited only by its design, and not by any inherent current or voltage limitations.

VII. Hollow Cathode Type of Rectifier

There are other types of control possible besides magnetic control. One of these is to use a space charge effect, the space charge being due principally to the positive ions. By the use of this principle, rectifiers may be produced which, while they do not have the versatility or all of the power possibilities of the manetically controlled tube, are yet preferable for some purposes on account of simplicity.

A cross-sectional diagram of one such tube is shown in Fig. 7. It will be noted that the cathode consists of a hollow carbon cup. The anode consists of simply a carbon button placed directly in front of the hole in the cathode. By the use of shields, all paths between anode and cathode, except those through the hole, are rendered too short for conduction at the gas pressure used. There is no magnetic field, and no auxiliary control device of any sort. Only two connections are made to the tube.

The principle by which this device operates is somesomewhat involved. A brief outline only will be presented here. In general, it may be stated that the action depends upon the wide difference between the mobility of electrons and positive ions, and upon the accumulation of a positive space charge.

When the device is conducting current, the space inside the cathode is filled with ionized gas, that is with a cloud of electrons and positive ions. It is due to the presence of these, and to their wandering toward the anode and cathode respectively, that conduction takes place. At any given instant, however, there will be a very great preponderance of positive ions. This is due to the much greater mobility of the electron. The charges on electron and singly ionized positive ion are equal. Their masses are, however, in the ratio of one to several thousand, the exact ratio depending upon the nature of the gas used. Accordingly under a given applied potential gradient, the electrons as they are freed acquire velocity and move out of the field with much greater promtitude than the positive ions. The slow-moving, heavy ions are left behind. Accordingly we have ordinarily in gaseous conduction devices, during conduction, in the space between anode and cathode a positively charged cloud.

Due to the form of the electrodes in the hollow cathode type of *S*-tube, the potential gradient in the hollow space inside the cathode is normally small. The cloud of positive ions is hence swept out of the field only slowly. Due to this fact the cloud is not cleaned up or discharged during the half-cycle in which no current flows through the device. If the electrodes were simply placed opposite each other, any cloud of positive ions would be completely removed during this inactive period if the potential difference between electrodes, which during this interval equals the back voltage on the rectifier, were high. The hollow construction prevents this from occurring, and the cloud of ions on which the operation of the device depends persists from cycle to cycle, when used at commercial or higher frequencies.

Refer to the simplified diagram of Fig. 2 for convenience. When the hollow electrode is negative, the tube conducts freely. Under these conditions positive ions are dropping from the cloud onto the interior surface of the hollow cathode, where they liberate electrons. These electrons proceed toward the anode, and on their way ionize neutral gas molecules and form new positive ions, so that discharge is maintained. The original electrons and those formed by ionization nearly all pass out sooner or later through the hole in the cathode, and thus reach the anode; which latter for this direction of conduction is the solid electrode. This they can do rapidly and with facility on account of their great mobility, which allows them to attain speed quickly. Thus conduction in this direction occurs with facility.

Consider now, however, that the potential is applied in the reverse direction, the solid electrode being now the cathode. Positive ions under this condition will wander out from the hollow space, through the hole, and impinge upon the solid cathode. Their progress for most of their journey is, however, painfully slow; for they are large and heavy and the gradient of the field up inside the cloud is extremely weak. Nearly all the potential drop, because of the geometrical construction and the space charge effect, occurs out in the region between the electrodes. Practically the only ions acted upon by the potential are those near the

exit. When an ion reaches here it speed up, drops into the cathode, and there may release an electron. This electron flies back into the cloud, and possibly produces ionization. The current that can pass is, however, limited to that produced by the number of ions arriving at the cathode; and this, on account of the conditions, is very small for potential in this reverse direction.

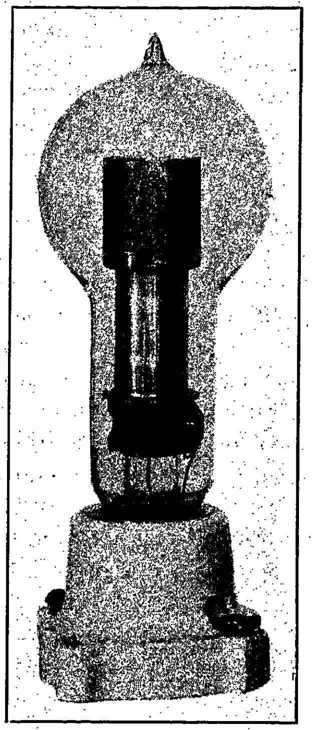

Fig. 8

For potentials in the conducting direction, the cloud of ions forms practically an extension of the anode projecting up into the hollow space inside the cathode. A large area is available, and a steep gradient, to pull ions over to the cathode and cause conduction. For a potential in the reverse direction, the cloud of ions serves again practically as an extension of the anode, in this case the hollow member, but now it acts effectively to plug up the hole in this electrode and render all possible paths for conduction substantially short. The area acting is small, and very few ions are pulled to the cathode to cause current.

The ratio of currents for the same applied potential in the two directions, when that potential is sufficient to cause conduction at all, is much greater in the working range than the ratio of the two cathode areas; the first being the inside area of the hollow electrode, and the second the projection of the hole onto the solid member. The ratio is much greater, for in one case conditions are correct for building up cumulative ionization and in the other case they are not.

There are secondary additional actions going on, such as recombination etc., which complicate the analysis. For example, when the tube is first started, there is a transient period during which the cloud of ions is being built up. The above does not pretend to be complete, nor entirely rigorous. It will, however, give some idea of how such a hollow cathode device, controlled by the presence of a space charge, utilizes the short path principle for rectification.

Tubes constructed in accordance with this principle are shown in the illustrations Figs. 8 and 9, and in section in Fig. 7. These tubes are constructed for low-power service where simplicity and long life are essen tial requirements. All that is necessary in order to connect them into circuit is to screw them into the ordinary lamp socket. Of course where higher potentials are desired, the socket must be made special in order to properly withstand the voltage.

This tube is exactly the same in principle as the simplified tube of Fig. 2. The additional parts employed are for several purposes. It is now being produced for engineering use, is arranged to be mounted on a single stem, which makes for accuracy and ease of assembly. Both leads are brought out from the same end, which is convenient in moderate voltage service. The working parts are far removed from the glass bulb, which avoids danger of overheating the glass. There is a considerable volume of reserve gas, which avoids sudden changes of gas density due to temperature effects.

The tube of Fig. 8, as now supplied commercially, has a rated capacity of 50 milliamperes, and is designed to be used for supplying 500-volt direct current. In both of these matters it has some overload capacity. This particular tube was designed for the use of amateur

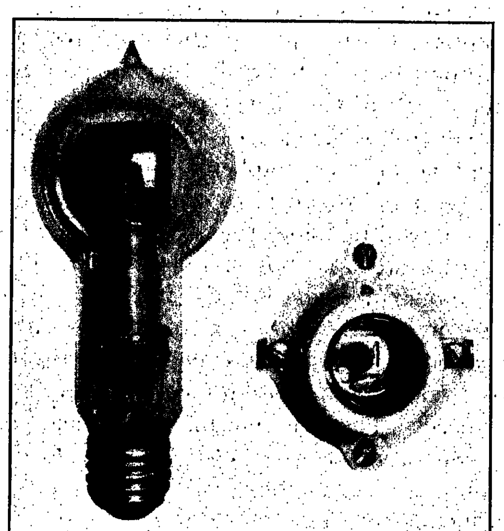

Fig. 9

radio enthusiasts for supplying plate voltage for use on their thermionic tube generators. It is also useful for charging small storage batteries, for fire alarm systems, and so on.

The behavior of this tube is shown by the characteristic in Fig. 10. This characteristic is taken on a continuous potential circuit. It is rising throughout

the working range, although nearly flat, and not drooping as is that of the arc. It differs considerably from the dynamic characteristic. The curve for reverse voltage is shown in Fig. 11. Measured on continuous potential and at a voltage of 1500, the reverse current

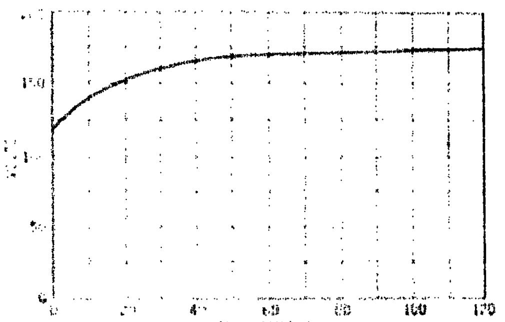

Fig. 10—Direct-Current Voltage Characteristic
Hollow electrode cathode

of the above tube is about 1.5 milliamperes. This completeness of rectification is also shown by the oscillogram of Fig. 12, which shows the current delivered to a resistance load with the tube operating on a 1000-volt a-c. circuit. Any of the usual rectifier circuits may, of course be used. Both halves of the a-c. wave may be rectified and the delivered d-c. potential smoothed out in the usual manner.

The tube noted above has a reasonable continuous overload capacity. Momentarily it can carry very much higher currents than normal. For a period of one second the tube may safely carry 10 amperes, or even more, and will rectify correctly under these conditions. Fig. 13 shows an oscillogram of current taken when the tube was thus handling a current of about this magnitude. Since the cooling of such a tube is largely by convection of the enclosed gas, the electrodes run normally much below a red heat, and the cooling is limited only by the facility with which the glass walls can dissipate to the surrounding air.

These tubes will operate in series and in parallel. In order to get very accurate sharing of current for parallel operation it is advisable to connect a small resistance in series with each tube. This is, however,

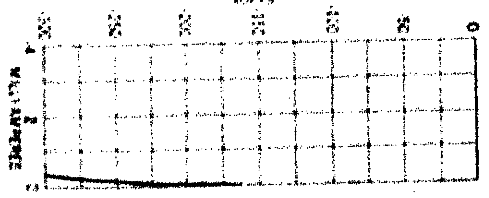

Fig. 11—Direct-Current Voltage Characteristics
Hollow electrode anode

not necessary if the tubes are correctly paired, for the characteristic is rising and parallel operation is accordingly stable. In series, no particular precautions are necessary. A high voltage will be equally shared between the tubes. It should be particularly noted in this connection that, when the tubes are used in series for the production of higher voltage, there is no problem of the insulation of filament batteries or other auxiliary devices. The tubes with their sockets as a whole are the only things that need to be insulated against full line potential.

When a tube of this model is operating, there is nothing that can be seen, except where a glow can be observed through a pinhole made in the cathode for this purpose. The heating of the bulb is the only indication that load is being carried.

The life of these tubes is very long. Tests made extending over several thousand hours on a number of models have not shown a change of 5 per cent in the characteristic at any time, and an examination of the

Fig. 12

electrodes at the end of such period has shown no measurable disintegration. It may be safely assumed for all ordinary purposes that the life is practically indefinite.

These tubes do not have the instantaneous current limitation of the thermionic rectifier. Also the characteristic does not pass through the origin, as is there the case. There are many uses in which such a current limit or characteristic is necessary. The internal drop in the present models is inherently higher than in other types of rectifiers now in use on low-voltage circuits. As is usually the case with electrical apparatus, the rectifier field will always be shared by a number of

Fig. 13

widely different devices each particularly adapted for the use to which it is put. The particular portion of the field which will be occupied by the tube here described may be fairly accurately predicted from an examination of its inherent properties as presented in the paper above.

VIII. Summary

Of the various types of non-metallic conduction, that employing electrons and gaseous ions is particularly noted. For practical purposes it has many advantages, such as the use of cold electrodes, comparatively unlimited current, and no inherent consump-

tion of the working parts. In the past, however, this gaseous conduction has been little utilized commercially for it has been erratic and unreliable, and disintegration of electrodes and loss of working gas have accompanied it, with resulting short life.

A new engineering principle, the short path law, and closely connected ideas, have resulted in practically removing these disabilities. The discharge can now be made to occur where it is wanted, and controlled; so that devices employing gaseous conduction may be made consistent in behavior and reproduceable. By limiting the discharge entirely to electrodes which are constructed of certain favorable materials, disintegration has been made to disappear, and with it all trace of gaseous clean-up. The result is the possibility of constructing gaseous conduction devices which can be depended upon and which will last indefinitely.

Many applications of the principles may be made. Two of these, both rectifiers, illustrate the possibilities of the new arrangement. The first, described only briefly, obtains its control by the use of a magnetic field. The second obtains a similar control by the use of a space charge. The control is so complete that a ratio of currents in two directions of several thousand to one can readily be obtained. These rectifiers will readily stand a back voltage of several thousand. The current which they can pass is limited only by the question of getting rid of the heat evolved. The internal drop is around two hundred volts with the usual arrangements of the device. Heavy currents can be passed for short intervals.

One commercial model of this form of S-tube is rated at 50 milliamperes continuously, and 1500 volts back voltage. It has a substantial continuous overload capacity. It is designed primarily for charging fire alarm batteries and for the use of radio amateurs. For convenience, it is built to be screwed into the ordinary standard lamp socket. No other appurtenances or auxiliaries are necessary. The life is very long. The efficiency depends upon the circuit, and is high when high voltages are rectified. Such tubes may be used in series or parallel to any desired extent in order to obtain a desired voltage, current, or output.

Discussion

C. P. Steinmetz: This paper is interesting in the deductions you draw from it, because the statement made that a short gas path will not carry a discharge at voltages which will go over a much longer gas path, is rather in contradiction of our present ideas of the nature of breakdown in gases as determined by constant breakdown gradient.

This paper thus throws some doubt on our present explanations of disruptive phenomena in gases as determined by a constant breakdown gradient and energy distance.

I understand that the author had a pressure of three millimeters of mercury, that is about 1/250 atmosphere. This, reduced to the atmospheric pressure by proportionality, gives a very short gap and such a gap should hold a high voltage.

The whole subject is rather interesting theoretically from our present conception of the nature of breakdown of gases, and the matter is worthy of further investigation, since it is rather in line with many data and much information which has been accumulated in the last few years, which throws some doubt on many of our conceptions of dielectric breakdown and reopens the question of the mechanism of the breakdown of our insulating materials, and Messrs. Hayden and Eddy have shown that this may apply even to gases.

J. B. Whitehead: One of the most noticeable characteristics of this rectifying tube is that it has no hot filament, simply a rectification occurring between two plain electrodes. It is well known, at least to those whose business it is to make themselves familiar with the theory of the ionization of gases, that the positive and negative ions of a gas have different values of mobility, or the rapidity with which they will move and diffuse. At these pressures, I suppose, we have a preponderance of simple electrons or negative ions, over the positive ion, *i. e.* the residual of the molecule after it loses a negative ion.

Of course, these two types of ions have widely different values of mobility, consequently it does not appear that we have here the ordinary phenomenon of the breakdown of gases as discussed by Dr. Steinmetz, but that we have the simple generation of ions, by the natural process of ionization, and that the uni-directional conductivity of the tube, results from the difference in the mobility of the two types of ion; in other words, in sustained action, the lighter negative electrons are drained away, leaving the excess of positive ions, and the presence of that excess of positive ions must necessarily result in a uni-directional conductivity.

J. E. Shrader: The experiment described by Messrs. Bush and Smith is the noted experiment described by J. J. Thomson where the electric discharge at diminished pressures takes place through a long path rather than the alternative shorter path. The principle involved is that of ionization by collision. To acquire sufficient velocity to produce other ions by collision the path should be sufficiently long before impact—with gas molecules. When this velocity is sufficiently great more ions are formed by collision with the gas molecules and these ions so formed may acquire sufficiently high velocity to produce other ions.

Messrs Bush and Smith have here well utilized the phenomenon of ionization by collision.

C. P. Steinmetz: I might answer one point Dr. Whitehead brought up. I do not see why the mechanism of breakdown of several cm. gap length at atmospheric pressure should be any different from that of minute gaps with higher vacuum.

As regards the uni-directional feature of the conductivity that exists in long air gaps, this was first investigated by Mr. Peek with different electrodes, but it is only in the last year that high and constant uni-directional voltages have become available for investigation.

Mr. Hayden has made a number of interesting tests showing the conductivity between the point and plate, at voltages of 100,000, with distances of many centimeters. This conductivity is undirectional, so much so that the disruptive strength of the needle point and plate or large sphere with one direction of voltage is more than twice what it is with the other. This can be used to rectify alternating voltages and we are using such a plate and needle point gap with large condenser to produce high uni-directional voltages.

So it seems we get phenomena at these high voltages and large gaps similar to those we are known to get in minute gaps at high vacuua.

V. Bush: The experiment of the long and short paths, which I believe was due to Hittorf, shows that in general the discharge

prefers a long path to a short one, when the short path is short under the definition of the paper, and the long path is not purposely suppressed. The point I want to emphasize is the extent of this preference, which has not been generally realized. The preference may readily be so strong that, if the long path is suppressed, the short path will not break down at, say, 10,000 volts, whereas, the long path would if allowed break down at 300 volts.

As to another point, brought up by Dr. Whitehead: Of course, if we attempt to apply this principle at atmospheric pressures, the distances involved are about 1/10,000 of a centimeter as Dr. Steinmetz points out. With the low pressures, we have to deal almost entirely with positive ions and electrons, whereas at the higher pressures, the effect of the negative ions is ordinarily also important. It is not at all settled that this would still be true with very close separations.

There is one further point. I would like to distinguish this apparatus from the rectifier which depends simply on dissymmetry of electrodes, and which thus depends for its action on the difference in breakdown voltage in the two directions,—such as the point and plate and the corona rectifier. In the non magnetic type of this tube the breakdown voltage in the two directions is approximately the same, but the characteristics in the two directions are very widely different.

Determination of Temperature of Electrical Apparatus and Cables in Service

BY E. J. RUTAN
Associate, A. I. E. E.
Test Dept. New York Edison Company

Temperature measurements constitute a large part of the work of the test department of an electric light and power company in the acceptance and maintenance of the electrical equipment. The methods of measuring temperature which are applicable to this work are discussed in this article. The characteristics of the different kinds of temperature measuring apparatus are brought out by describing a number of actual tests.

In the article considerable attention has been given to various forms of thermocouples which have been found very useful in obtaining temperature measurements on cables and in underground conduit systems.

THE following paper is intended as a discussion of the various commonly used methods of determining temperature, such as would be employed in the test department of an electric light and power company. The temperature measurements, as a matter of fact, constitute a large part of the acceptance tests of electrical equipment and supplies, and form a considerable part of the investigation of service performance and characteristics after the equipment has been accepted and placed in service.

The four commonly used means of measuring temperature are by thermometer, by resistance thermometer, by thermocouple and by change in resistance in the winding or circuits of the apparatus under test.

If an electric light and power company rigorously maintains the policy of testing for acceptance, as far as possible, equipment and materials purchased, it results in the presentation of many varied kinds of equipment and material with consequent problems in connection with their test. This paper proposes to discuss the adaptation or application of the various methods of measuring temperature to specific kinds of equipment and material, rather than to discuss the various methods in a general way. It is understood that the temperature measuring devices themselves are well established and are not presented here as novel and probably not new in their application. However, many test details arise in connection with the use or application of the various forms of measurement to the particular equipment under test. The discussion of a number of specific test conditions will bring out some of the characteristics and limitations of the various methods of measuring temperature.

Presented at the A. I. E. E. Annual Convention, Niagara Falls, Ontario, June 26-30, 1922.

The work of a test department of this character covers a fairly broad field, but it does not require the use of every type of temperature measuring apparatus, nor are all types suited for the conditions encountered. In general, the temperatures which are measured are less than 200 deg. cent. and in most cases are confined within the limits permissible in electrical apparatus. The measurements usually need not be made more precisely than to the nearest degree centigrade. Accordingly, the discussion which follows will pertain to measurements in this temperature range and of this general precision.

Before describing the detailed applications, some of the types and characteristics of the four kinds of temperature measuring apparatus will be briefly discussed.

The thermometer method is the simplest and most convenient to use. With the thermometer the indication of temperature is obtained directly without the use of any auxiliary equipment.

The following forms of thermometers are found to supply the general demands of test work.

1. Indicating (mercury and spirit).
2. Recording.
3. Maximum and minimum indicating (constricted-bore type and Six's type).

The mercury indicating thermometers of the gas filled type are to be preferred for most work. These thermometers are calibrated for partial immersion

(frequently 3 inches). This is desirable as in ordinary use only the bulb is in contact with the apparatus. The spirit thermometers are calibrated for full immersion and are used in locations where air or fluid temperatures are desired and danger from high voltage makes it inexpedient to use mercury thermometers. In case of breakage of spirit thermometers, the hazard from voltage breakdown in high tension apparatus is less than with mercury thermometers, due to the quick evaporation of the fluid.

The recording thermometers are standard instruments which can be purchased in various types and ranges. It is found that the self-contained instrument suited for ambient air temperature measurements has the widest application for portable use.

Where apparatus is inaccessible or where there is hazard from high voltage, it is frequently not practicable to use thermometers. In such cases, the resistance thermometer or thermocouple properly insulated or the change in resistance method are used.

The shape and bulk of the resistance thermometer units do not always make them readily applicable to test conditions. In order to obtain sufficient strength, the unit must be made large, the small units being fragile and expensive. This type of apparatus has been found better suited for permanent installation rather than for portable testing work.

In general test work, the thermocouple has proved more useful than the resistance thermometer. It is small, strong, easily made up, and will give readings at a distance with a sufficient degree of accuracy. A copper constantan couple is used for temperatures up to 200 deg. cent. The indication is obtained by means of a potentiometer type temperature indicator calibrated directly in degrees for this type of couple. This is a null method of measurement which avoids correction for lengths of connecting leads and permits accurate determination of temperatures at considerable distance from the instrument.

The thermocouple wire for use with these instruments can be purchased with a guarantee that the results will be correct within one degree centigrade over the entire scale. This is sufficiently accurate for the work encountered, and presupposes that the constantan wire has been carefully selected. The two conductors are made up in a duplex wire and each insulated with rubber. Surrounding both wires there is a weatherproof covering. Rubber insulation should cover each wire separately as cotton insulation alone is liable to absorb moisture and produce internal galvanic action introducing errors in the temperature readings.

It has been found desirable to give each shipment of thermocouple wire on receipt acceptance tests to insure that its characteristics are as guaranteed and to insure against defective insulation.

1. Each coil of wire is tested as a thermocouple between 20 deg. cent. and 150 deg. cent. with the portable direct reading potentiometer temperature indicators, in order to ascertain that its e. m. f. agrees with the standard curve.

2. The insulation resistance between the two conductors of each coil is measured with a 1000-volt megger.

3. A 50-foot sample is cut from the coil and its insulation resistance is measured as in (2).

4. The sample in (3) is heated to 100 deg. cent. for one hour and then connected to a temperature indicator with the end open circuited in order to determine whether any electrochemical e. m. f. is generated.

5. The insulation resistance of the sample is measured while hot, following the same precedure as in (3).

After passing these tests, the wire is ready for use. Couples can be made up in the field by simply twisting the copper and constantan together and soldering the junction. The length can be made to suit the field conconditions, and no further calibration is needed.

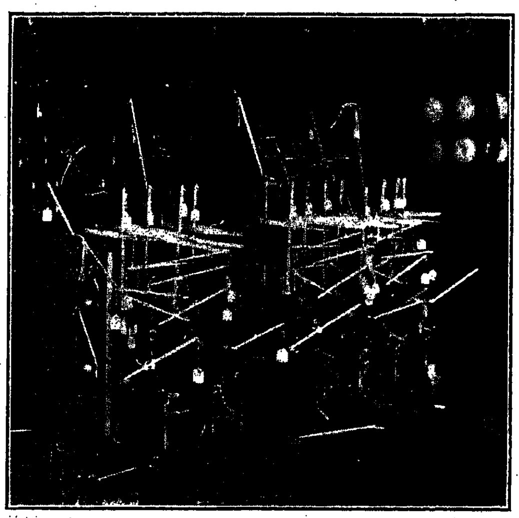

FIG. 1

The fourth method of measuring temperatures makes use of the change in resistance of the windings. The results obtained by this method are accepted as the average temperature of the conductors. It is not possible to measure hot spot temperatures by this method. In tests on transformers, regulators, reactors and cables, the resistance method is extensively used.

With the above methods available, the selection of the method depends on the character and the location of the apparatus to be tested. Some of the typical tests are described below, and also the reason for selecting the various methods discussed. In describing the tests only brief mention is made of the technical details except as they affect the methods of measuring temperatures. In order to give a clearer idea of the equipment under test and the temperature measuring apparatus, illustrations and diagrams of many of the tests have been included.

In Fig. 1, a group of circuit breakers is shown set up for test. The thermometer method was used because

the apparatus was easily accessible and this method was the simplest. The thermometers were placed at the points where the highest temperatures were expected, at the contacts and joints. The bulbs were placed in contact with these parts and were covered with putty. On account of the small size of the breakers, the area covered by the thermometers and putty was kept to a

Fig. 2

minimum so that the radiating properties were not appreciably altered. The thickness of the putty covering was sufficient to protect the bulb from the influence of the air.

In tests where the radiating surface is very small, thermocouples have the advantage over thermometers. The arrangements for such a test are shown in Fig. 2, which is an illustration of small copper catches set up for test. The thermocouples were soldered to the

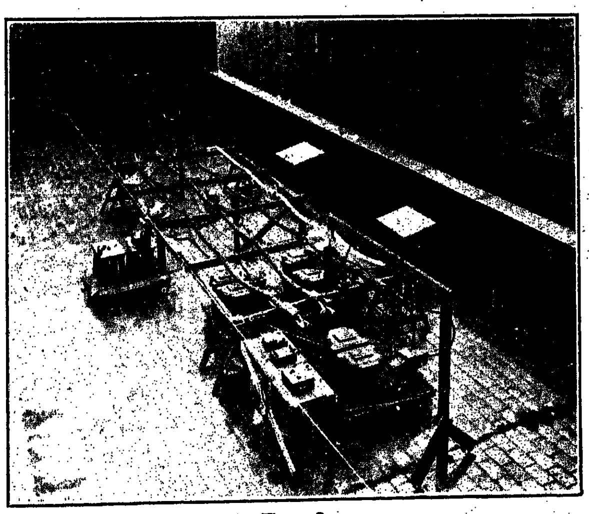

Fig. 3

catch, bus and lug. If thermometers had been used, the bulb and putty would have seriously reduced the radiating surface. The thermocouple junctions and the spot of solder did not appreciably alter the radiation, so that it was possible to make a detailed temperature survey with very little change in normal operating conditions.

In some cases, a number of methods find application. Fig. 3 is an illustration of the cable and equipment. In Fig. 4 a diagrammatic layout of the cables is given which shows the location of the thermometers and thermocouples. The cable was a three-conductor cambric-insulated high-voltage cable. Over the outer belt of insulation, there is a steel armor and over this, a weatherproof covering. The surfaces of the cables were painted so as to give different radiating effects.

The conductors of the various sections were connected together so that current from a low-voltage supply could be circulated through each of the phases. The rated potential difference was maintained by another source, so that the net dielectric losses were the same as in normal service. In arranging the circuits, provision was made so that by using a switch to throw from a-c. to d-c. supply, the conductor resistance could be measured immediately after opening the test current. The leads for the voltage measurements were permanently soldered to the conductors and brought to a central point so that the readings could be quickly taken and sources of error due to poor connections avoided. From these measurements, the average

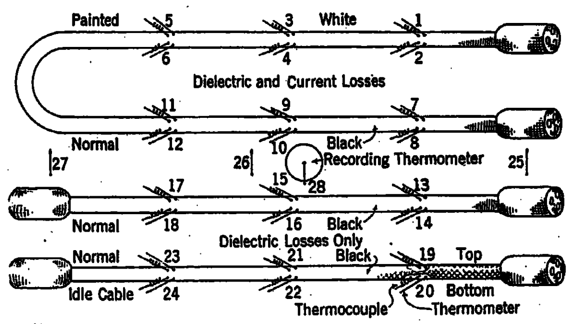

Fig. 4—Aerial Cable Test
Location of thermometers and thermocouples.

temperature of the conductors in each section was determined.

The temperature of the steel armor was measured by means of thermocouples inserted under the armor through slits in the weatherproof covering. The thermocouple wires were brought back to a dial switch shown at the center of Fig. 3. The temperature indicator was placed on an insulated platform on which the observer also sat when taking readings. This safeguard was necessary as the thermocouple leads might become alive due to a failure in the insulation.

On the surface of the cables, thermometers were used to obtain the temperature. These thermometers were held down with putty. The air temperatures were measured by means of both indicating and recording thermometers.

When it is desired to obtain maximum internal temperatures, such as in a splice, the thermocouple is the best method. The location of the probable hot spots is determined and the thermocouples are located at these points.

For example, a test was made on a splice of a concentric one million-cir. mil, lead-covered cable. The

problem was to analyze the temperatures in and around the splice after it was completed as it would be made up in service. The thermocouples were therefore built into the splice as it progressed and the normal lay of the cable insulation and lead armor was disturbed as little as possible. One thermocouple was placed at the joint in the inner conductor. This was fastened to the wiping solder used at that point. Other thermocouples were spot-soldered to the inner conductor about four inches each side of the joint, and the leads brought through a small triangular slot cut in the paper insulation, the cut being so made that the insulation could be bent back in place after the thermocouple was located. A cross section of the splice is shown in Fig. 5 and the location of the thermocouples on the inner and outer conductors and sheath are indicated.

The leads to the thermocouples were made as small as possible so that they could be all grouped together and brought out through a hole in the lead sleeve of the splice which was securely sealed. Fig. 6 shows an external view of the splice and the connections to the temperature indicator.

Another application of thermocouples was in tests on air-blast transformers. Thermocouples composed of flat strips were found useful for this work. These thermocouples were from one to three feet long and were made up of the copper-constantan strips encased in a micarta covering. The strips were joined to form a junction at one end and at the other the regular thermocouple wire was soldered to the strips and extended to the temperature indicator. These junctions were wedged between the low-tension winding and the separators.

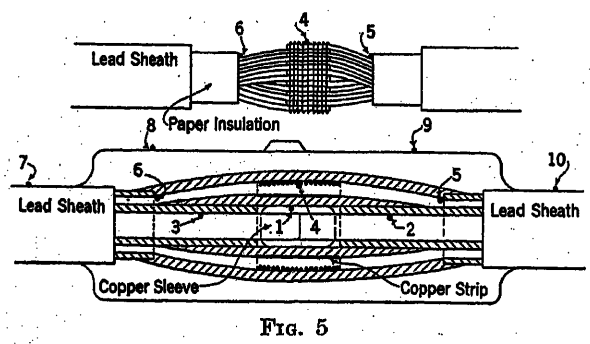

FIG. 5

Such thermocouples could not be placed in contact with the high-tension windings with safety. In order to measure the temperature of the high-tension windings, thermometers were used. These were fastened on the coils usually at the top. The readings of the thermometers were obtained through the top of the transformer by protecting the eyes with goggles, (on account of the air blast). If the thermometers were located at greater distances than two feet a galvanometer telescope was used. In addition, thermometers were lowered on strings in the air passages in order to obtain the air temperature. Spirit thermometers were used for this purpose as they were less liable to cause a ground if broken inside of the transformers.

On rotating machinery, the temperatures are obtained by thermometers when the apparatus is accessible. For example, on synchronous converters, and generators and motors, the thermometers are placed on the stationary parts such as the field coils, pole tips, frame, bearings and brush brackets and collector buses. On induction motors and other apparatus on which the major part of the windings are imbedded the resistance method gives the best results. However, thermometers are always used if possible to supplement this method.

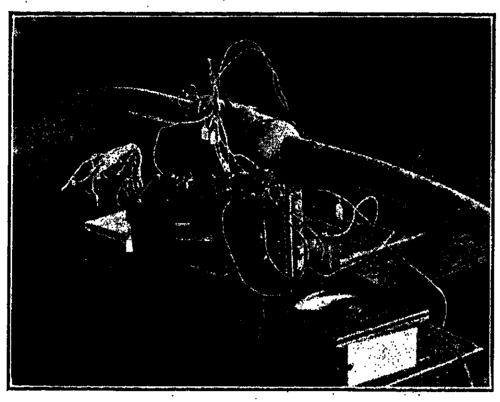

FIG. 6

The temperature measurements of the rotating parts are made after the machine has come to rest at which time thermometers are quickly placed on the commutator slip rings and armature windings. These readings are taken at intervals of a minute or less until the temperature has started to decrease.

On the larger higher-speed, high-voltage equipment such as turbo alternators, the temperature measurements are made by means of imbedded thermocouples or resistance thermometers usually placed by the manufacturer. The temperatures of the stationary parts, if accessible, are measured by thermometers, or thermocouples.

For investigating temperature conditions in the various parts of an underground transmission and distributing system, the thermocouple was found to be very convenient and adaptable. Tests made on cables in manholes, sheath temperature and manhole air conditions were made with thermocouple and recording thermometers. On low-tension cables, the thermocouple junctions were soldered directly to the sheath. On high-voltage cables, the junctions of the thermocouple wire were preferably soldered to small pieces of sheet copper about ½ in. by 1 in., and these securely held in contact with the sheath of the cable by means of small wooden blocks of about the same area.

The piece of sheet copper increased the contact area of the junction, thus insuring that the thermocouple junction assumed as nearly as possible the temperature

of the sheath. The thermocouple junction alone produced a very small contact. Due to this relatively small volume compared to the size of its own connecting leads, the leads may conduct the heat away if they are of a lower temperature than the thermocouple in contact with the cable, which is usually the case. Such a condition would result in a lower indication of temperature than actually existed on the sheath of the cable.

The foregoing point is of general application and it has been found necessary to analyze the above effect from various angles. As a result, the junctions of the thermocouple wire were fitted in special copper slugs which have been developed by the test department of the New York Edison Company. This slug is shown in the insert in Fig. 7. This form was designed primarily for measurements of duct temperatures which by nature do not change rapidly. It is about two inches long and 3/8 of an inch in diameter, with grooves cut parallel to the axis so as to give a larger exposed area. The slug increased the exposed surface of the couple and eliminates any error which may be due to the leads conducting heat away from the couple. The increased mass of the couple made the measurements of air temperature more reliable, in that the couple did not show temperature changes with each slight draft of air. The time lag introduced by the increased mass was less than one half hour and was considered satisfactory for duct temperature measurements. Obviously this time constant may be increased or diminished by varying the mass and relative radiating surface of the terminal.

Fig. 7

Extensive underground temperature surveys have been made in duct banks by means of gang-cables of thermocouples, approximately 350 feet long. The entire gang-cables are built up beginning with a 3/8-in. steel-wire rope to which the thermocouples are attached. The thermocouples fitted with the above mentioned slugs are spaced every 30 feet and the pair of leads to each one brought back to one end of the cable. All the leads are bound with cord about every foot. Four layers of tape are wrapped over the entire length to protect the cable from abrasion and slight moisture.

In attaching these junctions on the cable, the copper slugs are heat insulated from the steel rope by means of a number of layers of tape. In order to make certain that the slugs do not come in contact with the duct walls, knobs were built up on the cable each side of the slug as shown in Fig. 6.

The complete equipment used with the cable is shown in Fig. 7. The thermocouple wires were brought back to a dial selector switch which permits any couple to be connected to the temperature indicator.

As this assembly was used throughout the year, tests were made on the dial switch and indicator when at different temperatures to determine whether the accuracy is influenced. It was found that throughout the range of temperature encountered, the precision is within one deg. cent. At extremely low temperatures, the standard cell in the indicator became unreliable. For freezing weather the standard cell was removed to a heavy heat insulated case so it could be used for long periods outdoors.

Based on the experience accumulated in using thermocouples and the gang cables, it is felt that the general accuracy of temperature measurement which should be obtained is within one degree centigrade. It will be appreciated that with a new application of temperature measuring apparatus such as the gang cable, a certain number of practical difficulties may be encountered in the field. This has been the case in this instance and several sources of error have been encountered and eliminated which are recorded here for the benefit of others who may desire to attempt similar investigations:

1. Thermocouple wire made by a reputable manufacturer was used at first which had unimpregnated cotton insulation between the conductors. It was found that this wire readily absorbed moisture of various and unknown chemical characteristics, which produced galvanic effects and caused errors in the temperature readings. Immediately this condition was understood, it was corrected by using rubber insulation around each individual conductor, and also around the pair of conductors comprising the thermocouple.

2. After the gang cables had been in service for a considerable period, it was found that breakages occurred in the copper conductor near the copper

slug terminal. Relatively few breakages occurred in the constantan wire. These breakages were due to the wear and tear in service incidental to pulling the cable in and out of ducts. It was exceedingly difficult to detect the breakage of the wire since mud and moisture from the duct entered the cable and produced galvanic action between the conductors at the break near the slug terminal. This error has been eliminated by substituting a stranded copper conductor for the solid copper conductor. Additional protection has been obtained by water-proofing the junction between the thermocouple insulation and the copper slug terminal to exclude moisture from the thermocouple wire.

3. It was found that the insulation ordinarily furnished with the thermocouple wire did not satisfactorily resist service usage. Accordingly, thermocouple wire was obtained insulated with especially durable insulation capable of standing considerably more wear and tear than the ordinary rubber insulation previously furnished.

This thermocouple gang-cable has been found very useful in plotting the temperatures along a duct bank. For analyzing temperatures which might emanate internally in the cables lying in the bank or externally from steam pipes and other sources of heat outside the bank. This gang cable is of such size that it can be used only where an empty duct is available in the bank, as it cannot be pulled through a duct already occupied by a cable.

In the morning the cable was pulled into an empty duct of a bank so that the first thermocouple extended into the next manhole. The manholes were closed and readings taken over the peak load period, after which time the cable was removed.

As a check on the accuracy of the thermocouple indications, and in order to prevent any discrepancies from entering, a thermometer was placed in contact with the terminal of the first thermocouple in the far manhole. Simultaneous readings were taken on the thermometer and thermocouple just before removal.

The life of a cable of this character in nearly continuous testing service at numerous locations is about three months.

In cases where the space was limited, or it was inconvenient to bring out thermocouple leads, the maximum indicating thermometer was used. There are the two types, namely the Six's maximum and minimum indicating and the restricted bore mercury thermometer which is only maximum indicating. These were placed in junction boxes in the middle of streets, where, due to traffic, thermocouples could not be used and where on account of the restricted space, it was impossible to set recording thermometers. The results obtained by these thermometers gave only the range of temperature during a load cycle.

The data and methods given above are intended to set forth some of the procedure being used to measure temperatures in the general testing work of a large public utility. They are advanced with the belief that they will be of value to engineers engaged in similar work and will bring out discussions of other methods for achieving the necessary test results.

Discussion

E. S. Lee: Those of us who are engaged in making temperature measurements know that heat is elusive and gets away from us very easily, and we have to take due consideration of the fact that it may go from one place to another by conduction or by convection or by radiation; the measurement of temperature is therefore complex.

As Mr. Rutan said, the thermometer method is simple and convenient. We make such extensive use of the mercury thermometer in our daily life that we sometimes apply it in our engineering without knowledge of the fact that errors may exist. Differences in temperature along the thermometer stem, poor contact of the bulb with the measuring surface, broken mercury column are the most frequent sources of error. Formulas are available for emergent stem correction; their use is not always productive of accurate results. Contact errors can be eliminated if care and thought are used. Felt pads and putty both provide means for affixing thermometers. Broken mercury columns can be detected by careful inspection.

If you want to find out something concerning the accuracy of the results that you are getting from any measurement with mercury thermometers, just make a measurement and remove the thermometer completely; replace it and take another observation. Do this half a dozen times and you may find there is considerable deviation. There may be a deviation of as much as 5 degrees, even when you are trying to keep everything else constant, and you must be careful to do that.

Mr. Rutan speaks of the resistance thermometer, and, in his particular case he has not made so very much use of it. Use can be made of it in a great many installations and it is particularly convenient in that you can read the indicator directly without having to make any manipulations, the exciting voltage remaining constant. For tests where facility of reading the indication is an important factor, the resistance thermometer should be considered.

In regard to the thermocouple, what Mr. Rutan has said about its being of wide application, is very true. In connection with his acceptance tests, in order to assure himself that the wire is according to the specification, I find that he speaks of testing it up to 150 deg. cent., and that he heats it up to 100 deg. cent. for an hour to see that there are no parasitic currents generated to affect the result. I am wondering if Mr. Rutan uses rubber thermocouples at such temperatures as 100 or 150, or 200 deg. cent.? If rubber is used at these temperatures, I think you will get into trouble. If you are using a thermocouple junction which will stand these high temperatures, with rubber and cotton covered leads out in the regions where the temperatures are low, you may be all right. Leads covered with rubber only are positively detrimental.

In item 4, on page 465, I understand from what Mr. Rutan says that he takes a 50-ft. sample, winds it up, and puts it in the oven a 100 deg. cent., allowing one end to extend into the open to which an indicator is connected. I would suggest another test whereby the entire length of thermocouple is extended in the room, the ends of this thermocouple being adjacent, one being connected to an indicator. Now heat the thermocouple to any desired

temperature at different points along its length. The indicator should give zero deflection if the thermocouple materials and insulation are without defect.

E. J. Rutan: Replying to Mr. Lee in regard to the use of rubber insulated thermocouple wire at 100 deg. cent. or above I wish to state that the temperature limits given were mentioned in connection with the junction temperature. The wire itself is usually in air at a much lower temperature. In cases where the wires may pass through high temperature spaces leads insulated with glass or vitreous beads are used in place of the rubber insulation.

Mr. Lee also suggested heating the wire under test at different points along the length in order to detect defects in the insulation. This method had been tried but was more time-consuming than the method outlined in the paper which gives the desired information on a full length with one test.

The Economics of Direct-Current Railway Distribution

With Particular Reference to the Automatic Substation

BY LAWRENCE P. CRECELIUS
Member, A. I. E. E.

and

VICTOR B. PHILLIPS
Consulting Engineers, Cleveland, O.

Review of the Subject.—*The comparatively recent development of the full automatic substation and also the automatic substation combined with remote control, has served to re-open the entire subject of the economics of distribution. But quite aside from the questions that the automatic substation has presented, the great fluctuations in the prices of materials and of labor have made necessary renewed study of this subject. In other words, the proper design of a distribution system should represent a balance between all of the different items of cost that go to make up the total cost of power. Any change in the relative cost of materials as against labor or of a certain class of materials as against another class of materials tends to upset such a balance. Now that we begin to emerge from the unsettled conditions of the past few years during which the old relationships have been substantially changed, it is necessary to ask the question whether or not the rules by which distribution systems have been planned in the past still apply.*

More specifically, it is the purpose of this paper to determine, first, the relations that govern the size of feeders and the correct feeder layouts for any given arrangement of substations, and second, the principles underlying the correct location, size, and type of substations, assuming the fullest development of automatic and semi-automatic control.

There is involved also the important question of stray currents. Regardless of the merits of the electrolysis controversy, the minimizing of stray currents is certainly to be desired by the electric railways. The most effective method of accomplishing this is increasing the number of distributing points. If a large number of distributing points be justified from an economic standpoint, and if furthermore this be found practicable from an operating standpoint, then the problem of electrolysis may perhaps cease to exist. Thus the inquiry is doubly pertinent.

The cost of distribution in large cities of the size of Cleveland, Detroit, or St. Louis, comprising the carrying charges on the feeder, the heating losses in the feeders and the carrying charges on the equipment necessary to supply these losses, is considerably in excess of $200,000 per year. It is apparent that a careful study of this item of cost will more than likely be justified by the savings that will result.

There are not at the present time sufficient accurate data on cost and performance of automatic substations to make possible a precise analysis of specific cases. In lieu of this it is the authors' purpose to show limiting conditions and by example to illustrate the relation of the various determining factors to the final cost.

CONTENTS

1. FEEDER CIRCUITS

THE total cost of feeder distribution comprises the following:

(1) Carrying charges on feeder investment.

(2) Carrying charges on (a) generating plant, (b) transmission lines, and (c) substations, for that part of the investment that supplies the losses in the feeders.

(3) Operating expenses of the generating plant, transmission lines and substations for that energy which is lost through heating of the feeders.

In cities of about the size of Cleveland the following conditions are fairly representative:

(1)	Feeder investment, $1,000,000. Carrying charges @ 13 per cent per annum	$130,000
(2)	Generating plant, transmission lines and substation investment per kw. (d-c.) demand, $165. At 14 per cent per annum these carrying charges are $23 per kw. Maximum demand, 40,000 kw. Distribution loss during peak, 10 per cent. Carrying charges, $0.10 \times 40{,}000 \times \$23$	92,000
(3)	Operating expenses of generating plant, transmission lines and substations. 0.8 cent per kw-hr. At 25 per cent loss factor the average system loss will be 1,000 kw. or 8,760,000 kw-hrs. per year	70,000
	Total	$292,000

Presented at the Annual Convention of the A. I. E. E., Niagara, Falls, Ont., June 26-30, 1922.

It is readily apparent that an increase in the copper investment will serve to cut down the heating losses and consequently those items of cost that depend on these losses. There must be, therefore, a proper size for every feeder representing an economic balance between the copper carrying charges on the one hand and the copper losses on the other, for which size the total cost is a minimum.

Three distinct types of feeders will be considered:

(a) Uniform cross-section, entire load concentrated at the end.

(b) Uniform cross-section, load uniformly distributed along feeder down to zero at end or neutral point.

(c) Uniformly tapering cross-section, load uniformly distributed along feeder down to zero at end or neutral point. This type of feeder is of course purely theoretical. It may, however, be considered as representing the limiting condition that is approached by stepping down the feeder size.

The items of cost set forth above will be expressed by the following symbols:

LIST OF SYMBOLS

C_F—Total annual cost of feeder circuit (dollars).
C_G— " " " " rail and ground circuit (dollars).
C — " " " " entire distribution circuit (dollars).
D —Distance to end of feeder or neutral point (feet). In the case of variable distributing distances D is the distance corresponding to peak load.
E —Voltage drop to end of feeder or to neutral point for maximum (peak) current.
E_F—Voltage drop to end of feeder or to neutral point for maximum (peak) current, in feeder only.
e —Operating expenses for generating plant, transmission lines and substation (dollars per d-c. kilowatt-hour).
f —Carrying charges on feeder in place (dollars per lb.).
G —Effective resistance of rail and ground circuit (ohms per ft.).
I —Maximum (peak) current in feeder at substation end (amperes), *e. g.* average of 15-minute peak or other basis for determining proper installed capacity.
L —Loss factor, average of the squares of the momentary feeder currents divided by the maximum current (I) squared.
m —Cross-section of feeder at substation end (circular mils).
p —Carrying charges (interest, depreciation and taxes) on generating plant, transmission lines, and substations (dollars per d-c. kw. demand per year).

The following equations in sections 1-3 (inclusive) are derived for the condition that distributing distances remain the same for all loads. The effect of varying distributing distances with load will be considered in section 4.

Type (a) feeder, uniform cross-section, concentrated load.

$$C_F = 3.67 \times 10^{-6}\, m\, D\, f + 0.001 \times I^2\, p\, D \left(\frac{10.35}{m}\right) + 8.76 \times I^2\, L\, e\, D \left(\frac{10.35}{m}\right) \qquad (1)$$

The factor 3.67 is pounds per foot per 1,000,000-cir. mil cable with triple braid weatherproof insulation, the factor is slightly greater, for smaller sizes of cable.

The first problem is to express m in terms of the constants D, e, f, I, L and p for the minimum cost (C_F), according to Kelvin's law of economy, *i. e.*,

$$m = I \sqrt{\frac{2820\, p + 24.7 \times 10^6\, L\, e}{f}}$$

$$C_F \text{ (minimum)} = 0.000390\, I\, D \sqrt{f\,(p + 8760\, L\, e)}$$

$$E_F = I \left(\frac{10.35}{m}\right)$$

EXAMPLE:

Let $D = 1.5$ miles or 7920 feet
$e = \$0.008$ per kw-hr.

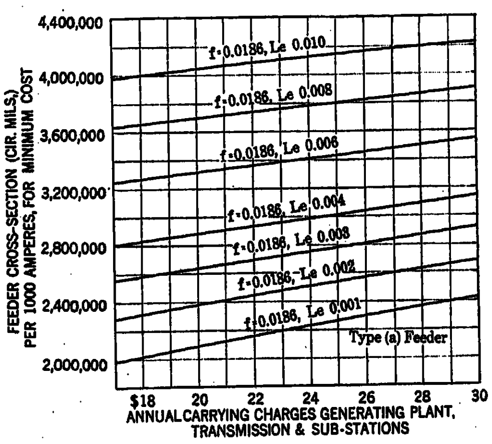

FIG. 1

f = 0.022 Multiply section by 0.9195
f = 0.025 Multiply section by 0.8626
f = 0.028 Multiply section by 0.8154
For type (*b*) feeder multiply section by 0.577
For type (*c*) feeder multiply section by 1.000
For 1,000,000-cir. mil, T. B. W. P. feeder multiply section by 1.000
For 500,000-cir. mil, T. B. W. P. feeder multiply section by 0.985
For 4/0 T. B. W. P. feeder multiply section by 0.985
For 2/0 T. B. W. P. feeder multiply section by 0.962
For bare feeder, all sizes, multiply section by 1.090

$f = \$0.0186$ = 12 per cent on feeder at \$0.155 per lb.
I = 750 amperes
$L = 0.25$ (For Cleveland Rwy. Co., load factor approximately 40 per cent)
$p = \$23.00$.

Then m = 1,860,000 circular mils.
C_F (min.) = \$2010 per annum.
E_F = 33 volts.

Type (b) feeder, uniform section and distributed load. In this type of feeder, the above equations become (see Appendix I):

$$m = 0.577\, I \sqrt{\frac{2820\, p + 24.7 \times 10^6\, L\, e}{f}}$$

$$C_F \text{ (min.)} = 0.000225\, I\, D \sqrt{f\,(p + 8760\, L\, e)}$$

$$E_F = I/2 \left(\frac{10.35\, D}{m}\right)$$

$$\left.\begin{array}{l} m \\ C_F \text{ (min.)} \\ E_F \end{array}\right(\text{for type (b)}$$

$$= \left.\begin{array}{l} 0.577 \times m \\ 0.577 \times C_F \text{ (min.)} \\ 0.866 \times E_F \end{array}\right) \text{for type (a)}$$

EXAMPLE: Using the same values for D, e, f, I, L and p as in the example for type (a)

$$m = 1{,}075{,}000 \text{ circular mils.}$$

$$C_F \text{ (min.)} = \$1160 \text{ per annum.}$$

$$E_F = 28.6 \text{ volts.}$$

Type (c) feeder, tapering section and distributed load. The feeder may be considered as the summation of small increments each of which is the same as type (a)

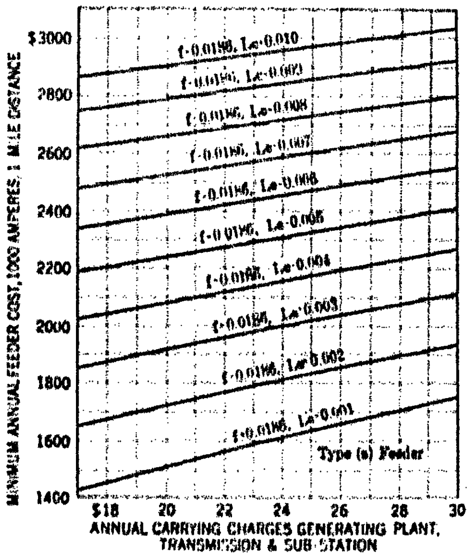

FIG. 2

f = 0.022 Multiply cost by 1.0875
f = 0.025 Multiply cost by 1.1593
f = 0.028 Multiply cost by 1.2264
For type (*b*) feeder multiply cost by 0.577
For type (*c*) feeder multiply cost by 0.500
For 1,000,000-cir. mil, T. B. W. P. feeder multiply cost by 1.000
For 500,000-cir. mil, T. B. W. P. feeder multiply cost by 1.015
For 4/0 T. B. W. P. feeder multiply cost by 1.015
For 2/0 T. B. W. P. feeder multiply cost by 1.030
For bare feeder, all sizes, multiply cost by 0.917

feeder, so that losses and amount of copper are one-half what they are for type (a). (see Appendix II.)

$$m = I \sqrt{\frac{2820\, p + 24.7 \times 10^6\, L\, e}{f}}$$

(same as for type (a))

$$C_F \text{ (min.)} = 0.000195\, I\, D \sqrt{f}\, (p + 8760\, L\, e$$

$$E_F = I \frac{(10.35\, D)}{m} \quad \text{(same as for type (a))}$$

EXAMPLE: Using same values for D, e, f, I, L and p as in examples for types (a) and (b)

$$m = 1{,}860{,}000 \text{ circular mils.}$$

$$C_F \text{ (min.)} = \$1005 \text{ per annum.}$$

$$E_F = 33 \text{ volts.}$$

2. RAIL AND GROUND CIRCUITS.

These circuits are not susceptible of precise determination principally on account of variation in joint resistance and leakage to ground. Were it not for these two factors it would be possible to calculate return circuit resistances and drops with a fair degree of accuracy. Fortunately, good practise is making this problem easier. The Report of the American Committee on Electrolysis in the "Summary of Good Practise" calls for (1) track construction and bonding that will cut down resistance to a minimum, with such cross-bonding as will serve to minimize the effect of joint failures, and (2) track insulation insofar as this is not inconsistent with other considerations. There are large differences in the resistances to ground of the several different types of roadbed construction now in vogue. Good practise, however, tends toward the roadbeds of higher resistance and the consequent reduction of stray currents.

The above report condemns the "reinforcement of rail conductivity" either by parallel copper, because this copper cannot be economically loaded, or by buried conductors which "increase the contact area between return circuit and the earth." It points out the high cost of insulated negative feeders. All of these recommendations make for the simplification of the problem which is being considered here.

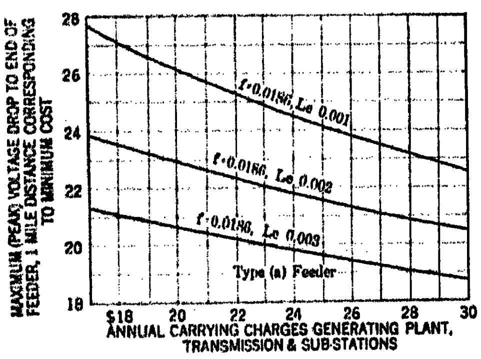

FIG. 3

f = 0.022 Multiply drop by 1.0875
f = 0.025 Multiply drop by 1.1593
f = 0.028 Multiply drop by 1.2264
For type (*b*) feeder multiply drop by 0.866
For type (*c*) feeder multiply drop by 1.000
For 1,000,000-cir. mil, T. B. W. P. feeder multiply drop by 1.000
For 500,000-cir. mil, T. B. W. P. feeder multiply drop by 1.015
For 4/0 T. B. W. P. feeder multiply drop by 1.015
For 2/0 T. B. W. P. feeder multiply drop by 1.030
For bare feeder, all sizes, multiply drop by 0.917

As the number of distributing points is increased, track drops decrease very rapidly, theoretically as the square of the distance. It is therefore apparent that decreased distributing distances will serve both to cut down stray currents and make possible the more exact determination of return circuit resistances.

For the purpose of an economic analysis the effective resistance of the rail and ground circuit in most cases may be based upon the rail resistance, without any great error. On a properly maintained city system,

current returned through other paths than the rails should not exceed 25 per cent. This is at least a rough measure of the maximum error that might result from using rail resistance as the basis for return circuit resistance. If, however, leakage is known to be approximately 25 per cent in the case of a certain line and proper correction is made for this in estimating return circuit resistance, the error should be quite small so as to be practically a negligible part of the total distribution circuit resistance.

If bonded joints are regularly tested and bad joints repaired when found, it is possible to reduce the number of joints having an equivalent resistance of less than 9 ft. of rail to 5 per cent or less of all joints. If the percentage of such bad joints be known, it becomes possible to determine the rail circuit resistance quite accurately, especially if there be proper cross-bonding. Welded joints frequently have a resistance less than that of continuous rail so that the resistance of such track may generally be assumed to be the same as for continuous rail.

The distribution of current in the track circuit will of course be the same as in the feeder provided it returns only the current of that one feeder. It follows therefore that the the second and third terms of equation (1) apply to the track circuit excepting that the resistance per ft. $\left(\frac{10.35}{m}\text{ in the case of the feeder}\right)$ will be changed to (G).

In those instances where the tracks return the current distributed by two or more separate feeders then the analysis of each of these separate distribution circuits may be made by increasing the track circuit resistance in inverse proportion to the ratio of the one feeder load to the sum of the feeder loads.

3. Entire Distribution Circuits

Type (a) Feeder.

$$C = 3.67 \times 10^{-6}\, m\, D\, f + 0.001 \times I^2\, p\, D \left(\frac{10.35}{m} + G\right) + 8.76 \times I^2\, L\, e\, D \left(\frac{10.35}{m} + G\right) \qquad (2)$$

$$C\ (\text{min.}) = 0.000390\, I\, D \sqrt{f\,(p + 8760\, L\, e} + I^2\, D\, G\, (0.001\, p + 8.76\, L\, e)$$

$$E = I\, D \left(\frac{10.35}{m} + G\right)$$

The introduction of G into the equation does not change the value of m as previously expressed for the feeder circuit.

Type (b) Feeder.

$$C\ (\text{min.}) = 0.000225\, I\, D \sqrt{f\,(p + 8760\, L\, e} + \frac{I^2\, D\, G}{3}\, (0.001\, p + 8.76\, L\, e)$$

$$E = \frac{I\, D}{2}\left(\frac{10.35}{m} + G\right)$$

Type (c) Feeder.

$$C\ (\text{min.}) = 0.000195\, I\, D \sqrt{f\,(p + 8760\, L\, e)} + \frac{I^2\, D\, G}{3}\, (0.001\, p + 8.76\, L\, e)$$

$$E = I\, D\, \frac{(10.35)}{m} + \frac{I\, D\, G}{2}$$

4. Distribution Distances Variable with Variable Load

All of the foregoing relations and equations have been based upon the assumption that the distributing distances are the same at all loads. Even with multiple-

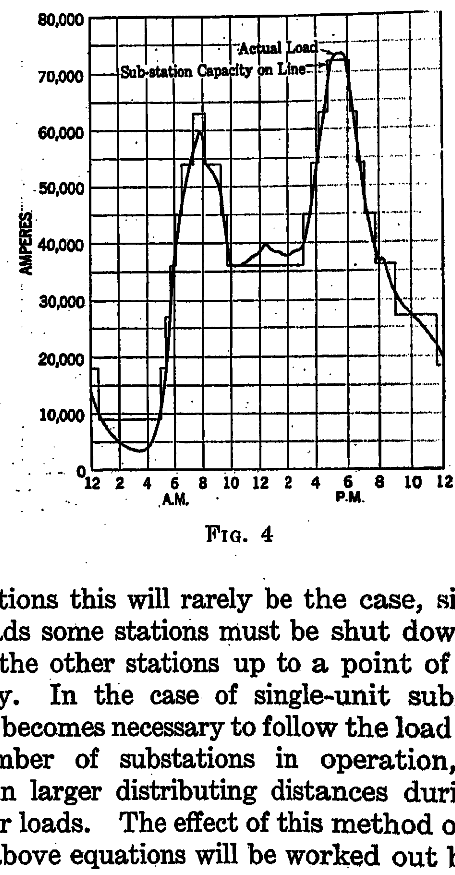

Fig. 4

unit stations this will rarely be the case, since during light loads some stations must be shut down, in order to load the other stations up to a point of reasonable efficiency. In the case of single-unit substations in cities, it becomes necessary to follow the load by varying the number of substations in operation, and this results in larger distributing distances during periods of lighter loads. The effect of this method of operation on the above equations will be worked out by an illustration.

The accompanying load curve (Fig. 4) shows the following of the load by putting on and taking off substation capacity. It should be possible with remote control and careful study of load conditions for the chief operator to follow the load quite closely and thus to keep all machines loaded to somewhere near rated capacity with the consequent high efficiency. It will be noted on the load curve that the substation capacity has been added in eight steps of 9000 amperes each. It will be assumed that each step represents an integral number of single-unit substations of uniform size and that the load on the different section of the systems varies about the same as the composite load curve. On a system of this kind with a large number of sub-

stations, it is necessary to use uniform section feeders between substations because of the shutting down of some substations during off-peak hours and the consequent necessity of feeding these substation areas from adjacent stations. Also on such a system the type (*a*) feeder would be used rarely if at all and the type (*c*) feeder would be used only in the outlying sections for the deadended feeders. It is therefore proper to assume that in the case of such a system as is being considered here, practically all feeders will be type (*b*) feeders (*i. e.* uniform section and uniformly distributed load).

Let D (constant) represent the distributing distance any one of substation when all substations are operating and I the proportional part of the substation rated capacity that is distributed through a single feeder. In this case, let I equal 1000 amperes. Equation (1) gives annual feeder cost for constant distributing distance (D). This equation may be expressed as

$$C_F = a\,m + b/m + c/m$$

In these equations the terms a and b will be the same as for constant distributing distance. The term b/m represents the carrying charges on that part of the generating plant, transmission line and substation investment necessary to carry the peak dis-

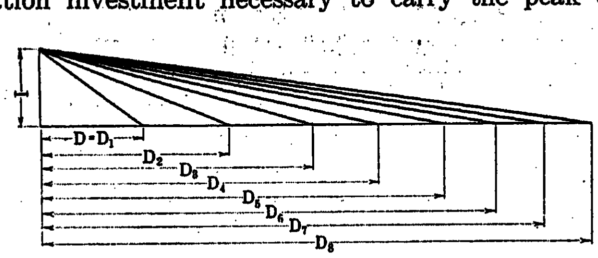

Fig. 5

tribution losses. During the peak load the distributing distance will be D (as defined above), so that b remains unchanged. The value of c, however, will be different for variable distributing distances since c/m represents the operating expenses for the heating losses twenty-four hours per day during which time distributing distance has changed several times as substations are put on and taken off the line. The value of c/m may be determined by dividing the twenty-four hours into periods within which the number of substations in operation is unchanged. On the accompanying load chart it will be seen that there are eight steps to the capacity curve and consequently for this case there are eight periods of constant capacity. Each of these periods may be treated separately and the value of c/m set down.

For the type (*b*) feeder c/m becomes $\dfrac{c}{3\,m}$ because of distributed load.

In Fig. 5, D_1, D_2, D_3, etc., represent distributing distances corresponding to the eight periods or steps into which the capacity curve of the system has been divided. I, which is a definite proportional part of the rated capacity of the substation, is of course constant. L approaches unity in proportion as the operator is able to make the capacity curve approach more nearly the actual load curve. During twenty-four hours the value of $\dfrac{c}{3\,m}$ for the distance D will be the summation of the values of $\dfrac{c}{3\,m}$ for each of the eight periods as follows:

$$(1)\quad \frac{c}{3\,m} = t_1 \times 2.92 \times I^2 L_1 e\, D_1 \frac{(10.35)}{m} \times D/D_1$$

$$(2)\quad \frac{c}{3\,m} = t_2 \times 2.92 \times I^2 L_2 e\, D_2 \frac{(10.35)}{m} \times D/D_2$$

etc.,

in which t_1, t_2, t_3, etc., are the percentages of time represented by each period. Hence for the distance D, twenty-four hours per day

$$\frac{c}{3\,m} = 2.92\, I^2 e\, D \frac{(10.35)}{m} (t_1 L_1 + t_2 L_2 + \ldots)$$

Thus L in the original equation simply becomes the weighted average loss factor of the several operating periods, approaching unity in value. For the conditions represented by the load and capacity curves used in this illustration L is about 0.90. Looking at the problem in a different way, we may say that the feeders are fully loaded a much larger part of the time under this method of operation than for constant distributing distance. From an economic standpoint, therefore, larger feeder sizes are warranted because the load factor on this copper is larger. With this difference, the equations and curves already presented for type (*b*) feeders with constant distributing distance apply to the case of variable distributing distances.

Example: Using the same values for D, e, f, I and p, as used in the previous examples for constant distributing distance, *viz.*: D = 7920 ft., e = \$0.008, f = \$0.0186, I = 750 amperes, p = \$23.00, and assuming 0.90 as the value of L

$$m = 1{,}570{,}000$$
$$C_F \text{ (minimum)} = \$1{,}690.$$
$$E_F = 19.6 \text{ volts.}$$

5. Generating Plant, Transmission Line and Substation Investment

Generating plant investment is independent of the distribution and substation layout, where power is supplied from a central station. In making distribution calculations, the generating plant investment per kilowatt should of course include a proper amount for spare capacity. On this basis the investment will lie within the limits of \$90 and \$150 per kilowatt (undepreciated) and the carrying charges \$11.70 to \$22.50 per year.

The investment in transmission lines will vary greatly with the number and size of substations and with the arrangement of the lines. It is of course apparent that this investment will increase with the number of stations. Should the same factor of safety be required for each of many small substations as is now required of the larger substations, the increase in investment would be in some cases nearly in direct proportion. This, however, should not be the case since the failure of one small substation is of smaller consequence. If there be a very large number of substations, for example forty or more in a city such as Cleveland, it is possible that two substations might be fed safely from a single transmission line. It would appear likely that a group system could be used to advantage in cities with many small substations. This would make possible a large factor of safety without an unduly large investment in transmission lines.

In any event it becomes evident that the transmission layout must depend largely upon the seriousness of a substation failure during the peak load. This question may be answered by reference to the voltage drop equations that have been given, provided of course, that there be the proper amount of copper to meet the condition of maximum economy. The limiting condition will be found in the case of multiple-unit stations since the feeder sizes are necessarily smaller than for single-unit stations. The proper cross-section for a type (*b*) feeder would in no case be less than 1,200,000 cir. mils per 1000 amperes. The total voltage drop (peak) would be 37 volts (assuming a four-rail return circuit, properly bonded or welded, 3×10^{-6} ohm per ft.) for a distributing distance of 6500 feet. If now a substation fails, about the worst condition will be doubling the load on the feeder and doubling the distance in which case the drop becomes 148 volts. On the average city system today there is not the proper amount of feeder copper for maximum economy. Furthermore, distributing distances are great, generally two miles or more. It therefore follows that the shut-down of a substation of such a system during the peak load becomes a matter of serious consequence resulting in trolley voltages so low that it is perhaps impossible to handle the traffic. The development of the automatic substation will without doubt lead to distributing distances (for peak load) of 6500 feet or less in larger cities. It would therefore appear that the failure of a single substation on such a system should not reduce line voltages to a point where the operation of cars would be hampered.

It is next to impossible to generalize on the per kilowatt investment in transmission lines. From 25 per cent to 50 per cent of the cost of underground lines is for conduit. If power is purchased from a central station company the investment allocable to the railway load will be substantially less than it would be if the railway company owned its own generating station and transmission lines. In such cases the transmission line investment would not necessarily be increased unduly by the installation of many small railway substations. In any event it is probably fair to say that this cost, including the distributing stations of the central station company, should not exceed $30 per kilowatt for underground construction in large cities even though the substation be as small as 1000-kw. capacity. The carrying charges on this amount would not exceed $4 per kilowatt per annum. The limits for the carrying charges on generating plant and transmission lines (including power company distributing stations) may be put approximately at $14 and $27 per kilowatt per year. (The term "carrying charges" is sometimes used to include standby operating expenses; the term is not so used here).

In this analysis the demand charge of the power company, if the railway company purchase power, will take the place of the carrying charges discussed above. In most cases this greatly simplifies analysis of a particular local situation. Similarly the power company's kilowatt-hour charge, will be used in place of "operating expenses for generating plant and transmission lines."

The item of investment which will vary through the widest range with the number of distributing points for a given load, is the substation investment. For any one size of substation this cost will vary between wide limits depending upon the character of building, the cost of land, whether the station is single or multiple-unit and the character of control. There is as yet nothing approaching standard practise. Automatic and remote control equipment is still in the development stage although its workability has been proved. The writers are in accord with the opinions expressed by the "Power Generation" Committee of the American Electric Railway Association in its 1921 report[3] as follows:

> The success of the automatic idea having been proved, the principal problem at the present time is that of deciding on the most satisfactory size and number of units for a station, to secure the greatest economy while not sacrificing the quality of service. (Pg. 33.)
>
> Apparently the ideal scheme of installation is to use the smallest possible single-unit stations located at relatively short distances from each other in a very simple and small building. This type of construction will undoubtedly find much favor in the eyes of the rapid transit lines in the small cities where service requirements are not so exacting and where the traffic density never reaches a point where a service interruption results in a more or less large monetary loss. (Pg. 33.)
>
> Experimental work is now being conducted to find a solution on a full automatic basis, for the difficulties outlined above, for both machine and feeder control as encountered in Metropolitan service. However, where warranted a system of remote control superimposed upon that of the automatic control will solve the difficulties. By this method the machines could be operated dependent upon the balance between the conversion efficiency and operating cost per car mile, dependent upon average trolley voltage conditions. In this manner the operation of machines may be controlled from a dispatching center, simulating manual conditions but with greater system flexibility. (Pg. 50)

3. This committee report contains a good statement of the case of substation costs in which are shown the various factors determining these costs.

The cost of remote control over telephone wires will be so small as to be almost negligible. It need not, therefore, be specifically included in this analysis although its use, in cities at least, should be contemplated.

The curves of Fig. 6 show in a general way the limits of substation investment (without land). The upper (multiple-unit) curve is based largely upon Cleveland substation costs. The buildings for these stations are spacious, and the construction elaborate. The exteriors are suitable for residential districts. There are toilet and heating facilities and decorative lighting fixtures. The lower (single-unit) curve on the other hand represents minimum cost based upon the smallest and simplest buildings possible.

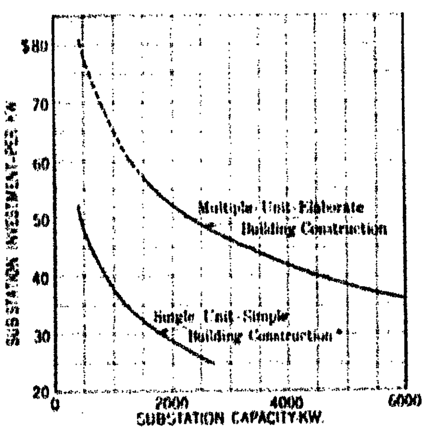

FIG. 6—AUTOMATIC SUBSTATION COSTS (WITHOUT LAND), 60-CYCLE SYNCHRONOUS CONVERTERS

*From 1921 report of A. E. R. A. Power Generation Committee

Consideration of investment charges involves the question of reserve capacity. The per kilowatt investment used in an analysis of this kind must be large enough to provide for this reserve capacity. The amount of such reserve of course depends upon the system of rating of electrical equipment. The Westinghouse Company rates its synchronous converters to permit 50 per cent overload for two hours. This amounts to 50 per cent reserve if the installed rated capacity is not less than the peak load requirements. The argument has been advanced that with small single-unit substations it is not possible to have the same reserve capacity for any one substation area excepting by the installation of a prohibitive amount of copper. This is not the case where distributing distances are not more than about 6500 ft. and feeders are of the proper size. This has already been pointed out. If under these conditions one station fails, its area will be fed through the tie lines (type (*b*) feeders) from two or more adjacent substations, the reserve capacity of which will be more than sufficient to carry the additional load. It may be seen from the previous equations and calculations that the total distribution cost is only 15 per cent more for this type of feeder than for the theoretical tapering feeder and in many cases this latter type of feeder (type (*c*)) could not be used regardless of the size or type of substation. Provided the saving in any particular case resulting from increasing the number of substations from a few multiple-unit stations to a larger number of single-unit stations is large, then the argument of the superior reserve characteristics of multiple-unit stations, is no longer valid. Indeed the reverse may hold true, because there is less chance of the failure of two equipments which are several thousand feet apart than of two machines in the same station and there may be some simplification of control equipment.

6. OPERATING EXPENSES OF GENERATING PLANT, TRANSMISSION LINES AND SUBSTATIONS

It should be pointed out here that the value of e in the foregoing computations includes all items entering into the cost of direct-current power excepting interest, depreciation and taxes, and that due allowance must be made for transformer, transmission and conversion losses so that e represents operating expenses per direct-current kilowatt-hour at the railway substation bus.

Generating plant operating expenses are independent of the distribution layout. Transmission line operating expenses will in general vary with the mileage in somewhat the same proportion as transmission investment. Unless there be a large difference in the transmission mileage required for two different distribution layouts it is probable that this item of expense may be neglected in making a comparison. It should not exceed 4 per cent of operating expenses even for very small substation installations.

The total converter substation operating expense (including maintenance) for the Cleveland manual substations is less than $0.0009 per d-c. kw-hr. Of this amount, approximately 30 per cent is for maintenance and 10 per cent for supplies; the remaining 60 per cent is for operator's wages. These figures are fairly typical, excepting that the labor cost is somewhat low because of large capacity stations. In the case of automatic control this last item is eliminated excepting for the labor of inspection and cleaning. This, together with maintenance, will increase somewhat with an increase in the number of substations used to serve a given load. For one thing, employes will have to spend more time in going from one substation to another. The transportation cost for men and supplies will also increase. The average manual substation capacity in Cleveland is approximately 6000 kw. for which the operating costs, exclusive of operators' wages are approximately $0.00036 per kw-hr. If the total operating expenses be assumed to be $0.008 per d-c. kw-hr., which is a low figure, then substation operating expense will be only 4.5 per cent. Approximately half of this amount is for labor and the rest for supplies and materials, the cost of which should not change appreciably for a larger number of small substations. Should the Cleveland system be supplied

with power from forty 1000-kw. substations, it is conceivable that the labor cost for maintenance and inspection might increase the total substation operating cost to 7.0 per cent. This would mean more than doubling present maintenance labor costs. Due to the fact that the automatic substation has not as yet come into general use, it is impossible to present precise data on operating costs. The above figure is only a guess as to an upper limit.

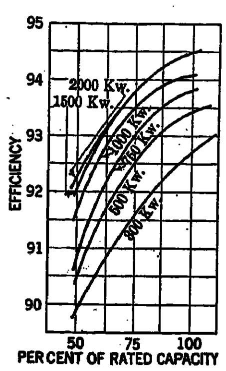

Fig. 7—Combined Efficiencies

Three phase, 60-cycle synchronous converters, with three single-phase transformers (Westinghouse).

Ratings based on 50 per cent overload for two hours, starting hot.

Another factor requiring consideration in a study of this kind is substation efficiency. Presumably at the time of peak load all substations will be operating at approximately full rated load and consequently at about maximum efficiency, no matter what scheme of layout may be determined upon. The combined efficiency of Westinghouse railway 60-cycle converters with their transformers increases about 2.5 per cent from one-half to full load. This range is somewhat less for the larger sizes (over 1000 kw.) and somewhat greater for the smaller sizes. Should the distribution system be so laid out as to necessitate operation of converters at an average of 75 per cent of rated load instead of full load, there would be a loss of 1 per cent of operating expenses per kilowatt-hour. If these operating expenses be $0.008, then for cities the size of Cleveland, or Detroit or St. Louis, this loss would amount to about $11,000 per year. It will be seen that this is small in comparison with total distribution costs. It is possible in some instances that smaller distributing distances and consequent decreases in distribution cost might justify the operation of certain substations at considerably less than rated capacity during off-peak hours instead of shutting down the substations and thereby increasing the distributing distances.

There is a considerable difference in the efficiency of converters with their transformers between the small and large sizes. The Westinghouse 300-kw. converter with transformers is 1.4 per cent less efficient than the 1000-kw. equipment at full load and 1.8 per cent less at one-half load. There is less difference between the larger sizes. In determining upon a distribution layout and consequently upon the size of converters this difference in efficiency must be considered. Suppose for example one layout calls for twenty-one 1000-kw. single-unit stations with an average distributing distance of 6000 feet and that the distributing cost figured out to be $56,000 per year; and another layout calls for seventy 300-kw. stations with an average distributing distance of 2500 feet so that the distributing cost was found to be $22,000. With a load factor of 40 per cent and power operating expenses of $0.008 for both cases, this difference in size of equipment alone would add more than $8,000 to the cost of power, which would be an offset to the saving in distribution cost. It must, of course, be borne in mind that other factors such as increased carrying charges and operating expenses may serve to increase the cost of power used by the cars to such an extent as to counterbalance the above apparent saving in distribution cost.

7. Economically Correct Substation Layouts

We are now confronted with the application of the several principles and relationships set forth above, to specific cases with a view to determining the most economical layouts. Specifically, the problem is two-fold, (1) character of substations, *i. e.*, multiple-unit or single-unit; (2) spacing and consequently the size of substations. Several typical examples will be considered. These examples are perhaps less complex than the average actual case. They will, however, make possible the formulation of some general conclusions which, it is hoped, will prove of value in the solution of the practical problems of distribution.

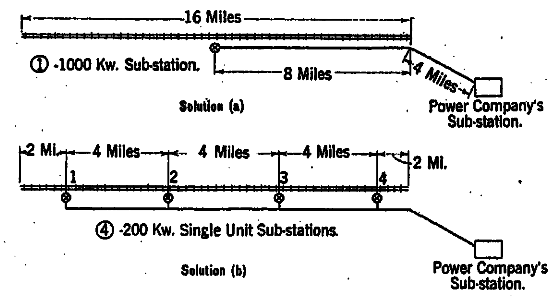

Fig. 8—Single Interurban Line

Schedule speed, 20 miles per hour.
Peak headway 12 minutes.
Number of cars on line, eight (peak).

(a) *Single Lines*

Case 1. Single Interurban Line. (See Fig. 8).

Length—16 miles, single track, open country.

Maximum load (with one substation) 1000 kw. 640 volts.

Load uniformly distributed over line.

Load Factor 35 per cent.

Loss factor for system 20 per cent.

High resistance roadbed—crushed stone ballast, exposed rail, bonded joints, 90-lb. rail.

No negative feeders.

Power purchased, delivery high-tension (22,000 volts) at power company's distributing substation.

Power rates — demand charge: flat rate 1.25 per kw. per month.

Kilowatt-hour charge: flat rate — $0.0075.

Substations, full automatic.

Cost of feeder in place — $0.155 per lb.

Solution (*a*) One 1000-kw. substation at middle of line, two 500-kw. units.

Cost of substation ($50.00 per kw.)........	$50,000
Cost of transmission line	
4 miles — $2100 per mile (includes poles)	8,400
8 miles — $1200 per mile (using trolley poles)........................	9,600
	$68,000
	or $68.00 per kw.
Carrying charges at 14 per cent — $9.52 per kw. per year........................	$9.52
Transmission and substation efficiency at peak load = 83 per cent. Hence demand charge per d-c. kw-hr. is $1.50 per month or $18.00 per year (1.50 = 1.25 ÷ 0.83.....................	18.00
Total carrying charges on generating plant, transmission line and substation.......	$27.52
Operating expenses up to purchased power delivery point (kw-hr. charge) — a-c....	$0.0075
Operating expenses (kw-hr. charge) — d-c.... (Efficiency of transmission and substation — 81 per cent)	0.00927
Transmission line and substation operating expenses per kw-hr. — d.c.............	0.0012
	$0.01047

e = 0.002094

Type (*b*) feeder cross-section (from curves) 780 amperes = 1,187,000 cir. mils. (one 1,000,000-cir. mil cable and 3/0 trolley)

Peak feeder drop[4] (8 miles = 144 volts

Rail and ground resistance (G) (2 rails) = 5.5×10^{-6} ohm per foot.

Peak distribution circuit drop[4] = 235 volts

Minimum line voltage[4] = 640 − 235 = 405 volts.

It should be pointed out that the condition of uniform distribution is satisfied over a period of time (*i. e.* car headway or longer period) but never instantaneously. Hence the above minimum voltage will not be the lowest instantaneous voltage. Were there a very large number of cars on the line, these two voltages would be practically the same. With eight cars, two miles apart and one of them at the end of the line the minimum instantaneous voltage would be 345 volts. It is possible to operate the average interurban car at this voltage.

4. Average during peak period, *i. e.*, corresponds to 780 amperes uniformly distributed.

The minimum annual cost of distribution for the entire sixteen miles of this interurban line is $18,000 (determined from the equations), based upon the type (*b*) feeder. Had this been a type (*c*) feeder (*i. e.*, tapering section) the theoretical minimum cost would have been $1,840 less. Hence the cost would be between $16,160 and $18,000 depending upon the number of steps by which the section of the feeder be decreased between the substation and the end of the line. The actual cost would be about $17,000.

Solution (*b*)—Four 200-kw. substations, one 200-kw. unit per station.

Cost of substations ($70.00 per kw.).........	$56,000
Cost of transmission line	
4 miles—$2100 per mile...............	8,400
14 miles—$1100 per mile...............	15,400
	$79,800
	$100.00 per kw.
Carrying charges at 14 per cent.............	$14.00
Transmission and substation efficiency at peak load — 82 per cent, demand charges.......	18.28
Total carrying charges.........	$32.28

During the peak load period all substations will operate continuously at about full load since there will always be two cars in the distributing zone of each substation. During the off-peak periods the load may be carried in one of two ways. One or two of the substations may be operated continuously distributing over correspondingly wider zones, or all four substations may be operated intermittently as cars pass through their zones, by means of the low-voltage relays. Under the first plan distributing cost will be higher and under the second plan substation operating efficiency will be lower. Both plans will be considered here.

Assume that as the system load decreases, substations are taken off the line in the following order: No. 2, No. 4, No. 1, and No. 3. It should then be possible to keep each substation loaded on the average to at least 70 per cent of rated capacity. Whatever this average loading may be it must necessarily be substantially better than in the case of a single substation having two 500-kw. units. At full load the difference in efficiency on account of size of units will be about 1 to 2 per cent. The difference in efficiency due to the machines being loaded on the average to different percentages of rating will be of this same order, but if anything a little less. It is probable, however, that the net difference in substation efficiency between the larger two-unit station and the four smaller single-unit stations (operated under the plan of taking stations off the line as the load decreases) will be less than 1 per cent. Transmission line efficiency will not be different for solution (*b*) as against solution (*a*) since the *average* distance is the same. The combined

transmission and substation efficiency will therefore be taken at 80 per cent.

The item of transmission line and substation operating expense will be increased as against the cost for the single two-unit station. There will be six miles more transmission line and the cost of inspection and maintenance of substations will be greater for reasons already pointed out. This item will, therefore, be taken at $0.0014 per d-c. kw-hr. Thus total operating expenses become $0.01080 per d-c. kw-hr. as against $0.01047 for solution (*a*).

Loss factor will be taken at 0.60. $L\,e$ is, therefore, 0.0065. Type (*b*) feeders (*i. e.*, uniform cross-section) will necessarily be used between substations in this solution because of the method of operating the substations. For the sake of simplicity, uniform section feeders will also be used on the two dead-ended sections at either end of the line.

Peak distribution losses for solution (*a*) will be

$$0.001\,\frac{I^2}{3}\,D\left(\frac{10.35}{m}+G\right)=H_a=2\times 0.001\times\frac{780^2}{3}\times 8\times 5280\left(\frac{10.35}{1{,}187{,}000}+5.5\times 10^{-6}\right)=247\text{ kw.}=24.7\text{ per cent}$$

The power used by the cars in solution (*a*) is therefore

$$1000-247=753\text{ kw.}$$

The peak distribution losses in solution (*b*) will be

$$H_b=8\times\left[0.001\times\frac{I^2}{3}\times 2\times 5280\left(\frac{10.35}{m}+5.5\times 10^{-6}\right)\right]$$

in which $m=0.577\,I\times\sqrt{\dfrac{2820\,p+24.7\times 10^6\,L\,e}{f}}=2122\,I$

Hence $H_b=28.2\,I^2\left(\dfrac{10.35}{2122\,I}+5.5\times 10^{-6}\right)=\left(I\times\dfrac{640\times 8}{1000}\right)-753$

$I=151.8$ amperes. $m=322{,}000$ cir. mils (including trolley)

$H_b=24.4$ kw.

Total power $=24.4$ kw. $+753$ kw. $=777.4$ kw.

$H_b=3.14$ per cent.

The minimum annual distribution cost for the 16 miles becomes:

$$C\,(\text{min.})=8\left[0.000225\times 151.8\times(2\times 5280)\times\sqrt{0.0186\,(32.28+56.94)}+\frac{151.8^2\times(2\times 5280)\times 5.5\times 10^{-6}}{3}\times(0.001\times 32.28+8.76\times 0.0065)\right]=\$4008$$

Following is a comparison of the total power costs for solutions (*a*) and (*b*):

COMPARISON OF TOTAL POWER COSTS

Solution (*a*)	
Power actually used by cars:	
Investment charges—753 × \$27.52	\$20,722.00
Operating expenses—2,300,000 × 0.01047 ...	24,081.00
	\$44,803.00
Distribution cost	17,000.00
	\$61,803.00
Solution (*b*)	
Power actually used by cars:	
Investment charges—753 × \$32.28	\$24,307.00
Operating expenses—2,300,000 × 0.0108	24,840.00
	\$49,147.00
Distribution cost	4,008.00
	\$53,155.00
Saving in favor of solution (b)	\$8,648.00

If, instead of cutting some of the substations off the line entirely, during off-peak periods, all substations be operated by the low-voltage relays so as to start up when a car comes within their distributing zones, then the above figures for solution (*b*) must be changed somewhat. In the first place, the average substation efficiency will be lower by reason of the stopping and starting losses. The difference is probably of the order of 5 per cent. To offset this there is some saving in cost, since the distribution distances during the off-peak periods will be the same as during the peak periods. Expressing this in the mathematical terms that have been used above, loss factor (L) becomes 0.20 instead of 0.60 as used for the other method of operation.

$$m=0.577\,I\sqrt{\frac{2820\,p+24.7\times 10^6\,L\,e}{f}}=1607.6\,I$$

$$H_b=28.2\,I^2\left(\frac{10.35}{1610\,I}+5.5\times 10^{-6}\right)=\frac{(I\times 640\times 8)}{1000}-753$$

$I=153.1$ amperes.

$H_b=31.23$ kw.

Total power $=31.23+753=784.23$ kw.

$H_b=3.98$ per cent

$C_{(min.)}=\$3054$ or \$955 less than for the other method of operation. Operating expenses per d-c. kw-hr. become \$0.0114 or an increase of \$0.0006

2,300,000 × \$0.0006 = \$1380.

It is apparent that in the case under consideration there is very little difference in cost between the two methods of operating. Under such conditions it would perhaps be better to adopt the first method (*viz.* cutting some stations off the line entirely during light load

periods rather than having these stations operate intermittently as cars come within their zones), for the reason that the additional copper provides that much larger factor of safety and also because the intermittent operation is somewhat harder on equipment.

It is apparent that a still further decrease in the size of substations, while perhaps netting some slight saving, would probably be unwise since the machines would be too small to carry the heavy swings when there are two cars in a distributing zone.

Total Power Cost as a Function of Distributing Distance—Single Lines.

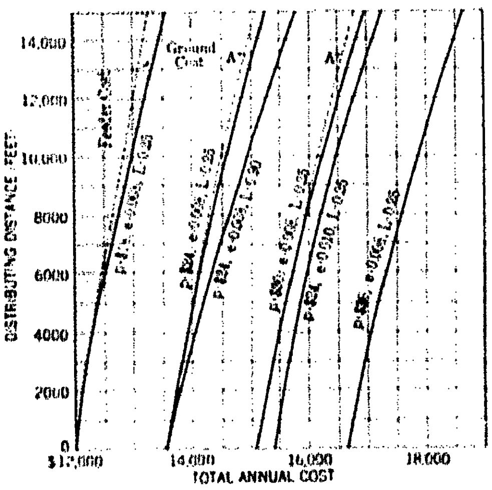

FIG. 9—ANNUAL COSTS

One mile double track.
Uniform traffic.
Power consumption by cars, 260 kw. peak.
Return circuit resistance = 2.5×10^{-6} ohms per foot
Feeder investment, $0.155 per lb.
D-c. bus voltage = 600
Type (b) feeder.
Curves A—two-mile double track power consumption by cars, 130 kw. peak per mile.

In Appendix III the equation for D in terms of the other variable factors is derived for type (b) feeder.

This relationship is presented in the form of curves (Fig. 9). These curves serve to show the relation between distributing distance and total annual cost of power for one mile of track on which there is a uniform distribution of traffic. It will be noted that the curves have been drawn for several different values of p (generating plant, transmission line and substation investment carrying charges), for different values of e (operating expenses) and for different traffic densities (viz., 130 kw. per mile and 260 kw. per mile). From these curves it is possible to generalize to some extent upon the question of how far we may go in reducing distributing distances and still make for saving in power cost. Take for example the curve for which p = \$24, $e = 0.008$, $L = 0.25$, $G = 2.5 \times 10^{-6}$, and power used by cars is 130 kw. per mile. Were it possible to reduce distributing distance on the single line under consideration from 13,000 feet to 5,000 feet by the installation of additional substations, but without increasing the per kilowatt investment or the operating expenses, the saving would be $420 per year per mile of track. As a matter of fact, the investment per kilowatt would increase with the number of stations, and the question arises how far may we go in increasing investment per kilowatt and still produce a saving in the cost of power. Provided operating expenses remain substantially the same, it is clear that p may be increased to $27 per kilowatt per year before the savings from decreased distance would be offset by increased carrying charges. The increase is $3 which capitalized at 14 per cent, amounts to $21.40. Investment in generating plant will presumably be the same for all solutions of this distribution problem. Hence we may spend up to $21.40 per kilowatt on transmission lines and substations before the saving is wiped out. Suppose now that for a particular railway system, or better yet, for a particular section of this system a 4000-kw. multiple-unit station will be sufficient to feed an area such that the distributing distance on the several single lines in this area will be 13,000 feet. Suppose also that the system be such that a 1500-kw. multiple-unit station will be sufficient to feed an area such as to make the distributing distance 5000 feet. According to the curve for multiple-unit substation costs the difference in cost would be about $15 per kilowatt. Suppose now that the increase in transmission line investment is $3 per kilowatt, making the total increase $18 of which 14 per cent amounts to $2.52. By interpolation between curves it may be seen that the cost of power for the one mile of track will be approximately $7330 as against $7420 for the larger substation. The difference is $90 per year. If operating expenses, after taking account of any difference in transmission and substation efficiency, be substantially greater per kilowatt-hour for the smaller substation, then the above saving of $90 per mile will be correspondingly less. A difference of 1.5 per cent in the substation efficiency would more than offset this $90.

The above analysis is based upon constant distributing distances twenty-four hours per day. Should single-unit stations be contemplated, some of which would be shut down during off-peak periods, the curve or equations for a loss factor (L) of say 0.60 or more would be used.

The above example serves to show that the margin of saving is small for the range of distributing distances that would obtain in large cities. It shows that the investment in transmission lines and substations must be held down to bed rock minimum if there is to be any appreciable saving in the total cost of power. Furthermore, it is evident that the efficiency of equipment and all other factors entering into the total operating expenses per direct-current kilowatt-hour must be carefully weighed before the adoption of small units.

In weighing these questions of cost there is another factor which must not be forgotten. Many railway companies have found it necessary to make comparatively large investments in insulated negative feeders

and in other provisions for reducing stray currents and the consequent electrolytic corrosion of underground structures. In the foregoing analysis no account has been taken of negative feeders or other special mitigative measures. In some instances this item of cost has been large. The City of Winnipeg has recently installed the three-wire system of distribution in order to comply with a law recently passed by the Province of Manitoba which limits the allowable track drops. In considering the merits of a large number as against a small number of substations, this factor must be given weight. If electrolysis is a serious matter in a particular locality, it may prove the deciding factor in favor of the larger number of substations.

(b) *City Networks*

It is not possible within the limits of a paper of this kind to analyze comprehensively the entire system of any one large metropolitan city. Even if this were possible it would be of doubtful value. In lieu of such an analysis, a simple illustration will be used in which the values used for the different determining factors are typical average values for cities such as Cleveland (or Detroit or St. Louis). Were a careful analysis made for a particular city, it would be necessary to treat each line separately and to find total costs by adding up these single line results. Hence if we would generalize, it is perhaps sufficient to treat a single line on which average conditions obtain.

If the railway system be a single line (an interurban for example) or, if a city network, be considered as composed of single lines so that each substation feeds in two directions only (*i. e.*, one dimension) then distributing distance will be inversely proportional to the number of substations in operation. If the railway system be a very dense network so that every substation feeds in four directions or in effect feeds an area rather than a single line, then distributing distance will be inversely proportional to the square root of the number of stations. In the case of a large city network the relationship between distributing distance and number of substations will be somewhere between the two extremes set forth above, and as the number of substations is increased the relationship for single lines will be more nearly approached.

In the present example distributing distance has been found from the formula:

$$D = K \times (\text{Substation Capacity})^{0.75}$$

This formula expresses approximately the conditions in Cleveland. It is half way between the relationship for a single line and that for a very dense network or area.

CASE 2. Heavily loaded metropolitan system.

Excepting purchased power rates the following values are approximately correct averages for Cleveland. In place of Cleveland power rates more typical values are used.

1. Average peak power required per mile of double track—260 kw. or 0.0492 kw. per ft.
2. Substation bus voltage—600.
3. Yearly load factor—0.40.
4. Yearly loss factor for system—0.25.
5. Demand charge at power company's distributing substations—$1.00 per kw. per month. (Unity power factor).
6. System power factor unity.
7. Kw-hr. charge at power company's distributing substations—$0.006.
8. Type (b) feeders only.
9. Effective return circuit resistance (G) = 2.5×10^{-6} ohm per ft.

The total annual power cost for one mile of track will be determined for the following cases:

	Substation Capacity	Units	Distributing Distance
(a)	6,000 kw.	4—1,500	12,000 ft.
(b)	4,500 "	3—1,500	9,800 "
(c)	3,000 "	2—1,500	7,500 "
(d)	1,500 "	1—1,500	4,700 "

Substation efficiency at peak load will be the same for all of the four different arrangements. It will be taken at 94 per cent. Transmission line efficiency should also be about the same for all solutions since the mean distance to substations in a particular district should not vary greatly for a larger number as against a small number of stations. This will be assumed to be 97 per cent. Thus generating plant carrying charges per kilowatt (direct-current) become

$$\frac{\$12.00}{0.94 \times 0.97} = \$13.16 \text{ (i. e. demand charge corrected}$$

for losses)

It will be assumed that the average distance from the power company's distributing station to the railway substations will be substantially the same for the different layouts. This distance will be taken at two miles and the following transmission line capacities will be used:

(a)	6000 kw.	substation	3—4/0	cables
(b)	4500 "	"	3—2/0	"
(c)	3000 "	"	2—4/0	"
(d)	1500 "	"	1—4/0	"

The cost of cable ducts will vary from $0.50 per duct foot for nine duct banks to $1.25 per duct foot for three duct banks. As the size of substations is decreased, and in consequence the number increased, it will not be possible to utilize to the same extent the main artery duct subways of the power company, with the result that the cost per duct foot will be greater for the smaller substations. The following costs per duct foot will therefore be used: (a) $0.65; (b) $0.77; (c) $0.89; (d) $1.00. To these costs will be added $0.15 per foot for pulling and splicing and the cost of

the cable itself which will be taken at $1.45 per foot for 4/0 cable and $1.11 per foot for 2/0 cable, both being three-conductor lead-covered 11,000-volt cables. Thus the investment in transmission lines per kilowatt of substation capacity becomes: (a) $11.91; (b) $14.29; (c) $17.53; (d) $18.30. In the case of the 1500 kw. station there is no duplicate service but in this case the distance between substations is small and the shutting down of one substation is not, therefore, of serious consequence for reasons already pointed out elsewhere.

The average efficiency of transmission lines over a period of time will be about 98.5 per cent. This will not vary appreciably for the several solutions to be compared here.

Solution (*a*)—6000-kw. station-four-1500-kw. units.

It would not be economical with the present cost of automatic control to operate a station of this size automatically. The same holds true for solution (*b*). Manual control will therefore be assumed for these two cases and automatic control for solutions (c) and (d).

Investment carrying charges per d-c. kw.:

Purchased power demand charges........	$13.16
Transmission lines 11.91 × 0.14	1.67
Substation (manual) 30.00 × 0.14........	4.20
Total (*p*)........................	$19.03

Operating expenses per kw-hr.—d-c.........

With four machines it should be possible to keep load on each machine near capacity with resultant high efficiency, *i. e.*, 91 per cent.

Purchased power kw-hr. charge—

$$\frac{0.006}{0.985 \times 0.91} = \ldots\ldots\ldots\ldots \quad 0.0067$$

Substation and transmission line operation	0.0011
Total (*e*)........................	0.0078

The substation will be operated twenty-four hours per day and distributing distance will be constant. Hence L for the distribution system may be taken as 0.25.

Annual cost (from curves) for one mile of double track........................	$13,270

Solution (*b*)—4500-kw. station—three—1500-kw. units.

Investment carrying charges per kw.—d-c.

Purchased power demand charge.....	$13.16
Transmission lines 14.29 × 0.14........	2.00
Substation (manual) 34.00 × 0.14......	4.76
Total (= *p*)....................	$19.92

Operating expenses per kw-hr.—d-c.

Average substation efficiency—90.5 per cent.

Purchased power kw-hr. charge

$$= \frac{0.006}{0.985 \times 0.905} = \ldots\ldots\ldots\ldots \quad 0.00674$$

Substation and transmission line operation..............................	0.00120
Total (= *e*)......................	0.00794

The substation will be operated twenty-four hours per day and distributing distance will be constant. $L = 0.25$.

Annual cost (from curves) for one mile of double track........................	$13,380

Solution (*c*)—3000-kw. station, two—1500-kw. units, automatic—remote control.

With substations of this size it is not desirable to operate all substations during the light load periods because to do so would mean a sacrifice of substation efficiency that would more than offset the difference in distribution cost. It should be possible to obtain an efficiency of 90.5 per cent by cutting out altogether some substations during the light load periods, that is, to equal the efficiency of the 4500-kw. station operating twenty-four hours per day. This performance cannot, of course, be had if there are very heavy load fluctuations and the machines are allowed to start and stop many times per day. This starting and stopping may easily result in an efficiency decrease of 5 per cent which under no circumstances can be justified on a large city system for it would be better and cheaper to use larger stations and distribute longer distances. Unless the load conditions be very unusual it should be possible to start and stop machines by remote control only as the regular system load increases or decreases. This method of operation will be assumed both for this solution and for solution (d). Inasmuch as the substation may be shut down a part of the time (*e. g.*, during the early morning hours), loss factor (L) will be greater, that is, the feeders will be loaded more during the light load periods than they would be if all substations were operated continuously. The exact value of L for a case such as that under consideration may of course be found for any particular load curve and plan of operation. It will suffice here to assume a value of 0.40.

Investment carrying charges per kw.—d-c.

Purchased power demand charge.........	$13.16
Transmission lines 17.53 × 0.14.......	2.45
Substation (automatic) 43.00 × 0.14 (heating, toilet facilities, etc. eliminated)............................	6.02
Total (= *p*)......................	$21.63

Operating expenses per kw-hr.—d-c.

Average substation efficiency—90.5 per cent

Purchased power kw-hr. charge

$$\frac{0.006}{0.985 \times 0.905} \ldots\ldots\ldots\ldots \quad 0.00674$$

Substation and transmission line operation..............................	0.00085
Total (= *e*)......................	0.00759

Annual cost (from curves) for one mile of double track............................ \$13,300

Solution (d)

Investment carrying charges per kw.—d-c.

Purchased power demand charge.........	\$13.16
Transmission lines 18.30 × 0.14.......	2.56
Substation (automatic) 53.00 × 0.14....	7.42
Total (= p)........................	\$23.14

Operating expenses per kw-hr.—d-c.

Average substation efficiency—89 per cent

Purchased power kw-hr. charge— $\dfrac{0.006}{0.985 \times 0.89}$	0.00685
Substation and transmission line operation..................................	0.00090
Total (= e)........................	0.00775

In this case loss factor (L) will be considerably increased over the value used in solution (c) since many of the substations will be operated only through the peak (see Fig. 4.) L will be taken at 0.60.

Annual cost (from curves) for one mile of double track............................ \$13,650

The foregoing calculations are all based upon the type (b) feeder since it is the most common. It is hardly necessary to repeat for the other types since the only effect would be to increase or decrease distribution costs and therefore change slightly the slope of the curves without materially changing the relative results of the several solutions. It is believed that whatever conclusions that may be drawn from these figures will apply equally to a system employing all types of feeder.

8. Conclusions

(a) The economically proper size of feeder where, as in cities, distributing distances are at most three or four miles, is such that the maximum voltage drops are too small ever to interfere with proper operation of cars. The difference in total annual cost between a properly proportioned feeder system and one designed to give the minimum voltage for satisfactory car operation is considerable, and should warrant a fairly careful examination of feeders and their loads at sufficiently frequent intervals to permit proper changes from time to time to take care of changing conditions. In general it may be said that in cities sufficient feeder copper is not used. This does not hold true to the same extent for interurban lines where distributing distances are great because economically proper trolley voltages more closely approach the minimum voltages necessary for car operation. This was brought out in the analysis for the single interurban line.

(b) The economic justification of the automatic substation is a reduction in distribution cost. In other words, the only reasons for adopting automatic control is to permit the use of small substations (3,000 kw. or less), because for such small substations the operating costs for manual control are prohibitive. The additional investment for automatic control is warranted approximately in proportion to distributing distance. Its principal field is, therefore, the interurban railway or long rapid transit line and also long electrified steam roads. In cities, on the other hand, the economic advantages of the automatic substation are relatively small because distribution cost is a correspondingly small part of total cost. For this reason automatic substation efficiency is of particular importance on city systems. A reduction of 2 or 3 per cent in the efficiency for automatic as against manual control may more than offset any saving that results from decreased distributing distance. The efficiency of automatic substations varies through wide limits for different load conditions and for different methods of operation.

(c) In a city district in which there are wide fluctuations in load, and in which full automatic control is used so that machines are started and stopped entirely by line voltage and load conditions, the average efficiency of a substation over a period of time may be reduced by as much as 5 per cent largely because of the frequent starting and stopping of machines. In many such cases it should prove far better to start and stop machines by remote control according as the average trend of the load is up or down. This may mean that the machines will be in operation for many short periods during which the load is far below their rated capacity, but even so, the reduction in efficiency resulting from such operation at a low percentage of capacity, will be of a smaller order than the reduction that may result from starting and stopping. If such a method of operation results in an average efficiency decrease of say 2 per cent or even less, it may be found more economical to shut down the substation altogether during off-peak periods. Thus it is apparent that the method of operation to be adopted and the substation efficiency that will result from such operation, must be thoroughly analyzed; otherwise, the use of the automatic substation may serve only to increase the cost of power. It is believed that in large cities it will prove necessary to adopt some form of remote control in conjunction with automatic control.

(d) The principal limitations in the reduction of substation sizes by means of automatic and remote control are (1) investment, (2) substation losses, (3) substation maintenance. In cities these factors may be increased only within very narrow limits without increasing the total cost of power. In such cities as Cleveland, it is doubtful if the capacity of substations can be profitably reduced below 3000 kw. with the control equipments now available for full automatic control, commencing at the incoming supply line and extending throughout the entire substation operation. It has been repeatedly pointed out that to produce an efficient result, some form of remote control will probably be required in order to prevent an excessive amount

of starting and stopping and the consequent loss in efficiency. Within the range of substation sizes considered in this paper for metropolitan systems (6000 kw. to 1500 kw.) the variation in total cost of power per mile of double track is small. There are, of course, some distinct advantages to be had by installing small capacity substations of say less than 3000 kw. These are principally the mitigation of electrolysis, and under certain conditions an increased factor of safety. Measures for the mitigation of electrolysis are receiving more and more attention. In a large substation having several units, trouble in one machine at peak load may result in failure of the entire station, whereas, if this capacity be separated by several thousand feet of feeder copper, trouble on a machine of one substation is much less apt to be transmitted to another machine in the adjacent substation, since the connecting circuit serves to damp out the surge.

The fact that the 3000-kw automatic substation in the examples cited apparently effects very little if any saving in the total cost of power as compared with the 4500 kw. or 6000 kw. manually controlled substations, is due to the increase in investment, substation losses, and increased maintenance, which just offset the savings in the cost of distribution. If, therefore, any substantial saving in the total cost of power is to be had by the smaller sizes of substations, automatically controlled, it will be necessary to reduce substation losses by improving methods of control. In the opinion of the writers, this should not be done by imposing upon a full automatic control substation additional remote control appliances. The complexity of such an arrangement is extremely undesirable. It is proposed that this result may perhaps be best secured by providing the simplest form of semi-automatic control substation, comprising a transmission line directly and permanently connected to the substation transformer primary circuit, and a synchronous converter arranged to start automatically from the transformer secondary circuit when the same is energized. This simplified semi-automatic control substation is absolutely under the manual control of the operator at the supply station and if the capacity of the substation be determined with regard to the economical capacity of the high-tension supply line, it may well be a single-unit station. On the other hand, if the reduction in capacity is carried to a point beyond this, a further division of a substation into smaller sizes may be had by grouping two such smaller substations on one economical supply line. Provided this method of control can be developed in a practical way, and there appear to be no serious obstacles, then there should result a substantial saving in the cost of power for substation sizes under 3000 kw. with the consequent advantages in the mitigation of stray currents and additional factor of safety as previously pointed out.

(e) Inasmuch as even a small difference in substation maintenance cost may be the deciding factor in a comparison between two distribution layouts, the standardization of substation equipment with the resultant economies is a matter of importance. While in some cases it may, at first thought, be desirable to use large units in the congested districts of a city and much smaller units in the outlying districts, it is quite possible that such an apparent advantage may be offset by an increase in maintenance expenses. The mechanism of the automatic substation is exceedingly complex and it is necessary to keep on hand a very large variety of spare parts, the investment in which is no small factor. If it be possible to adopt a standard size of unit and a standard control layout to be used in all substations, there will be an appreciable saving in the investment for spare parts. Furthermore, it is probable that maintenance labor may be reduced by such standardization. It is difficult to find and train good maintenance men and this difficulty would be substantially increased by the use of machines of various sizes and different control layouts.

Inasmuch as the heating losses in return circuits increase as the square of the current, it is apparent that smaller distances in the congested districts of a city and the consequently smaller track currents, are justified. If a substation of standard size be adopted, it would, of course, be necessary to space substations at smaller intervals in the congested districts than in the outlying districts. Other things being equal, this would be quite proper for the reason set forth above.

Appendix I

In equation (1) for total annual cost for type (a) feeder the heating loss is

$$I^2 \left(\frac{D \rho}{m} \right)$$

but for the type (b) feeder in which the load is uniformly distributed, heating loss is

$$I^2/3 \left(\frac{D \rho}{m} \right),$$

or

$$(0.577\, I)^2 \frac{D \rho}{m}$$

since

$$i = \frac{I x}{D}$$

where x is the distance from end or neutral point to any point on feeder and

$$\text{heating loss} = I^2 \int_0^D x^2/D^2 \, \rho \, \frac{d x}{m}$$

$$= I^2/3\left(\frac{D\,\rho}{m}\right)$$

Appendix II

$$i = \frac{I\,x}{D}$$

$$m_x = \frac{m\,x}{D}$$

$$\text{loss} = \int_0^D i^2\,\rho\,\frac{d\,x}{m_x} = \frac{\rho\,I^2\,D}{m\,D^2}\int_0^D x^2/x\,d\,x$$

$$= \frac{I^2}{2}\,\frac{D\,\rho}{m}$$

Appendix III

Type (*b*) feeder.

$$m = 0.577\,I\sqrt{\frac{2820\,p + 24.7\times 10^6\,L\,e}{f}}$$

$$= 30.64\,I\sqrt{\frac{(p + 8760\,L\,e)}{f}}$$

$$H_b = 0.001\,\frac{I^2}{3}\times D\left(\frac{10.35}{m} + G\right)$$

Let P = power per foot of track actually used by the cars during the peak.

Let V = substation bus voltage.

$$P\,D + H_b = \frac{I\,V}{1000}$$

$$H_b = 0.001\,\frac{I^2}{3}$$

$$\times D\left\{\frac{10.35}{30.64\,I\sqrt{\dfrac{(p+8760\,L\,e)}{f}}} + G\right\}$$

$$= \frac{0.000112598\,I\,D}{\sqrt{\dfrac{p+8760\,L\,e}{f}}} + \frac{0.001}{3}\,I^2\,D\,G$$

$$D\left\{1000\,\frac{P}{I\,V} + \frac{0.112598}{\sqrt{\dfrac{p+8760\,L\,e}{f}}} + \frac{I\,G}{3\,V}\right\} = 1$$

$$D = \left\{\frac{V}{\dfrac{1000\,P}{I} + \dfrac{0.112598}{\sqrt{\dfrac{p+8760\,L\,e}{f}}} + \dfrac{I\,G}{3}}\right\}$$

EXAMPLE:

Let V = 600 volts

P = 130 kw. per mile or 0.0246 kw. per foot

Load factor = 0.40

$G = 2.5\times 10^{-6}$ ohm per foot

f = \$0.0186

p = \$24.00 $\qquad p + 8760\,L\,e = 41.52$

$$\left.\begin{aligned} e &= 0.008\\ L &= 0.25\end{aligned}\right\}\ L\,e = 0.002$$

$$\sqrt{\frac{p + 8760\,L\,e}{f}} = 47.25$$

I	D	Used by Cars $P\times D$	Kw-hr. per yr.

Discussion

V. E. Thelin: The manually operated substations now in operation on railway systems in large cities offer a wonderful field for the use of automatic equipment, due to the fact that the line losses can be reduced considerably, schedule speeds increased, and in many cases sufficient copper can be taken down to pay for the cost of the land and new buildings as well as that of moving the machines. If the manually operated substations, which have a capacity of from 4000 to 20,000 kw., are redistributed into any number of single-unit or, at the most, two-unit automatically controlled substations, the service rendered by same no doubt will be far superior to that now obtained in the manually operated substations, due to the fact that each operation in the automatic substation has been worked out beforehand and the entire sequence is carried through without any hesitancy or error such as frequently happens to the operator in manually controlled stations. In the large manually operated substations with many units it is necessary to clear the board of practically all the feeder sections before the first rotary can be connected to the bus, whereas a single-unit automatic substation will have a maximum of say from five to eight feeders, and there should be no difficulty experienced in the station picking up all the sections

simultaneously. It is possible, through the use of special devices which I have in mind, to isolate each substation district from all other districts, and by using automatic reclosing circuit breakers service can be restored quickly, whereas if all substations were tied together through bus lines the first station to be connected to the system would open up an overload through excess of load fed from the surrounding substation districts through the bus lines.

It seems, for many reasons, that the ideal automatic substation layout in a large metropolitan city is the single-unit substation layout. A two-unit substation requires the use of high-tension

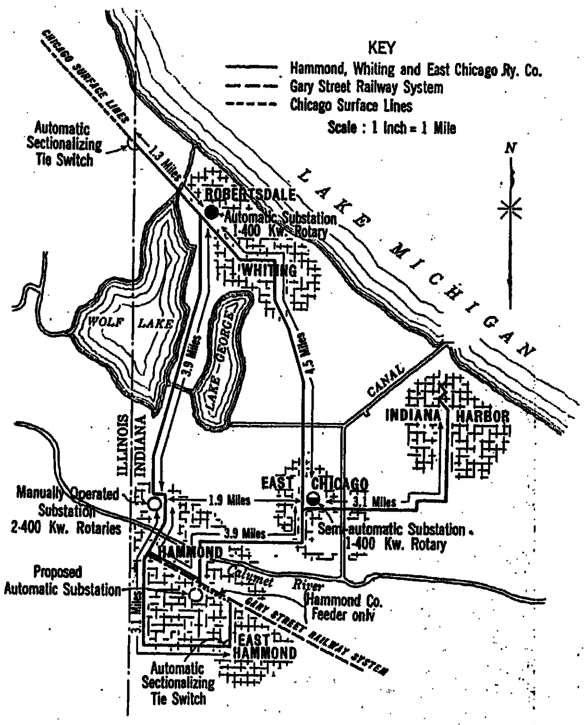

FIG. 1—HAMMOND, WHITING AND EAST CHICAGO RY. CO. SYSTEM

line oil switches, rotary oil switches and transfer switches, together with the expensive bus bar compartment construction for line busses, transfer busses and rotary busses, and where compound rotaries are used equalizer busses must be used, and the automatic control for a multiple-unit substation becomes very complicated, due to the fact that arrangements must be made for one rotary to carry the load in the light portions of the day and for additional rotaries to be brought into service as the load increases. Also, if trouble is experienced in the operation of one rotary, the automatic equipment must be so arranged as to cut in one or more rotaries, and the remaining rotary or rotaries are therefore called upon to carry the load which was originally carried by all of the rotaries originally in service in the station, which fact results in the remaining rotary or rotaries, as the case may be, being subject to an overload. On the other hand a single-unit substation can be constructed very economically, due to the fact that it is necessary to put in one oil switch only, which acts both as line and rotary switch, and which eliminates practically all of the expensive high-tension bus bar construction. By using one rotary, only, in the substation it is possible to put a 1000, a 2000, or even a 4000 kw. rotary in a building of simple construction on a 25-ft. lot. In case an oil cooled transformer is used, it is not necessary to build a basement in the substation, the cables being run in ducts under the floor and the rotary being set on a foundation with a pit in same, in order to get under the rotary for necessary repairs, etc. If air blast transformers are used, such as is now the case in a great many of the present hand-operated railway substations, the oil switch and transformers can be placed over a small basement-like compartment, which compartment would only have to be big enough for a man to enter to make the necessary repairs. The blower for cooling purposes is connected directly to this basement.

I do not agree with the authors of the paper in their statement that a 3000 kw. unit is the minimum size which can be economically installed in city service, as I feel that with single-unit substations and simplified type of automatic control equipment it is possible to economically install substations with as low as 1000 kw. capacity.

The following figures might be of interest in connection with the application of automatic substations in city service. Fig. 1, shows the present layout of the Hammond, Whiting & East Chicago Ry. system. This system, which operates approximately 30 miles of track, originally was fed from one manually operated substation located in Hammond, which station contained four 400-kw. rotaries. In order to improve operating conditions, one of these rotaries was moved to East Chicago and equipped with various protective devices, which prevent any damage occurring in case of trouble arising due to hot bearings, over-speed, reverse current, etc. The feeders and the rotary are protected by means of automatic reclosing circuit breakers. The station is started in the morning by an inspector and left to run by itself all day, being shut down at night by means of a clock, which first trips out the circuit breaker and then opens the oil switch. This substation has been in operation as a semi-automatic station for approximately four and one half years, and has given very satisfactory results in normal operation. Shortly after this station was put in service another station was built at the north end of the system, viz. at Robertsdale. The power supplied to these three substations is furnished, however, from

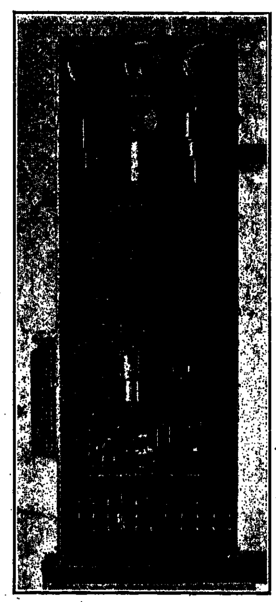

FIG. 2—AUTOMATIC CONTROL PANEL

the same high-tension line, and after any interruption on this line it was necessary to carry the load on the two rotaries in the manually operated substation in Hammond until the inspector was able to get over and start the East Chicago substation, after which the Robertsdale substation was started. Having had some experience as a substation operator, I felt that a simplified automatic substation control equipment, with fewer parts than had been used heretofore in any automatic substation, could be

developed, which would do electrically exactly what an operator does manually when starting a substation. After various tests and experiments such an equipment was developed, and has been in daily operation for approximately two years, having given very satisfactory results.

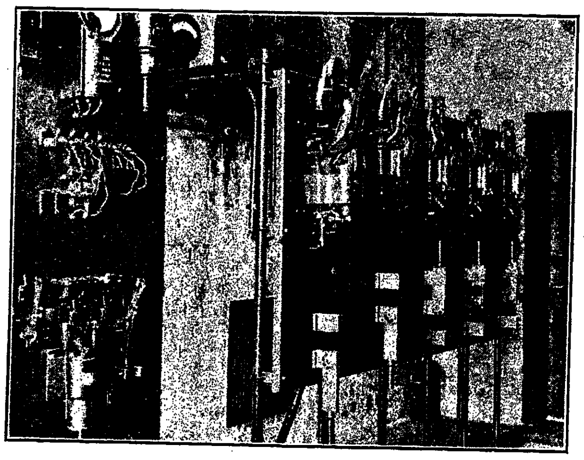

Fig. 3

Fig. 2 shows the details of the automatic control panel in this station, as follows:

Directly below the time clock which starts the operation of the station is a master relay which energizes the various circuits in the station. Below that is a polarized relay, which determines,

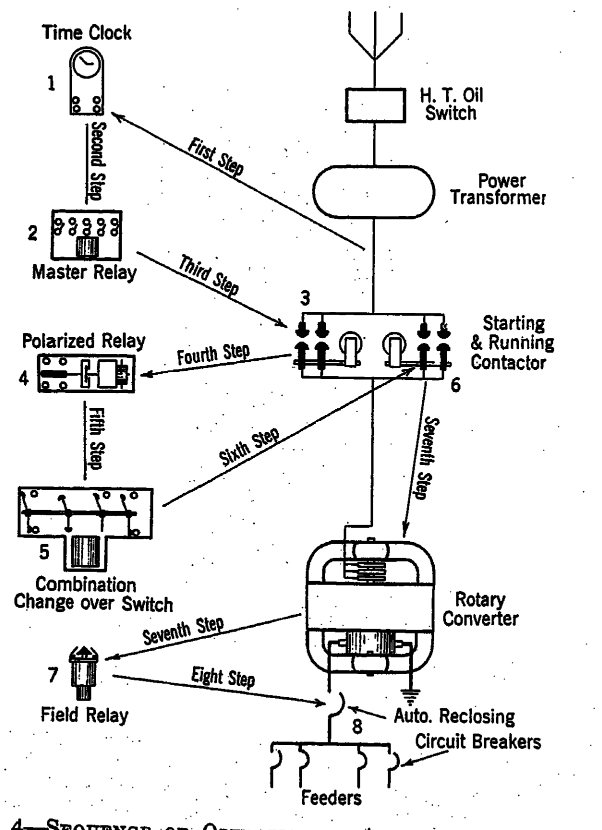

Fig. 4—Sequence of Operation of Automatic Equipment

whether or not the balance of the operation should be carried through or whether the polarity of the rotary should be corrected in case it came up wrong. Beneath the polarized relay is a combination field control and change-over switch, which, in addition to changing the connection of the field from the station bus to the rotary itself, also performs various other operations either simultaneously or with a certain time relay. The various protective devices shown at the top of the panel protect the rotary from all possible cases of trouble that may arise, such as reverse phase, phase failure, reverse current, over-speed, etc. The switches at the bottom of the panel are used for the purpose of cutting out the automatic equipment and reconnecting the balance of the equipment in such a way as to enable the substation to be operated as a semi-automatic in case any of the various automatic devices are out of order.

Fig. 3, shows, reading from left to right, the automatic reclosing circuit breakers on the rotary converter, the auxiliary bus and three feeders, respectively. The feeder breakers are bus sectionalizing breakers which are capable of being operated either with the station in operation or shut down, *i. e.* with power fed from the station bus or with back feed from some other substation through the bus tie feeders.

Fig. 4, shows the sequence of operation of the automatic equipment as follows: (1) Contact making time clock 1 operates. (2) Closing master control relay 2, which in turn (3) Closes starting contactor 3, which starts rotary. (4) Magneto-motor driven polarized relay 4, then operates, (5)

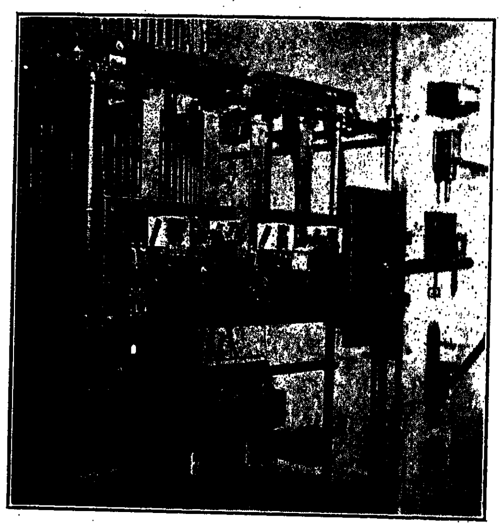

Fig. 5

Closing combination feed control and automatic change-over switch 5, which in turn (6) Opens starting contactor 3 and closes running contactor 6, (7) After which field-circuit time-limit relay 7 closes and, (8) Automatic reclosing circuit breaker 8 on machine panel closes, picking up station load. All of which operations require approximately 25 seconds.

In case the station comes up with reversed polarity, polarized relay, 4 shuts the stations down, after which the rotary starts again and operations 1, 2 and 3, shown above, are repeated until the rotary comes up positive, after which the regular sequence of operation is carried through. This condition, however, will rarely occur, due to the fact that the field of the rotary is excited with one-tenth full strength field from the station bus during the time that the rotary converter is being started up, which causes the field to come up with correct polarity. Out of approximately 500 tests that were made with the field connected to the bus in this manner, there was only one case noted where the rotary converter came up negative, which possibly might have been caused by poor contact of some of the fingers, etc.

The equipment is so designed that each operation in the sequence is a function of the one preceding it, *i. e.* each operation must be carried through successfully before the next one can take place. It is also so designed that if the d-c. automatic reclosing

machine circuit breaker does not close and pick up the station load within a certain predetermined time after master relay 2 has closed, the self-correcting relay shown to the left of the time clock will then trip out the master relay, which in turn shuts down the rotary. The rotary then starts up again and if the trouble was caused by an imperfect contact or the sticking of some interlock, it may operate perfectly now and the entire sequence of operation is carried through, and the station load is picked up.

Fig. 5, shows, reading from left to right, the starting and running contactors for the automatic equipment; the manually operated starting and running switch; and, at the extreme right, the a-c. oil switch control panel.

The only other equipment in the station that is not shown in any of the accompanying photographs is that of the rotary converter, which I did not consider it was worth while to show, inasmuch as it does not show any new equipment.

D. W. Roper: The authors of this paper have brought out one point which cannot be emphasized too much, and that is that if the introduction of the automatic station for railway distribution will provide a method of increasing the number of feeding points for the railway system, the electrolysis problem will largely disappear. The tendency has been to put in substations as large as possible so as to reduce the operating expense, that is, the expense of the substation operators, and that has served to make the feeding distances very long. With the automatic substation the tendency is in the other direction, to make the substations comparatively small, and in this way greatly increase the number of feeding points. As the length of the feeders diminishes very rapidly with the increase in the number of substations, so also does the length which the railway return current travels the rails reduce in the same way: and not only does this affect a reduction in the voltage drop in the railway return circuit, but also effects a material reduction in the losses in the return circuit.

If the operators of the railway systems in planning the rehabilitation which they are looking forward to, after the long period of depression—would install as many substations as economically possible, and in this way reduce their feeding distances, it will very materially reduce the complaints and the damage which have heretofore been caused by electrolysis.

W. E. Bryan: The subject of economics of railway distribution, especially in view of the advent of the automatic substation, merits the most careful study by the electric railway engineer. The economic side of this question has been too often neglected in the past, due in large measure to the fact that railway systems have grown through the process of consolidation and ideal distribution layouts were, therefore, difficult of attainment. The automatic substation has interjected an important element into the field and railway engineers must be prepared to take full advantage of this new development which means some readjustment of our previous ideas as to size of stations, type of buildings, etc.

As the writer has pointed out previously, variation in local conditions makes general conclusions applicable to cities of a given size not only difficult of determination, but of doubtful value as well. Not only must conditions in any particular city be studied as a problem by itself, but a solution applicable to one section of a city may not be the best solution for another section, due to variation in the cost of land, availability of conduit, etc. Another point which has an important bearing is the question of power supply. In St. Louis, for instance, the railways receive power from three sources, namely, purchased water power at 55 per cent load factor; purchased steam power at 40 per cent load factor and power generated in its own plants at 14 per cent load factor. St. Louis has several d-c. feeders which are admittedly poorly designed from a distribution standpoint, but which, nevertheless, considering the different costs of the various sources of power, provide the best arrangement from an economic standpoint.

The authors on page 363 derive a figure for the cost of distribution amounting to $250,000 per year which they state is fairly representative of cities of the size of Cleveland. As the figures in this tabulation are used more or less throughout the paper, the writer has drawn up comparable figures for St. Louis which indicate that the annual cost of distribution in that city amounts to approximately $505,000 per year. It should be stated that the investment data used is based on conservative valuation figures recently prepared for presentation in a case before the State Public Service Commission, and corrected as of April, 1922. Incidentally, it might be brought out at this point that the larger the distribution loss, the greater the possible saving which can be effected by the use of an increased number of substations. In other words, if as the authors conclude, stations of 3000-kw. capacity are best adapted for cities where the annual distribution cost is $250,000 per year, it seems logical that if the distribution loss is considerably in excess of this figure a greater number of stations and, therefore, stations of smaller capacity are justified.

In view of the wide difference in the annual costs of distributions just referred to, a brief explanation of how the writer's figure of $505,000 was obtained is in order. The carrying charges on feeder investment are found to be $135,000 as compared with the figure of $130,000 used in the paper. The writer's figure represents a 10 per cent charge on a valuation of $1,350,000 for positive and negative distribution circuits. In view of the low depreciation of copper the writer considers 10 per cent preferable to the 13 per cent fixed charge rate used by the authors.

The principal variation, however, comes in the second item, namely, the carrying charges on that portion of the investment in generating plant, transmission lines and substation equipment necessary for supplying the peak load distribution losses. The writer's figure is $240,000 as compared with the figure $92,000 derived in the paper. This difference is due to two factors; first, an increase in the cost of investment per kilowatt of direct-current demand from $165 to $258: second, the distribution losses during the peak, based on many readings taken at various points scattered throughout the city, was found to be for St. Louis practically 15 per cent as compared with 10 per cent as used in the paper.

Returning to the first item just mentioned, namely, the investment per kw. in generating plant, transmission lines and substation equipment, it is important to bear in mind that this figure is based on the d-c. demand at the substation bus. With a coincident half-hour average d-c. demand of 45,000 kw. (the figure for St. Louis), the demand at the generating bus amounts to 53,000 kw., the average loss at the time of peak load for transmission and conversion amounting to 15 per cent. If it is assumed that the generating plant should have a reserve capacity of 25 per cent and that its present day cost would amount to $125 per kw. of capacity (which is considered by the writer a very conservative figure), the investment cost in generating plant reduced to the basis of d-c. demand amounts to $183 per kw. The addition for transmission cable, underground conduit and substations brings the total to $258 per kw. It would seem that the figure used by the authors, namely, $165, is considerably lower than could be realized in practise, especially in view of the statement at the bottom of page 367 of the paper, that generating plant investment alone might be as high as $150 per kw.

This factor, that is, fixed charges on investment necessary to supply peak load losses, is the most important of the three factors entering into distribution costs and if automatic stations, especially in congested districts are properly adjusted as to voltage, a very material saving in the item will result due to the saving in distribution losses.

For the third item entering into the cost of distribution, namely, operating expenses of generating plant, transmission

lines and substations necessary to supply distribution losses, the writer obtains $130,000 per year as compared with $28,000 given in the paper. Although the same "Loss Factor" is used, the writer has applied it to the peak load loss, multiplying the resulting figure by 8760, and not to the annual kw-hr. output, as was inadvertantly done by the authors. The difference is further increased by the use of 15 per cent distribution loss on the peak instead of 10 per cent, and to a slightly higher energy charge for power.

A comparison is given on pages 374 and 375 of the use of stations of various sizes ranging from 1500 to 6000 kw. Messrs. Crecelius and Phillips have determined the probable distribution distance for each of the stations considered and have worked the problem out on this basis. The railway engineer is usually confronted with the necessity of taking care of a given district and the question to be determined is whether the district shall be fed by one, two or perhaps more stations. This would seem to be, therefore, the more logical basis of comparison, and in his comments on the conclusions presented in the paper the writer will give actual figures derived from the downtown section of St. Louis. In passing, however, it might be pointed out that the investment costs of the 3000-kw. station and the two 1500-kw. stations used by the authors are $43 and $53 per kw. respectively. A comparison of a 2000-kw., two-unit station and two 1000-kw. stations for St. Louis resulted in investment costs of $38.25 per kw. for the former and $39.75 per kw. for the latter. These figures are based on the actual purchase price of equipment recently bought by the United Railways and estimated costs for land and buildings, these latter, however, being obtained from figures for land actually purchased for substation sites and buildings recently built for two automatic substations now in service. In explanation it might be pointed out that the cost of the control equipment for the two-unit station is, as might be expected, slightly higher than the cost at the two single-unit stations, due to the additional control devices necessary in a two-unit station. This difference is more than offset, however, by the increased cost of land and buildings for the single-unit stations, but as we have been able in St. Louis to secure inexpensive land (rear portions of lots, etc.) and erect simple and inexpensive buildings, these factors are not of great importance. The writer wishes to stress the point, however, that the maximum advantage of automatic stations can only be obtained where land and building costs are held to a minimum. Automatic equipment lends itself to simple and inexpensive types of buildings.

In the operating costs derived by the authors for 3000-kw. and 1500-kw. stations, the larger station is given a material advantage in efficiency. This point will be covered later, but it is evident that if the efficiencies were practically the same there would be little advantage from an economic standpoint in favor of the 3000-kw. station. What advantage remains would be more than offset by increased freedom from electrolysis and greater reliability, advantages which are brought out in the paper.

Commenting on paragraph (b) of the conclusions (page 376), the writer cannot agree that, "in cities . . . the economic advantages of the automatic substation are relatively small, because distribution cost is a correspondingly small part of total cost." As shown previously, distribution costs are a material item in the cost of supplying power to a railway and the automatic station undoubtedly has a large field in urban work. Further study and experience is necessary before the question of its relative value for interurban, as compared with urban service, can be definitely answered.

In paragraph (c) the authors conclude that in view of the lower efficiency which they say is to be expected with automatic stations, some plan of remote control will probably be found advisable, so that converters can be operated at or near their best efficiency. This conclusion evidently is based on the efficiency curves of 60-cycle converters which constitute a minor portion of the converters in use on railway systems. Efficiency curves of the 25-cycle converters differ from those of 60-cycle converters in two important respects. First, very little increase in efficiency is obtained as the size of the unit is increased above 1000 kw.; and second, the variation in efficiency from three-quarters to one and one-fourth load in the case of 25-cycle units is about ¼ of one per cent. These figures are based on the combined efficiency of converter and transformers. Manifestly, it is of comparatively little importance at what point the unit is operated, provided it is above three-quarters load. Even at half load the efficiency of a 25-cycle 1000-kw. converter and transformer is only ¾ of one per cent, less than its maximum. The curves on page 370 of the paper giving the efficiencies of 60-cycle units at various loads show that the efficiency of a 1000-kw. unit at 50 per cent is 2½ per cent rating less than its efficiency at full-load rating.

In St. Louis the five new automatic stations recently purchased are laid out to carry approximately 125 per cent of rating for the maximum half hour which would result in an average load of about two-thirds of rating. The relays will be set so that the stations will run practically continuously for sixteen to eighteen hours per day, the slight loss in station efficiency at the lighter loads being more than offset by the saving in distribution losses. The stations and feeders are so designed that if one station is out of service the overload on adjacent stations will not reach the danger point, nor will the distribution voltage be seriously affected. It should be remembered that such equipment is capable of 50 per cent overload for two hours and, furthermore, the stations being small and comparatively close together, prolonged overload at any one station is very unlikely.

In connection with the conclusion set forth in paragraph (d), namely, "in such cities as Cleveland, it is doubtful if the capacity of substations can be profitably reduced below 3000 kw., . . .," the writer cites the following: In St. Louis it was desired to reduce the load on a 12,000-kw. substation feeding principally the heart of the downtown section. It was decided to move two 2000-kw. interpole rotaries from their locations in existing stations into the downtown district fed by the 12,000-kw. station. Three alternatives for the use of this equipment presented themselves. First, a single 4000-kw. station manually operated; second, a single 4000-kw. station automatically operated, and third, two 2000-kw. stations automatically operated, spaced approximately 4500 ft. apart. Without going into detail, (the writer will be glad to furnish the detailed figures upon request) the following figures represent the annual costs, based on the investment necessary for *additional* equipment, and land, buildings, transmission cables, distribution cables, together with allowance for distribution losses: 4000-kw. station manually operated, $14,250; 4000-kw. station automatically operated, $13,800; 2-2000-kw. stations automatically operated, $13,000. In view of these figures, together with the greater freedom from electrolysis and increased reliability, it was decided to adopt the plan involving two 2000-kw. stations automatically controlled, and equipment has been purchased and land for these stations acquired. Each station is supplied by two transmission cables.

In view of the figures just given the writer feels that for cities similar to St. Louis, the 3000-kw. station is not the minimum size justifiable. Furthermore, if automatic stations of 2000 kw. can be justified in a congested downtown district, where the feeding distances are comparatively short, it seems evident that in districts outside of the downtown area, where conditions more nearly approach interurban conditions, the automatic station of smaller size, say 1000 kw., finds a useful field. It is not contended that in areas like the loop district of Chicago, where concentration of load is extremely heavy, that automatically controlled equipment will be found advisable.

The conclusion expressed in paragraph (e) that if possible, standard size of unit and standard control layout be used in all stations, is open to the objection that if units of one size are used

exclusively, the maximum distribution economics cannot be obtained. Division between various sizes, of course, should not be carried to too fine a point, but it would seem that for a city the size of St. Louis, 1000-kw. units would be best for general use, with 2000-kw. units for the downtown district and other points of heavy load concentration, and say 500-kw. units for use at outlying points and on interurban lines. Such a plan will not, it is believed, materially increase the necessary stock of spare parts, since many items of the control equipment are the same for various size units.

Relative to adopting a standard control layout, while this plan has material advantages, it also has certain commercial disadvantages and, furthermore, it should be borne in mind that we can expect to see changes of a more or less radical nature in automatic control equipment as the art develops.

M. J. Lowenberg: In the design of a distribution system, whether it is for a small railway system or a heavy electrification, it is necessary to determine the permissible voltage drop. Often, especially today when capital costs have to be kept down, irrespective of any economy that theory may show according to Kelvin's law, that value is the minimum value to operate the trains or cars.

A very simple law is that for the most economic layout the cross section at any point should be proportional to the square root of the current at that point.

I have found from computations checked by tests, that whether it is a single car or a long train, or a number of cars or a number of trains, that a very accurate method is to assume that this current at any point (to which the cross section is proportionate to its square root), is the maximum starting current of any single unit—(which in a street railway would be a car and in a subway would be a train)—plus the current due to average load uniformly distributed along the line.

In using Kelvin's law great care must be taken not to throw an undue burden upon the stockholders. Kelvin's law is subject to a tremendous variation, without changing the economy derived from theory. As a matter of fact, 35 per cent less copper than shown by Kelvin's law would in theory give approximately only 10 per cent increase in annual cost, and if you put the question to a banker he would tell you to leave out the 35 per cent copper.

Another point in the paper which is not entirely in agreement with practise is the variation of the size of cables. In most systems, especially large systems, there is more or less standardization—especially on underground work. There you must standardize on a certain sized cable, irrespective of what your theory shows. These things will often upset Kelvin's law, to which too much weight must not be given.

The extent of spare equipment, whether feeders, substations or rotaries, must be determined in co-operation with the transportation department; for then only can you determine the value of service and therefore the amount of relay equipment which has to be installed.

E. R. Shepard: The paper is of particular interest to me because of its possible bearing on the question of electrolysis. If, through, the use of semi-automatic or remotely controlled substations, the feeding capacity at any one point in a city system can economically be reduced to from 1500 to 3000 kw. we may find in such systems a final and satisfactory solution for this baffling problem. That such will be the case is by no means a foregone conclusion as the establishment of numerous substations throughout a city will create new positive conditions on the underground structures which in some soils may prove injurious.

The application of insulated negative feeders for the mitigation of electrolysis, while improving the general conditions, have in a number of instances created new positive areas with consequent damage to pipes and cables.

Where relatively few and large generating or supply stations are in use they are frequently located outside of the congested or highly developed sections of cities, and in such cases electrolysis conditions are often either endured or taken care of by local treatment. With the use of frequent automatic substations, some would usually be located in congested areas where the underground utilities are not only of great value but where the interruption of service or the failure of water pressure cannot be threatened.

The use of additional supply points for power distribution is, of course, in the right direction to eliminate electrolysis, and I am not unmindful of the great benefits which may be derived from carrying such a system to the economic limit. It is not evident, however, to what extent such a system will remove the cause of electrolysis and the railways may well assume that they will have this problem with them until direct current has been supplanted by some other form of motive power.

L. P. Crecelius and V. B. Phillips: Mr. Thelin has said "I do not agree with the authors of the paper in their statement that a 3000-kw. unit is the minimum size which can be economically installed in city service, as I feel that with single-unit substations and simplified type of automatic control equipment it is possible to economically install substations with as low as 1000-kw. capacity."

The authors agree with Mr. Thelin that some simplified form of control may justify the installation of substations of less than 3000 kw. capacity. To correct any wrong impression that may have been created as to the opinions expressed by the authors, it may be well to quote from conclusion (d) of the paper. "In such cities as Cleveland, it is doubtful if the capacity of substations can be profitably reduced below 3000 kw. with the *control equipment now available for full automatic control*, commencing at the incoming supply line and extending throughout the entire substation operation" * * * * * "If, therefore, any *substantial saving* in the total cost of power is to be had by the smaller sizes of substations, automatically controlled, it will be necessary to reduce substation losses by improving methods of control" * * * * "There are, of course, some distinct advantages to be had by installing small capacity substations of say less than 3000 kw. These are principally the mitigation of electrolysis, and under certain conditions an increased factor of safety."

It would appear that Mr. Bryan has not correctly interpreted the mathematical procedure and examples upon which the authors have based their conclusions, with which conclusions Mr. Bryan is not altogether in accord. Mr. Bryan refers to the tabulation given on the first page of the paper as being "used more or less throughout the paper." It should perhaps be pointed out that this tabulation was given simply for the purpose of illustrating in a general way the magnitude of the several elements which go to make up the total cost of distribution. These figures are not used or referred to again in the body of the paper.

Mr. Bryan has preferred to use 10 per cent in arriving at the carrying charges on copper. This is, of course, a matter of opinion. The authors arrived at 13 per cent by using an 8 per cent return on the investment, which percentage has been quite generally allowed throughout the country by the state public utility commissions; 2½ per cent for taxes, which is the tax rate in Cleveland and which in view of steadily increasing tax rates throughout the country is not believed to be excessive; and 2½ per cent for depreciation. It is true that depreciation on the copper itself is very slight, but it must be remembered that the rate applied to the cable in place must take account of the rather rapid depreciation of insulation and cost of stringing. It is believed that in a comparative study of this kind, depreciation of feeder insulators and fixtures need not be included for the reason that this investment is practically the same for different sizes of feeder. If these items be included the result will not be substantially affected.

With regard to the amounts used by Mr. Bryan for generating plant, transmission line, and substation investment, it may be

said that the unit values used will depend upon the basis of valuation. There is a wide difference of opinion among rate making bodies as to the weight that should be given to the high prices prevailing during the last few years, especially in appraising for rate making purposes such plants as were installed prior to 1915. On the basis of present day costs Mr. Bryan's figure of $258.00 per kw. is undoubtedly more nearly correct than the figure of $165.00 used by the authors. At the same time, the figure of $165.00 is quite consistent with the valuations used by a number of different public utility commissions in determining rates. The present tendency is toward the purchase of power from central stations by electric railway companies. On account of the diversity of load on these stations the investment properly allocable to a single consumer or class of consumers is substantially reduced. The demand charges for purchased power in the larger cities range from as low as $12.00 up to $27.00 per kw. of demand per year. The figures used on the first page for these carrying charges, viz: $23.00 per d-c. kw. of demand per year, including carrying charges on substation investment and taking due account of the substation losses, is believed to be reasonably consistent with the demand charges mentioned above, as well as consistent with the valuations on power plants and transmission lines accepted by many rate making bodies.

In the opinion of the authors, Mr. Bryan's discussion of the paper presents figures and observations of no little interest and value. Mr. Bryan touches upon a number of points that must certainly receive due consideration in any study of the problem of distribution.

Mr. Lowenberg's statement that "Kelvin's law is subject to tremendous variation without changing the economy derived from theory" is, in the main, true. In other words, the cost curve is fairly flat on either side of the point of maximum economy. It must, however, be borne in mind that the load on feeders in most progressive American cities is continually growing, for which reason it may prove wise to install more than the minimum copper as contemplated by Mr. Lowenberg. The application of Kelvin's law in cities gives substantially more copper than is necessary to satisfactorily operate cars. On the other hand, in the case of interurban lines on which distribution distances are necessarily much greater, Kelvin's law will call for little, if any, more copper than will generally be necessary to obtain satisfactory car operation. The authors certainly did not contemplate such strict application of the law of economy as to depart from that "more or less standardization" of cable sizes to which Mr. Lowenberg refers. Very few theoretical engineering laws of this sort can be precisely applied in practise. Kelvin's law gives the theoretically proper sizes of cable corresponding to maximum economy in distribution. In other words, it affords a standard of performance to be approached as nearly as may be practicable, but which of necessity must be modified in many cases by reason of various practical considerations. Mr. Lowenberg points out that it may be difficult or unwise to invest more than the minimum of capital necessary to conduct transportation. This is, of course, a matter of financial policy rather than engineering computation. It is one of those practical limiting conditions referred to above.

Mr. Roper and Mr. Shepard have referred to the mitigation of the electrolysis difficulty by the installation of a larger number of distributing points. In their analysis, the authors have not specifically considered the savings that may result from the use of a large number of small substations in cutting down electrolysis damage claims or in reducing the necessity and cost of various mitigative measures. This omission must not be interpreted as indicating any lack of appreciation on the part of the authors as to the importance of this phase of the subject. It is scarcely possible, however, in an analysis of this kind to introduce the factor of electrolysis because of the tremendous variation in local conditions governing corrosion from stray currents. The examples worked out in the paper for a typical mile of track show a rather small variation in total cost for the several different substation sizes. It may frequently happen that a serious electrolysis situation will justify the use of smaller substations than would be dictated by the other purely economic factors.

In conclusion, the authors wish to say that their primary purpose in preparing this paper has been to set up a procedure for the study of the distribution problem in a comprehensive way. The various examples which have been worked out have been intended more for the purpose of illustrating the application of the principles involved than for the purpose of reaching any very definite conclusions. Railway substation practice is still in process of development. There is a great variation in the many factors which go to determine the proper solution of the distribution problem in different localities. As previously pointed out, questions of financial and operating policy, including the importance attached to continuity of service and the resultant provisions that may be necessary to reduce the possibility of shut down, must be given consideration along with the theoretical economic factors. At the same time, it is believed that the starting point at least is a purely economic analysis along such lines as have been suggested in this paper.

Light Without Glare

BY WARD HARRISON

Engineer, National Lamp Works, Cleveland, Ohio.

The object of this paper is to show what factors must be controlled in order to produce satisfactory illumination without glare.

The relative importance of brightness of light sources, their candle power, position in the field of view and contrast with the background are discussed. The paper includes tables from the Illuminating Engineering Society Code of Industrial Lighting in which for the first time various light sources, both natural and artificial are classified from the standpoint of glare. The use of these tables is explained and illustrative examples are given.

ARTIFICIAL lighting is an old art, so old in fact, that one's mental attitude toward it is influenced largely by tradition if not by heredity. How many there are who still judge the desirability of a lighting unit simply by its whiteness and dazzling power, criteria which served well in the days when vegetable oil lamps and tallow candles were the only light sources available and when perfect combustion, as evidenced by a brilliant white flame, was a phenomenon altogether too rare. There are many also in whose minds the thought of excessive heat is associated as the inseparable accompaniment of a high level of artificial illumination; they forget that the 200-candle power lamp of the present generates no more thermal units than did a single candle in the days of our forefathers. And as to the question of expense in lighting, it may be added that the cost per hour for the 200-candle power lamp is today only about equal to that of the aforementioned candle. In this connection, it is not without interest to take cognizance of the apparent anomaly, that, for some locations artificial light has actually become cheaper than natural light. For example, a number of our larger public buildings and even our art galleries have found it much more satisfactory and in the end less expensive to provide for the use of artificial light exclusively rather than to assume the high initial cost and the up-keep expense of large areas of exposed skylight.

It would be interesting also, to turn aside and see how modern developments have made it possible for our great industries to have daylight levels of illumination, and daylight quality of illumination, available throughout the twenty-four hours and ordinarily at the very moderate expenditure of from 1 per cent to 2 per cent of their labor cost. Just what this means, just what the difference is between 1 to 2 foot-candles, the old levels of artificial illumination and 10 to 20 foot-candles, the daylight level of interior lighting must be seen to be appreciated. One who has tested out for himself his acuity of vision and the difference in his speed of perception under these different levels of illumination has no difficulty in understanding why production invariably falls off with fading daylight in the great majority of our older and inadequately lighted industrial establishments; and how even a night shift in these same plants can be made profitable if proper lighting is supplied.

Presented at the Annual Convention of the A. I. E. E., Niagara Falls, Ontario, June 26-30, 1922.

On the other hand, almost every one of the invaluable developments of modern applied science, such for example as the high-tension transmission of electric power, or the gasoline motor car, has brought its own particular hazards and a capacity for serious abuse. High power artificial light sources, or for that matter, modern prism glasses for the control of daylight, are no exceptions to this rule. Unfortunately, it is true that the potentialities of the newer lamps as aids to progress are only one-half utilized or appreciated and, by the same token, their flagrant abuses have for the most part been allowed to run along unchallenged. A typical machinist substitutes for his old stubby candle an unshielded incandescent lamp of 100 times its power and 1000 times its brilliancy; remarks, per-

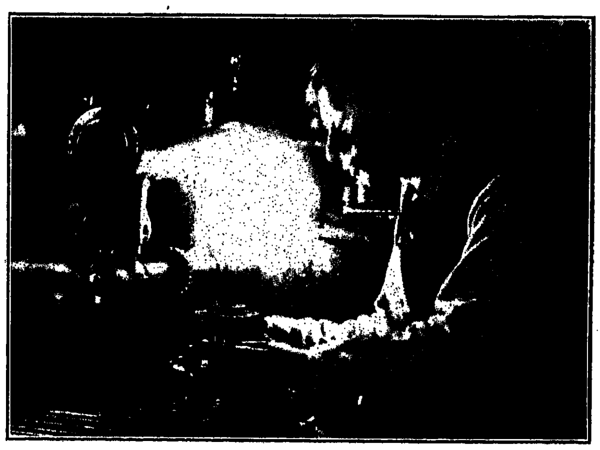

FIG. 1—GLARING LIGHT FROM UNSHADED LOCAL LAMP WHICH IS A MENACE TO SAFETY AND TO VISION

chance, that it is such a fine light that it almost blinds him; and calmly goes on with his work for as many days as his eyes—or the law—will allow him.

Now it is obvious that bare 100-watt lamps on drop cords will cause serious glare, that raising the lamp a foot or two above the direct line of vision, or perhaps enclosing it in a white diffusing globe will mitigate the harmful effect, but just what is the quantitative value of each of these factors, and just how far one must go to obtain reasonably satisfactory conditions for vision, are subjects regarding which there is still much lack of real information and of uniformity of opinion.

It is generally accepted that for a fixed position of light source the degree of glare experienced is a function of (a) brightness of the source—candle power per unit area; (b) total flux of light directed toward the eye from

the source—candle power in the direction of the eye; and (c) contrast in brightness between the light source and its background. Authorities differ greatly as to the relative weights to be assigned to the three quantities and formerly (a) and (c) were particularly stressed. More recent investigations have, however, pointed toward the total flux of light which reaches the eye from a light source as being the most important single factor in the production of glare. The trend of present

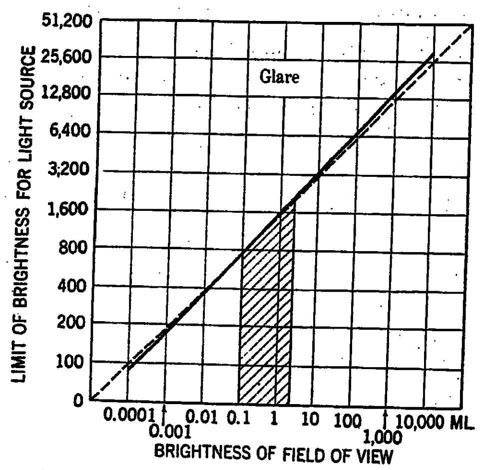

Fig. 2—Nutting's Data on Limits of Brightness

thought on this subject may be summarized in the form of four principal propositions as follows.

I. Dr. Nutting[1] found (see Fig. 2) that with a fixed area of light source at a fixed distance from the observer, increasing the brightness of the surroundings tenfold only permitted of approximately doubling the

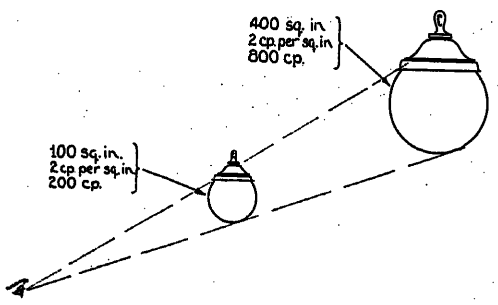

Fig. 3—Doubling the Distance between the Eye and Light Source Permits of Increasing the Candle Power Four Times

candle power (and brightness) of the source if no increased sensation of glare were to be experienced. In other words, the final contrast between the source and its background must be reduced to one fifth of its former value if it is desired to double the candle power of the source.

II. The results of other investigations[2] suggest that one may approximately double the candle power of a source having a fixed location if the area of that source is increased 10 times, which, of course, involves decreasing its brightness to one-fifth of the former value. It will be observed that in this case as in the preceding one, the resulting contrast between the source and its background is reduced to one-fifth in order to double the candle power of the source, without increasing the glare effect.

III. It is obvious from a consideration of Fig. 3, that if the brightness of the light source and the brightness of its background are both held constant and the distance between the eye and the source is doubled it will be permissible to quadruple the candle power of the source, since the brightness of the image on the retina will be the same in both cases and the diameter of the source is doubled to hold the area of the retinal image constant.

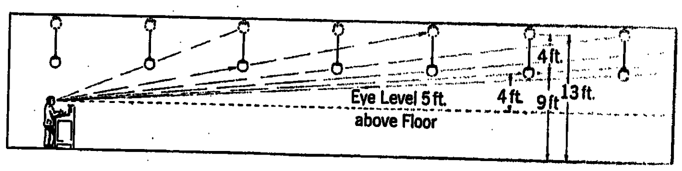

Fig. 4—Raising the Mounting Height of the Light Sources Well Above the Eye Level is the Greatest Single Factor in the Reduction of Glare

IV. If after doubling the distance between the eye and the light source and at the same time increasing the candle power and area four times to preserve the glare balance it is decided to cut in two the candle power of the source in this new position, it is then permitted by (II) to cut the area of the source to one-tenth and by cutting the candle power again in half the area may again be reduced to one-tenth so that with the candle power of the source the same as when in the first position close to the eye, the area of the source need only be 1/25 of that required by the first position. It may be said then that doubling the distance between the eye and a light source permits of dividing its area (and increasing its brightness) by 25.

These four illustrations should serve to make clear the major importance of candle power and distance from the eye, in a word "flux entering the eye", rather than the brightness or contrast as the dominant factors in glare. In truth, small bare incandescent lamps are under some circumstances really less obnoxious than frosted lamps of say five times the candle power used in the same location.

Formulas, in which these various relations are expressed algebraically are included in the Appendix. It should be borne in mind that the avoidance of glare is

1. P. G. Nutting, *Transactions I. E. S.*, Vol. XI p. 939.

Dr. Nutting's data show that if the candlepower of the source and the brightness of the background are both raised indefinitely, in this logarithmic ratio, a point is finally reached at which the brightness of the background is as great as that of the source. This point, which might be termed the glare limit, represents the brightest surface on which the eye can focus without immediate discomfort no matter what the surroundings. This brightness is approximately 50,000 millilamberts or about five times the brilliancy of white cardboard exposed to full sunlight.

2. Ward Harrison, *Transactions I. E. S.*, Vol XV p. 34.

still far from being an exact science and the numerical values in these formulas may require very material revision as a result of later investigations.

As a specific application of these relations, assuming for the time their correctness, take the case of a lighting installation in a large office devoted to bookkeeping in which the lamps are suspended in glass diffusing globes four feet above the eye level (about nine feet above the floor) and in which the contrast between the units and the walls which form their background is found to be about 25 times too great for comfort. If no change is to be made in the size of the lamps the trouble can be remedied in any one of three ways.

(a) The brightness of the globes can be reduced to 1/25th of the former value by increasing the diameter of the globes five times.

(b) The brightness of the background can be increased 25 times by painting it a lighter tone and directing more flux toward it.

(c) In accordance with IV the units can be raised four ft. or to a height of eight ft. above the eye level (thirteen ft. above the floor—see Fig. 4).

Where the head room is sufficient this latter method certainly presents the easiest solution of the problem. In fact, the importance of locating interior lighting units well up toward the ceiling cannot be over-

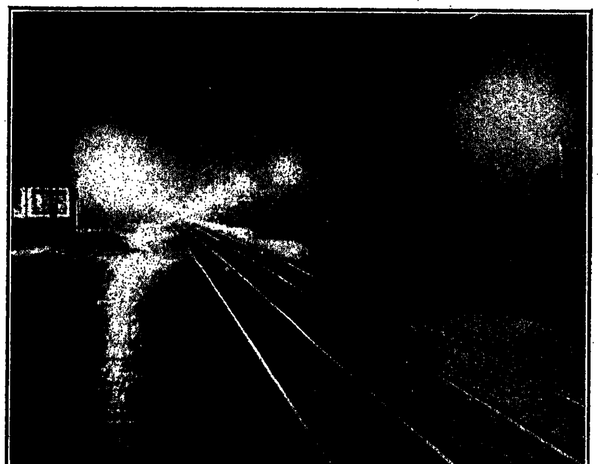

FIG. 5—SPECULAR REFLECTION OR GLINT MAY SOMETIMES PROVE AN AID TO VISION ESPECIALLY IN STREET LIGHTING

emphasized. In street lighting, where, in nearly all cases the lamps are seen against an almost perfectly black background the need for high mounting is even more urgent.

The first comprehensive tabulation in which various light sources, both natural and artificial, are classified as to glare and in which proportionate weight has been given to the location of the source in the field of view, is included in the Illuminating Engineering Society's revised Code of Lighting. This Code was prepared by the Society to make available authoritative information for legislative bodies and others who are interested in regulations covering lighting and it also serves as a guide for factory owners and operators in improving the lighting conditions in their own plants. The Code is now an American Standard indorsed by the A. I. E. E. and many other national organizations. Tables III, IV, V and VI and the appended matter are reprinted from the Code.

TABLE III.

CLASSIFICATION OF LIGHT SOURCES FROM THE STANDPOINT OF GLARE

Grade I indicates sources of maximum softness.
Grade X indicates sources of maximum harshness.

Maximum Visible Brightness	Total Candle Power in Direction of Eye				
(Apparent candles per sq. in.)	Less than 20	20 to 50	50 to 150	150 to 500	500 to 2000
	Grade	Grade	Grade	Grade	Grade
Less than 2	I	I	II	II	III
2 to 5	II	II	III	IV	V
5 to 20	II	III	IV	VI	VII
20 to 100	IV	V	VI	VII	VIII
100 to 1000	V	VI	VII	VIII	IX
1000 and up	VI	VII	VIII	IX	X

In Table III, Light Sources are classified from the standpoint of glare, taking into account both the maximum visible brightness and the candle power in the direction of the eye. However, it is not con-

i. e., their horizontal distance from the observer, and their height above the floor. To be glaring, a light source must either be located in a position close to the eye or, if at a distance, it must lie within a small angle from the ordinary line of sight. Light sources in positions denoted by the first letters of the alphabet in Table V are close to the eye or close to the line of vision, and are most likely to be the cause of discomfort. Light sources in positions *E*, *F* and *G* are farther from the eye or without the direct line of vision and are less likely to cause glare.

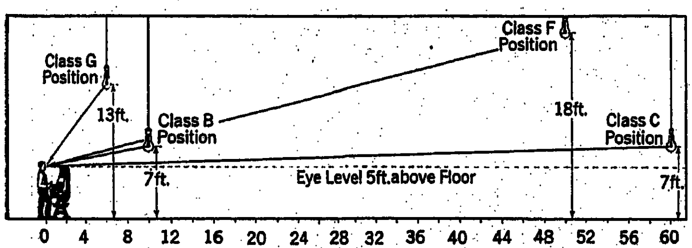

FIG. 6—TYPICAL POSITION GIVEN IN THE CHART OF THE FIELD OF VIEW, SEE TABLE V.

Table VI of the Code combines Tables IV and V and shows the limiting grades of light sources permissible for various types of work, when the light sources are located in the different positions in the field of view.

In addition Table VI-A which is not contained in the Code has been computed. This table shows the Grades which are recommended for various conditions. It should be used in preference to Table VI in planning new installations and in all other cases, except when the question is simply one of whether the lighting system is acceptable from the legal standpoint.

These tables may appear formidable, however, they are in reality very simple to use as may best be demonstrated by trying them out in one or two examples. For instance, consider the lighting in the machine shop of an industrial plant which is being inspected to find whether it comes within the requirements of the lighting code.

Because of the very low ceiling the lighting system which had been recommended by a competent engineer for this shop consisted of *R L M* dome reflectors with 150-watt bowl-enameled lamps mounted 8½ ft. above the floor and spaced 10 ft. apart. The owner of the plant, however, decided that he would save himself a little trouble by using clear lamps instead. Otherwise the lighting was installed as recommended. A number of machinists work in this room. Their work does not keep them in one position for a long period of time.

The inspector found that the most troublesome light source from the point of view of any one workman was the second[3] unit directly in front of his machine, at a horizontal distance of ten to twelve feet. Referring to Table V, the inspector found that for units located at a height of eight to nine feet and a horizontal distance of ten to twelve feet their position in the field of view is classified as *D*. By referring to Table IV, he also found that a dome reflector and 150-watt clear lamp the filament of which is visible, is classed in Grade IX, and again, that in Table VI under the column headed "Ordinary Manufacturing Operations" in the fourth line, opposite *D*, the harshest grade of light source which it is permissible to use is given as Grade VII. The lighting system in this plant, therefore, did not meet the Code requirements as far as provision against glare was concerned and the inspector's position was that the owner of the shop must change the lighting and he suggested that bowl-enameled lamps be installed as originally recommended. According to Table IV dome reflectors with 150-watt bowl-enameled lamps fall in Grade V which is well within the Code requirements and which, incidentally, is the grade of source which Table VI-A mentions as representing good practise for this class of service. It is of interest to note that one large manufacturing concern which recently rehabilitated its lighting found in the course of experiment that not only did the substitution of bowl-enameled lamps for clear lamps provide greatly increased comfort for the employes but it also resulted in a measurable increase in production in the departments where the change was made.

The following explanatory notes for the guidance of inspectors and industrial plant operators are taken verbatim from the I. E. S. Code.

"From Table IV the majority of bare incandescent lamps are seen to have a relatively poor rating; that is, most of them fall in Grades VII to IX, and it is evident from Table VI that Grades VII to IX are never to be permitted in work rooms in positions *A*, *B* or *C*. That is, the use of bare incandescent lamps is prohibited in working areas except when they are located at considerable heights above the floor or when they are so placed as to be out of the field of vision. At the present time it will be found necessary from a practicable standpoint to delay the strict enforcement of this provision in a very few instances, particularly in the case of extension cord lamps used in temporary work, such as in setting up machinery and in repairing automobiles, etc.

3. With a flat reflector the third or fourth unit ahead might have caused still greater discomfort on account of its closer proximity to the line of vision but with an R. L. M dome at a height of eight feet to nine feet the lamp filament in these more distant units is cut off from view by the skirt of the reflector.

"It will be noted from Table IV that the sources of natural light, side and ceiling windows, usually fall in Grade IV. This means (see Table VI) that no mandatory rules are established as to the use of shades, awnings, etc., except in those cases where the sky is visible through portions of the sash in position *A*, that is, less than 6.5 ft. above the floor, or where the sun itself comes within the range of vision.

FIG. 7—AN AMPLE SUPPLY OF SOFT WELL DIFFUSED LIGHT AND PARTICULARLY FREEDOM FROM SHADOWS IS REQUIRED FOR DRAFTING ROOMS

"However, Grade II is the limiting value for light sources less than 6.5 ft. high, in offices, and other locations where the workers are seated facing in one direction for considerable periods of time. Hence, in these cases, to comply with the Table, the work must be so arranged that the employees are not required to face windows where the sky is visible through the lower sash; that is, less than 6.5 ft. above the floor.

Prism glass when so located as to catch the sun's rays ordinarily has a very much poorer rating than clear glass; hence, where it is used the installation of window shades or curtains should ordinarily be required.

"*Glare by Reflection.* Another way in which glare is produced is by the reflection of light from polished surfaces in the field of vision. The difficulty experienced in protecting the eyes from this kind of glare is sometimes very great. The brightness of the image on the working surface is, of course, proportional to the brightness of the light source above it, and hence one way in which to minimize this effect is to diffuse the downward light; that is, to use a bowl-frosted, or bowl-enameled lamp or an enclosing fixture, or to employ semi-indirect or totally indirect lighting fixtures. In some cases the light source can be so located that its reflection is directed away from, rather than towards, the eyes of the workers. The avoidance of highly polished surfaces in the line of vision is another good way to minimize reflected glare.

"There are some instances, on the other hand, where sharp shadows and specular reflection from the materials worked upon actually assist vision. For example in sewing on dark goods the thread is much more easily distinguished when illumination is secured from a concentrated light source, such as a brilliant lamp filament, which casts sharp shadows and gives rise to a distinct glint from each thread. However, in these cases the light source must be particularly well shielded from the eyes of the worker."

Lest in his efforts to minimize glare one should arrive at the conclusion that the best way of all to accomplish this purpose is to extinguish the lamp, the following quotations from the closing paragraphs of the Code are also included.

ADVANTAGES OF GOOD ILLUMINATION

"While the advisability of good natural and artificial illumination is so evident that a list of its effects may seem commonplace, these effects are of such importance in their relation to factory management that they are worthy of careful attention. These effects of good illumination, both natural and artificial, and of bright and cheerful interior surroundings, include the following:

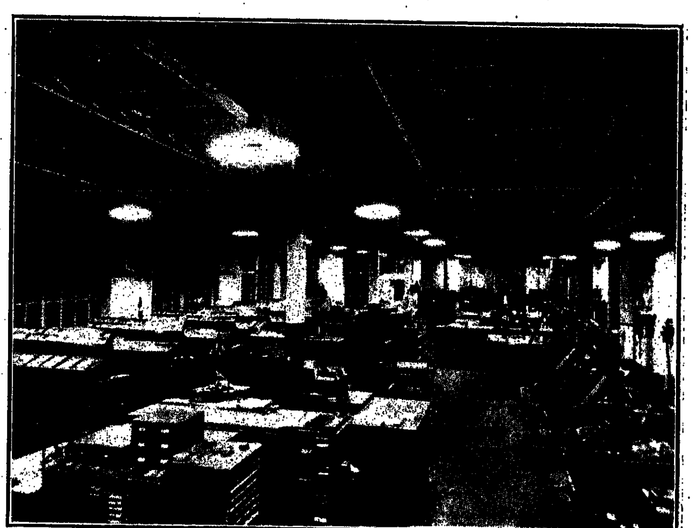

FIG. 8—AMPLE ILLUMINATION WITHOUT GLARE

"1. Reduction of accidents.
"2. Greater accuracy in workmanship, resulting in improved quality of goods.
"3. Increased production for the same labor cost.
"4. Less eye strain.
"5. Greater contentment of the workmen.
"6. More order and neatness in the plant.
"7. Supervision of the men made easier.

"While it is difficult to place a definite money value on the savings effected in increased production and improved quality, by good illumination, it by no means follows that such savings are insignificant or unsubstantial. The factory owner who ignores them neglects his own interests. Other items in the foregoing list, even more difficult to value definitely, are none the less real; taken together, they constitute a power-

ful argument in favor of the best available illumination."

Appendix

Let a_1, a_2 represent area of light source
b_1, b_2 represent brightness of background
c_1, c_2 represent candle power of source
d_1, d_2 represent distance from source to eye

I. Where the area of the source and its distance from the eye are held constant and the candle power of the source is varied then to maintain equality as to glare

$$\frac{b_2}{b_1} = \left(\frac{c_2}{c_1}\right)^{\frac{1}{\log 2}} = \left(\frac{c_2}{c_1}\right)^{3.3}$$

II. Where the brightness of the background and the distance from the eye to the source are held constant and the candlepower of the source is varied then

$$\frac{a_2}{a_1} = \left(\frac{c_2}{c_1}\right)^{\frac{1}{\log 2}} = \left(\frac{c_2}{c_1}\right)^{3.3}$$

III. Where the brightness of the source candle power per unit of area and the brightness of the background are held constant and the candle power of the source is varied then

$$\frac{d_2}{d_1} = \left(\frac{c_2}{c_1}\right)^{½} = \left(\frac{c_2}{c_1}\right)^{0.5}$$

IV. Where the candle power of the source and the brightness of the background are held constant, and the area of the source is varied then

$$\frac{d_2}{d_1} = \left(\frac{a_1}{a_2}\right)^{\frac{\log \sqrt{2}}{\log 5}} = \left(\frac{a_1}{a_2}\right)^{0.216}$$

V. Where the brightness of the background and the area of the source are held constant and the candlepower of the source is varied, then

$$\frac{d_2}{d_1} = \left(\frac{c_2}{c_1}\right)^{\frac{1}{2-2\log 2}} = \left(\frac{c_2}{c_1}\right)^{0.71}$$

Discussion

F. C. Caldwell: The lack of understanding on the part of the public of the whole problem of lighting was well brought out by Mr. Harrison's paper. One point needs a little more emphasis and that is the erroneous idea that glare is solely a function of brightness. Mr. Harrison has clearly demonstrated that the glare produced by excessive quantity of light is more serious than that produced by too great brightness. This is just one example of the general misapprehension of these simple laws on the part of even intelligent people.

H. Calvert: There is one statement, made in the first paragraph which may be correct, but does not appear to be so. I refer to the statement:—"they forget that the 200 candle power lamp of the present generates no more thermal units than did a single candle in the days of our forefathers." It would be interesting to know how this conclusion was reached.

G. H. Stickney: Glare in lighting represents an undesirable effect, which is readily recognized, but not so easily defined. In a general way there is more or less of an agreement as to what conditions of lighting constitute glare, but to express systematically, the relative importance of brilliancy, contrast, flux, position etc. as contributing causes, has so far baffled the illuminating engineer.

He recognizes that there are degrees of glare, that the glare encountered in one place is worse than that met in another. It, therefore, follows that there should be some way of measuring glare.

A glareometer which would give a reasonable measure, would be a great boon to the lighting art. It would not only facilitate research, but also would assist greatly in the specification of good lighting, the writing of codes, and the inspection of any individual lighting installation.

A number of engineers have given quite a bit of study to this problem, and have made brilliancy meters, contrast meters and pupil meters, but none of these, so far as known to the writer, has proved sufficiently comprehensive or practically applicable to various conditions. While it is still to be hoped that a suitable instrument will be forthcoming, the necessity of the art is such that, some other method, of at least classifying conditions in terms of the relative degree of glare, is required. This method, described by the author, seems to present the most practical scheme that has yet been suggested.

The scheme is really comparatively simple. From observation and experience, the various ordinary illuminants are graded from I to X with regard to their glare reducing powers. Then with a similar symbol, the permissible degree of various operations are tabulated, with reference to the position of the illuminant in relation to the eyes of the subject workman. This provides a means of deciding that a selected illuminant does not exceed the limits.

Of course, this is empirical and perhaps arbitrary, but at least it is fairly definite. It appears to be reasonable and in line with experience. In case later experience should show that certain changes in classification should be made, it would seem practicable to make such changes. But in the interest of practical utility, the author's classification should be adhered to for the present. Having been incorporated in the Illuminating Engineering Society's Industrial Lighting Code, now an American Engineering Standard, the glare classification seems to be ready for useful service.

On the other hand, it is to be hoped that research, which may lead to an absolute instrument or method, may be continued, neither interfering with the other until a real improvement is brought out.

Ward Harrison: Mr. Calvert asks about the relative amount of heat generated by a candle and an incandescent lamp of 200 times its intensity. The comparison is about as follows:

An ordinary paraffin candle 13/16 inches in diameter burns down at the rate of 1¼ in. or a little less than 0.025 pounds per hour. The generally accepted B. t. u. value for hydrocarbons such as paraffin is from 18,000 to 22,000 B. t. u. per pound; 20,000 × 0.025 equals 500 B. t. u., the approximate heat units liberated by a candle in one hour.

A 150-watt Mazda lamp generates 2100 lumens or approximately 200 horizontal candle power. The heat equivalent of one kw-hr. is 3410 B. t u., hence, the 150-watt lamp liberates 515 B. t. u. per hour or approximately the same amount as the candle. As a matter of fact, the ordinary paraffin candle gives about 10 per cent less light than the standard candle used in photometry, and furthermore, the art of candle making has improved considerably during the past 100 years.

Mr. Stickney emphasizes the desirability of a glareometer. Such an instrument is certainly much to be desired but it seems as if its mechanism must be possessed of an almost human brain in order to integrate brightness, flux, location in the field of view, etc. in the same way that we do.

Philadelphia-Pittsburgh Section of The New York-Chicago Cable

BY JAMES J. PILLIOD
Member, A. I. E. E.
American Telephone & Telegraph Company, New York, N. Y.

Engineering and construction features involved in a complete telephone cable system over 300 miles in length and connecting Philadelphia and Pittsburgh, Pa. are described in the following paper. This cable is designed to operate as an extension of the Boston-Washington underground cable system with which it connects at Philadelphia. It is also designed for operation in connection with the Pittsburgh-Chicago cable now under construction, and other cable projects included in a comprehensive fundamental plan.

Beginning with the fundamental factor of public requirements for communication service between cities separated by various distances, there are next considered the methods available to provide this service. Small-gage, quadded, aerial cable, which was decided upon for use in this section after careful economic studies, is described in a general way and the important advantages of the application of loading and telephone repeaters are outlined. The use, in connection with this cable, of the recently developed metallic telegraph system for cables is referred to and some facts are given regarding power plants, test boards and buildings. A few of the many possible combinations of cable and equipment facilities into complete telephone circuits, which will furnish the service required as economically as now possible, are illustrated.

The necessity of complete coordination of the many factors involved in a project of this kind is emphasized.

Introduction

The placing in service in the latter part of 1921 of the final section of a continuous telephone cable over 300 miles in length between Philadelphia and Pittsburgh marked a new point of achievement in the steady development and construction of facilities designed to render to the public the best possible long-distance telephone service. Furthermore, this cable forms an important part of a comprehensive plan of long-distance cable construction throughout that section of the United States lying in general east of the Mississippi River and north of the Ohio and Potomac Rivers.

In the discussion of a project of this kind which involves many new practises and the expenditure of several millions of dollars and which, with related work already completed, forms the groundwork for large expenditures in the future, it is usual to inquire first into the underlying reasons for carrying out the project and then into the methods adopted. In the following discussion an endeavor will therefore be made to furnish some information on these two items in their relation to the Philadelphia-Pittsburgh cable, although, as will be obvious, the many different points can be covered in only the most general way in the space available.

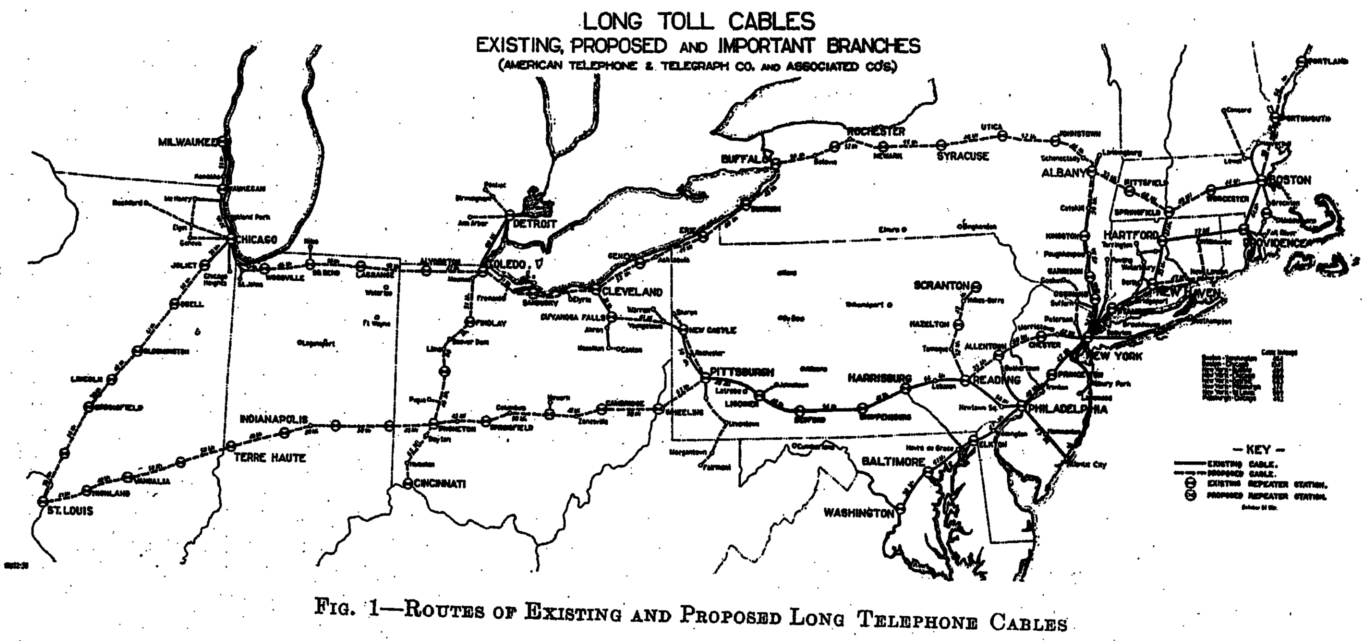

Fig. 1—Routes of Existing and Proposed Long Telephone Cables

However, before going ahead with the discussion, I would like to point out that this project is not unlike many others in that, as a whole and in the component parts, there have been required, first, the careful consideration and decisions of the executives, then the underlying work of many scientists, inventors and engineers, then the skilled work of the manufacturers and construction forces, and finally the maintenance and operation by trained people who are responsible for the

Presented at a meeting of the Philadelphia Section of the A. I. E. E., January 9, 1922, and at the Annual Convention of the A. I. E. E., Niagara Falls, Ont., June 26-30, 1922.

continuous service so vitally necessary to the industrial and social structure of the country. The point to be emphasized here is that the coordination of all of these factors and the close cooperation of all of the many hundreds of people concerned are the important things.

General Cable Plans and Routes

Fig. 1 is an outline map of a section of the United States and shows the routes of existing and proposed long telephone cables of the Bell system. It will be noted that the present and proposed routes follow in a general way the routes of trunk-line railroads. This general section contains more than 50 per cent of the entire population of the United States but less than 15 per cent of the area, and the industrial and telephone development is, of course, very great. Furthermore, the nearby surrounding states, supplying as they do

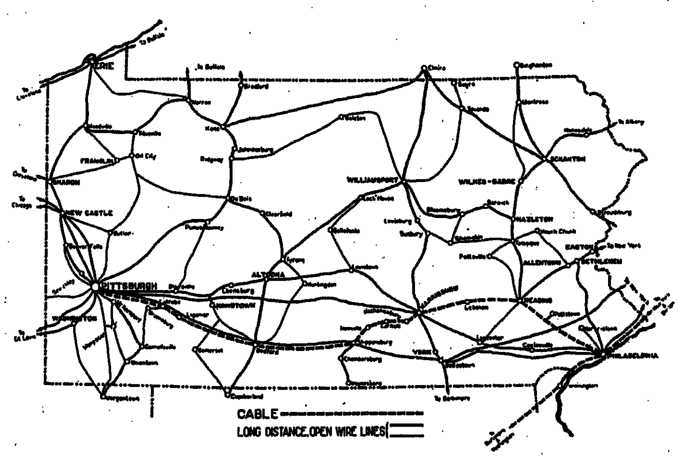

Fig. 2—Outline Map of Pennsylvania, Showing Aerial Line and Cable Routes

large quantities of food products and raw materials, are commercially related to this section in a very peculiar way and this fact greatly influences the long-distance telephone development along the particular cable routes indicated. The routes through the State of Pennsylvania and the offices at Philadelphia and Pittsburgh, which are the terminals of the cable that is more particularly the subject of this discussion, occupy strategic positions in this system.

Circuits of the American Telephone and Telegraph Company and the Bell Telephone Company of Pennsylvania are carried over these routes and this cable was jointly planned and installed by these companies.

Fig. 2 is an outline map of the State of Pennsylvania and shows the situation in this section a little more in detail. On this map are shown some of the larger cities and routes of the longer and more important toll and long-distance telephone lines. As indicated, these lines are mainly of the familiar aerial wire type which has been generally used in the past for this purpose and which is today the most efficient and economical type of construction for many cases. In the general section between Philadelphia and Pittsburgh the requirements for circuits are very heavy and in addition, as is well-known, the topography of the country is such that the through routes which can economically be used for pole lines are limited. At present, these few

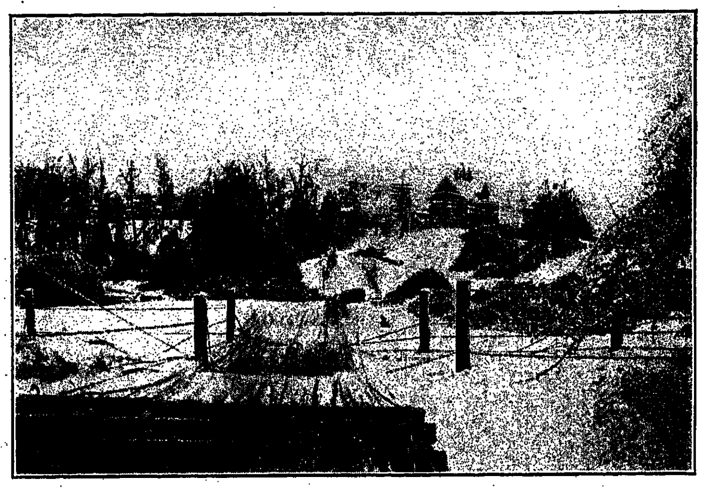

Fig. 3—Damage to Section of New York-Boston Main Line Near Worcester, Mass.
Storm of November 28, 1921.

routes are fully occupied by the pole lines of the various utilities and included in these lines are three fully loaded telephone trunk lines. Another item of importance in the consideration of aerial wire construction is the very severe damage frequently experienced in many sections of the country on heavy aerial wire lines from ice and wind storms. Even lines built

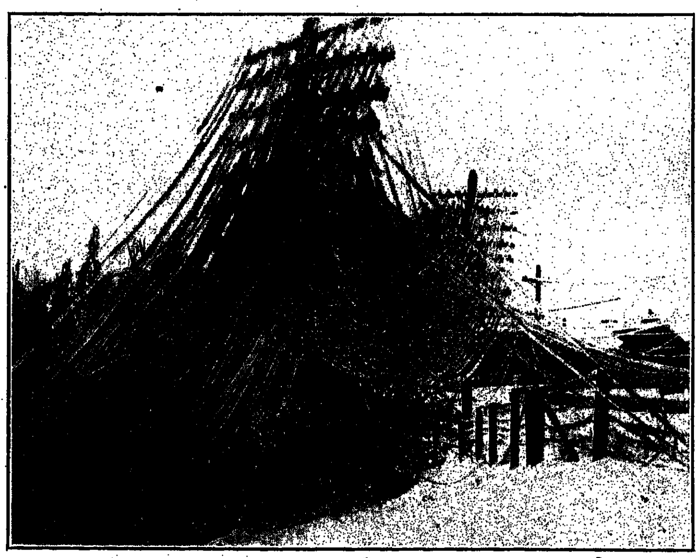

Fig. 4—Section of New York Boston Main Line Showing Wires Heavily Loaded With Ice
November 28, 1921.

with exceptional strength fail in these storms and the interruptions to service are serious matters to the users as well as to the telephone companies. The restoration costs under the conditions that naturally exist at such times are abnormally high.

Figs. 3 and 4 show the effects at one point of the ice and wind storm in New England on November 28, 1921, and are proof that this problem is real. This particular spot is near Worcester, Mass., and the line is a section of one of the principal aerial wire routes between New York and Boston. In this storm, many thousands of poles were broken and even where a few poles remained standing due to specially strong construction, the load of ice combined with the wind

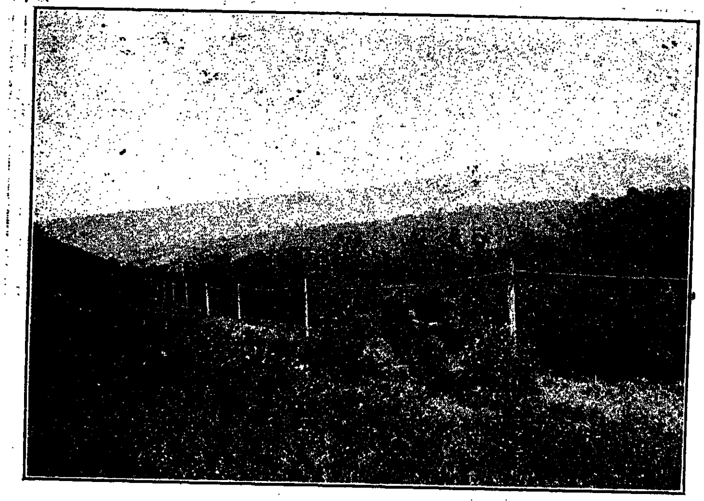

Fig. 5—General View of Pole Line Carrying Aerial Cable

was too great for the wires to withstand. There is therefore a practical limit to the number of wires that can be safely and economically carried on a pole line.

Where the practicable routes for pole lines are limited, where the existing pole lines are fully loaded, and where estimated future circuit requirements are of considerable magnitude, it is obvious that different methods of providing facilities, if available, must sooner or later be given serious consideration. The conditions between Philadelphia and Pittsburgh and in general along all of the cable routes shown on Fig. 1 are now, or are expected within a few years to be, such as to make the use of some type of construction other than aerial wire desirable for most of the circuits.

After careful studies of the circuit requirements for future periods and of the methods available for providing long-distance telephone facilities, which in general are aerial wire and cable, it has been decided that for relief in these sections the cable method will give the best and most economical results. Long underground cables, as is well-known, have been in operation for many years between Boston, New York, Philadelphia, Baltimore and Washington, Chicago and Milwaukee and in other sections. However, the type of cable and associated apparatus which is now being used in the development of the more comprehensive plan is quite different from that originally used between Boston and Washington and in the other sections, particularly in the use of copper conductors of a smaller gage combined with improved loading coils, the vacuum tube telephone repeater and other methods and apparatus which are the result of recent developments. Lead-covered aerial cable supported on wooden pole lines is to be used in general on all of the routes except in the two sections just mentioned and through cities or where special conditions exist for short distances. The possibility of now using conductors of No. 16 and No. 19 A. W. G. instead of conductors up to No. 10 A. W. G. as in the older cables, has contributed to make aerial construction rather than underground conduit the more economical in many sections, as one cable will provide for a much greater number of circuits and consequently fewer cables will be required.

Line Construction

The general type of aerial construction which was used for over 250 miles of the total distance of 302 miles from Philadelphia to Pittsburgh may be seen from Figs. 5 and 6 which illustrate the poles, steel suspension strand, metal supporting rings and the cable. The poles are 25-foot untreated chestnut spaced 100 feet apart and designed to carry additional cables in the future. While the poles are new and carry only one cable they have a factor of safety of about 9 under the most severe storm conditions expected, but this will of course be reduced as other cables are placed and will gradually be decreased on account of decay at the ground line until it becomes necessary to start replacing the poles. Many of these poles were grown near the locations where they now stand. In other sections, it is planned to use butt-treated chestnut or cedar poles, or creosoted pine poles where these prove to be the more economical.

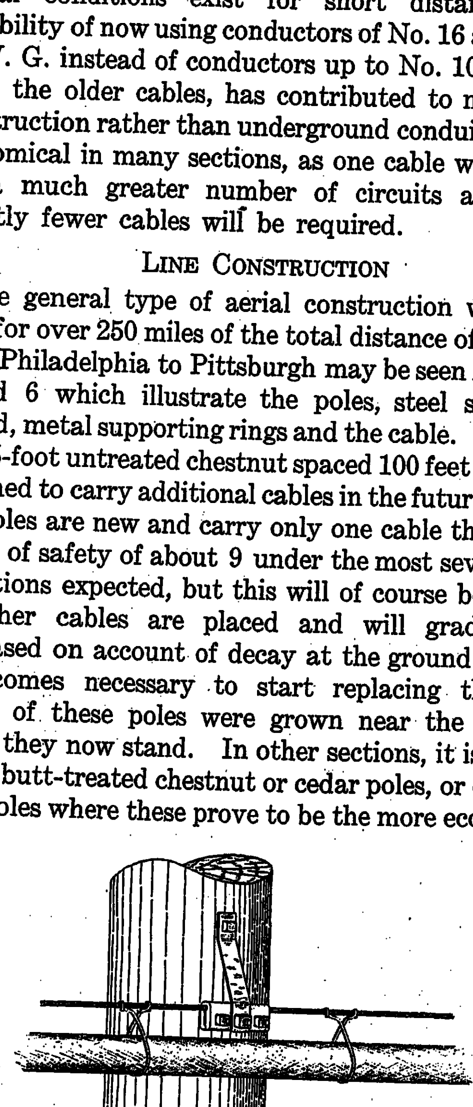

Fig. 6—Method of Supporting Aerial Cable and Messenger

The galvanized steel suspension strand has a breaking strength of about 16,000 pounds and the actual tension under normal conditions is about 7000 pounds. In placing the strand, it is necessary to pull it to just the right tension in order that when the cable is hung it will have the proper sag. The correct tension is readily determined by what is known as the "oscillation" method. The metal rings are spaced 16 inches apart and the cable weighs about $7\frac{1}{2}$ pounds per foot.

The size and make-up of the cable vary somewhat

with the number of circuits of the various types that are to be provided in the different sections, but in general it is full size, that is, its over-all diameter is $2\frac{5}{8}$ in. which is about the maximum size of telephone cable. The sheath is of lead-antimony alloy, one-

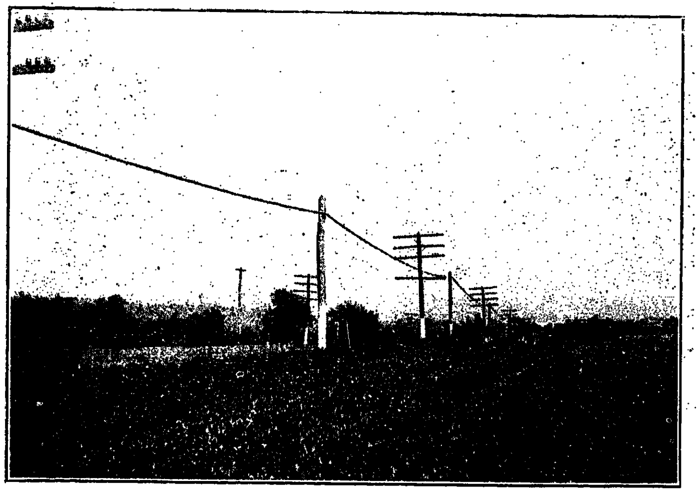

FIG. 7—CABLE LINE ON SEVEN-MILE STRETCH OF LINCOLN HIGHWAY
Aerial wire line to be dismantled later.

eighth of an inch thick, and under normal conditions it is, of course, air-tight to keep moisture from entering. The cable for the aerial section was received from the factory in 500-foot lengths, this being largely determined by the arrangement necessary to permit the proper installation tests.

FIG. 8—CABLE LINE ACROSS VALLEY AT GRAND VIEW

ROUTE

We might next consider the route selected and for this purpose Fig. 2 will again be helpful. It will be noted that starting at Philadelphia, the cable is routed to Reading touching Pottstown, Phoenixville and other points. From Reading to Harrisburg the cable follows closely the William Penn Highway, although in sections it was necessary to obtain private right-of-way or to use longer routes removed from this highway on account of the lines of various kinds already in operation there. It is very desirable for economic reasons to keep the length of these cables as short as possible

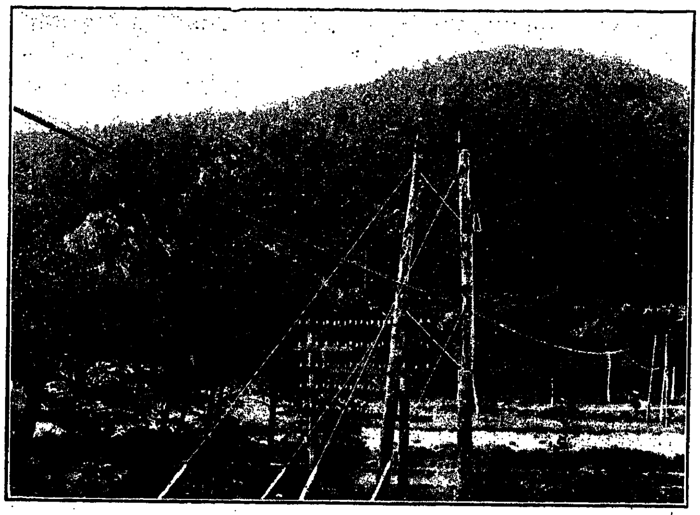

FIG. 9—CABLE CROSSING AT JUNIATA RIVER

and in some cases this is absolutely necessary to obtain proper operating conditions. However, the most direct routes cannot always be used, for many obvious reasons, and this problem required careful consideration in all sections of the cable.

FIG. 10—CABLE LINE ON STEEP SLOPES

Between Harrisburg and Pittsburgh the Allegheny Mountains had to be crossed and for this crossing only two general routes were found practicable, the first following an existing pole line which is the New York—Chicago telephone line through Lewiston, Altoona, etc., and which we may call the northern

route, and second a southern route through Shippensburg, Bedford and Ligonier for the most part along the Philadelphia-Chicago line and also the Lincoln Highway. A middle route which is now used for the Harrisburg-Pittsburgh line was not seriously considered as the country was too rough for economical construction and maintenance and no important advantages were to be obtained. After careful surveys and cost studies, taking into account all existing and anticipated conditions, such as circuit requirements and towns to be reached, length of practicable routes, maintenance conditions, freedom from probable physical and electrical interference, etc., it was decided to build on the southern route.

This route, while of nearly the same length as the northern one and offering some important advantages, was not free from difficulties as it crosses the Allegheny Mountains within a few miles of the highest point. Fig. 7 shows the cable line on what is known as the seven-mile stretch of the Lincoln Highway east of

Fig. 11—Narrow-Gage Mountain Railroad and Flat Car

Ligonier, and here the going was fairly good. The Philadelphia-Chicago aerial wire line is also shown and two of the crossarms carrying 10 wires each are to be removed in the near future and the circuits operated in the cable. It is planned to remove the remaining two crossarms later on. Fig. 8 shows the cable across a valley and is taken from the point on the Lincoln Highway called Grand View. Fig. 9 shows the crossing of the Juniata River east of Bedford where special construction was used. Fig. 10 shows just one example of the conditions encountered in crossing the many mountains and a photograph does not do the scenery or the construction difficulties justice. On account of the steep slopes, clamps are used at many points to fasten the cable to the strand.

Narrow-gage timber railroads were used in the mountains where possible to get material to the job and Fig. 11 shows one of the regular flat cars adapted for our purpose. Fig. 12 shows two 5-ton tractors in action on top of one of the mountains. As many sections of the country are very rough and highways several miles distant it seemed that no other method of transporting the cable reels, which weigh nearly 5000 pounds, could possibly be used, and certainly no

Fig. 12—Tractors Placing Cable Reels in Rough Country

other means would have been as satisfactory. Even with these methods the cable reels could not always be delivered where desired and in some cases it was necessary to pull the sections of cable through the rings for a distance of nearly a mile to get them in place.

Fig. 13—Piece of Cable with Sheath Partly Removed

Cable Make-Up

As stated before, the make-up of the cable varies somewhat with the circuit requirements in the different sections but the wires and arrangement in a typical section of cable are roughly illustrated in Fig. 13.

The cable is of quadded construction, that is, the wires are first wrapped with dry paper for insulation and twisted into pairs and then two pairs are twisted into what is called a quad. These quads are arranged in concentric layers as shown and great care and skill are required in the design and manufacture or there is

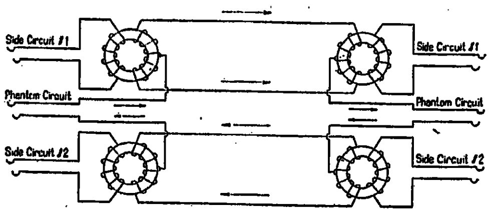

FIG. 14—GENERAL PHANTOM CIRCUIT ARRANGEMENT
Four wires providing three circuits.

certain to be serious cross-talk between the several hundred circuits when used for long-distance service. Even after the application of the best present manufacturing methods, tests are made on all circuits at three points in each loading section of 6000 feet while the cable is being spliced. These tests are made in order to determine the best possible arrangement of conductors for still further reducing cross-talk between circuits, and the splicing is done accordingly.

There are 19 quads of No. 16 A. W. G. and 120 quads of No. 19 A. W. G. pure copper conductors in one of the principal sections, and the arrangement of the four wires in each quad is such that two physical circuits and one phantom circuit are made available. The method of obtaining three telephone circuits from two pairs of wires is old and extensively used. It is illustrated in Fig. 14. The method results in a 50 per cent increase in the number of available circuits and its application to this project is therefore of very great economic importance. Now the total of 139 quads multiplied by 3 gives 417 circuits or as many as could be carried on about 14 heavily loaded pole lines if aerial wire were used, but as will be described later, we will have to use two of these circuits to make one telephone

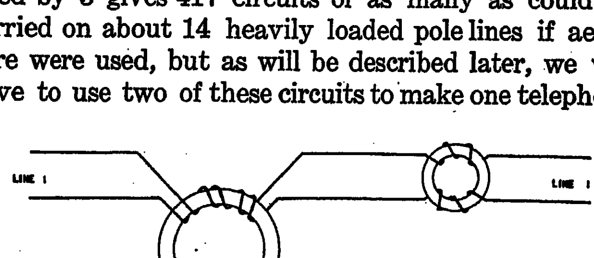

FIG. 15—LOADING COILS CONNECTED TO A GROUP OF FOUR WIRES AND ARRANGED FOR PHANTOM OPERATION

circuit in some cases where the distances are comparatively great, so it is expected that only about 300 telephone circuits will be obtained for regular service. This is as many as could be carried on 10 heavily loaded pole lines if aerial wire were used. It is now thought that in some sections this number of circuits will take care of future demands for about 10 years after allowing for the dismantling of some existing aerial wire.

As these cables can be obtained in any size desired up to the maximum, the period for which they should be engineered can be determined from studies of circuit requirements and costs. These studies are of very great importance and the cost considerations include of course annual costs of the various plans over proper periods as well as first costs.

LOADING

Loading coils are now connected to many of the circuits and all of the circuits in this cable are intended to be equipped with coils located at 6000-foot intervals. The theory and practise of loading are described in papers previously presented before the Institute[1] and

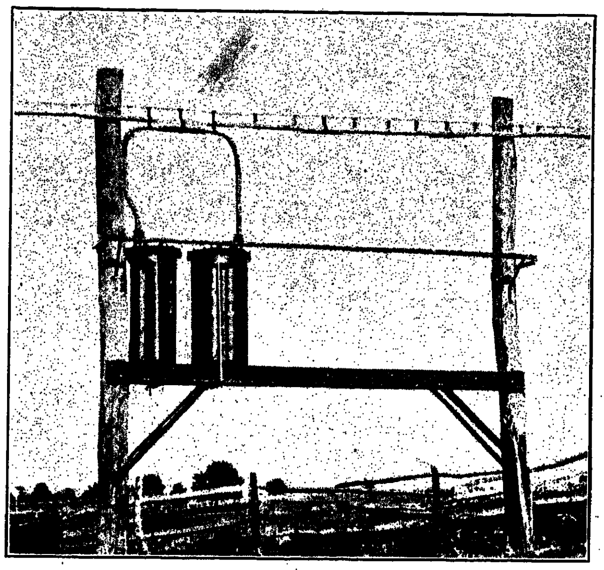

FIG. 16—LOADING FIXTURE

for our purpose it will be sufficient to state that these loading coils very materially reduce the attenuation losses and improve the quality of transmission as compared to cable circuits not so equipped. The improvement in so far as the attenuation losses are concerned, varies with the type of circuit and loading coils, but with one of the No. 19 A. W. G. circuits in this cable loaded with coils having an inductance of 0.175 henry located at 6000-ft intervals, the losses are only about one-third as great as in a similar circuit without the coils. The connections and arrangements of the coils are shown in Fig. 15 and it will be noted that coils have been connected to both the physical and phantom circuits. The arrangement is such that there is no appreciable interference between circuits due to magnetic action in the iron cores of the different coils or to the necessarily close electrical relation in the windings.

1. Papers by M. I. Pupin, TRANSACTIONS of A. I. E. E., XVII, May 1900 and XV, March 1899.

Paper by Bancroft Gherardi, TRANSACTIONS of A. I. E. E., XXX, June 1911.

The loading coils are potted and sealed in iron pots, two of which are shown in Fig. 16, and in the country these are mounted on pole fixtures. Each pot contains 36 groups of 3 coils each. The pots are nearly 30 inches in diameter at the flange, 52 inches high and weigh

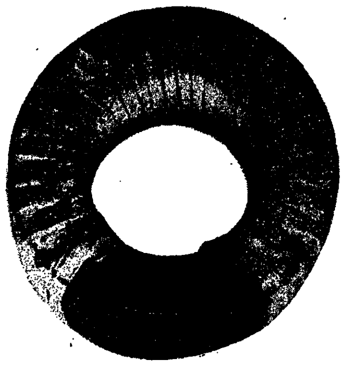

FIG. 17—LOADING COIL CORE

about 2700 pounds. The pots can be obtained in different sizes depending upon the number of coils which it is desired to install at one time. When the cable was installed, extra lead sleeves were placed at the loading points and a little slack left in the wire to facilitate the connection of four additional loading pots to the cable at some later date when the circuits are needed. The loading points must be uniformly spaced in order to obtain the proper impedance characteristics in the circuits as will be referred to later. Fig. 17 shows the iron core of a loading coil, and Fig. 18 shows this core wound with insulated wire and then wrapped with cloth and the terminals brought out nearly ready for potting.

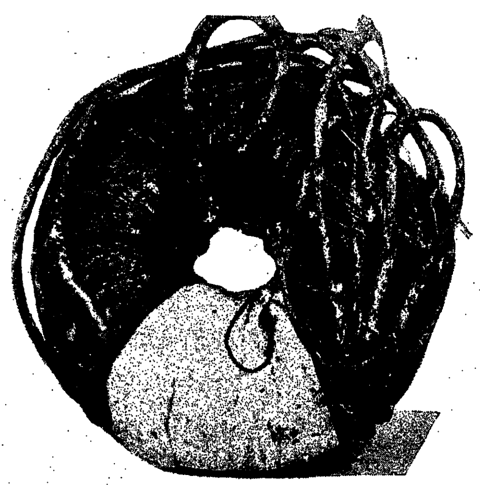

FIG. 18—LOADING COIL WITH WINDING COMPLETED

Fig. 19 shows several coils arranged on one of the spindles which will be placed in the iron pot also shown. This particular pot will hold 7 spindles and when they are in place, the pot will be filled with compound and thoroughly sealed.

TELEPHONE REPEATERS

Even with the improvement in the quality of transmission and reduced attenuation losses effected by the use of loading coils, loaded cable circuits alone of No. 16 and No. 19 A. W. G. could be satisfactorily operated for distances less than 100 and 60 miles, respectively, and this is far short of our requirements in this case. In fact, we wish to operate some telephone circuits on these conductors and through this cable and future cables up to at least 1000 miles in length. This can be accomplished by the use of telephone repeaters connected to the loaded conductors.

Telephone repeaters have been developed to a high state of perfection and are completely described in a paper presented by Messrs. Bancroft Gherardi and Frank B. Jewett at a joint meeting of the A. I. E. E. and the Institute of Radio Engineers in New York,

FIG. 19—LOADING COILS ON SPINDLE, IRON LOADING COIL CASE AND SPINDLE CABLES

October 1, 1919. Briefly, the purpose of a telephone repeater is to receive small telephone currents, amplify them and send them on, preserving all the while the original wave shape. Therefore, if one or more telephone repeaters are properly inserted in circuits adapted to their use, the range of satisfactory transmission can be greatly extended. As many hundreds of vacuum-tube repeaters are in operation on the Philadelphia-Pittsburgh cable and connected cables, and as a great many more are planned for future installation, we will briefly consider the elementary features of some of the types of repeaters used.

Fig. 20 shows the structure of the vacuum tube which is an essential element of this type of repeater. It is a small glass bulb with a vacuum that is as good as is practicable to obtain. In the tube is a filament which is heated to incandescence during operation,

and a grid and plate. The circuits directly associated with the tube are shown in more detail in Fig. 21, and this would constitute a device for amplifying currents from one direction. As is well understood, any change in the potential impressed on the grid causes a change in the current flowing in the plate-filament

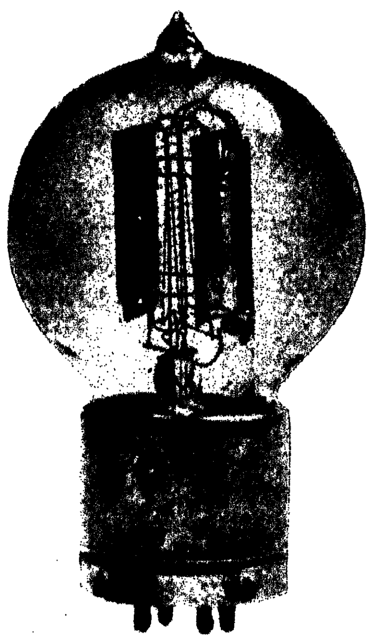

FIG. 20—VACUUM TUBE

circuit. To obtain complete two-way repeater action two of these amplifier arrangements are combined with the circuits shown in Fig. 22.

It will be noted that the line circuit from one direction, for instance, the one designated "line west," is connected through a three-winding transformer to a balancing network which is so made up as to balance

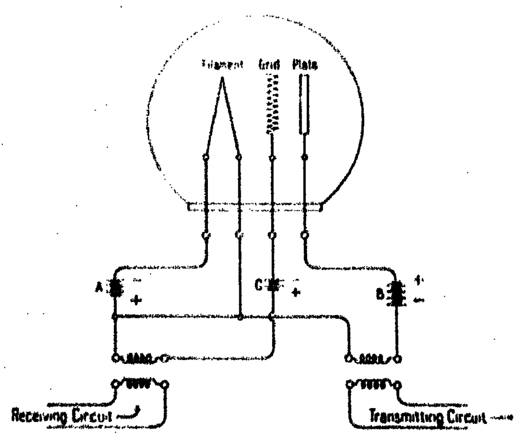

FIG. 21—VACUUM-TUBE REPEATER ELEMENT

the line as nearly as possible at telephone frequencies. This balance is essential to proper repeater operation. The circuit arrangement is such that part of the incoming energy is diverted to that part of the circuit containing the input coil directly associated with this three-winding transformer. By the action of the vacuum-tube arrangement amplified energy is transmitted to the line east. That part of the original incoming energy from the line west that goes through the balancing network or the output coil is not, of course, transmitted along into the line east. The operation in the case of currents incoming from the line east is similar and it will be noted that the complete repeater circuit is made up of two symmetrical parts. This circuit arrangement constitutes what is known

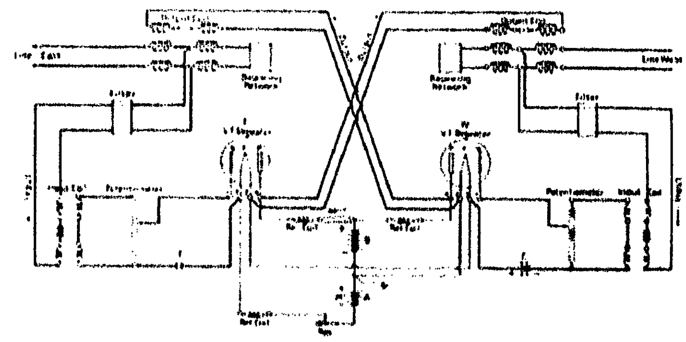

FIG. 22—TWO-WAY VACUUM-TUBE REPEATER CIRCUIT

as a two-wire repeater and the apparatus is, of course, all closely associated in the same office.

Several of these repeaters may be inserted in tandem at appropriate points in a circuit, but there is a limit to the length of circuit that can be satisfactorily operated with this arrangement, this length depending upon the type of the facilities used. When longer circuits are required, a four-wire arrangement is used, as shown in Fig. 23. It will be noted that in this arrangement the three-winding transformers are not located in the same office but may be in offices several hundred miles apart. At each of the intermediate stations a vacuum-tube amplifier arranged for amplification in one direction only is connected to each of

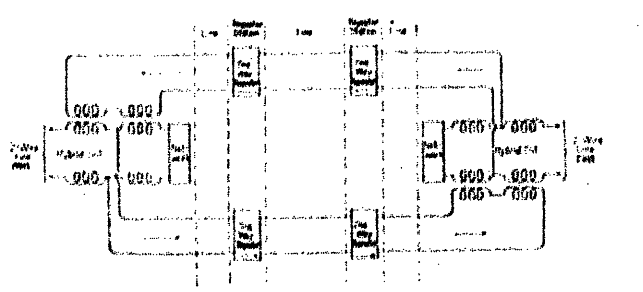

FIG. 23—FOUR-WIRE CIRCUIT
Equipped with telephone repeaters and arranged for connection to two-wire circuits at the terminals.

the two branches of the circuit. Two circuits are, of course, required between the terminals and these may be either physical or phantom circuits.

An advantage of this arrangement is that balancing networks are not required at each repeater station and the general matter of balance and consequently good repeater operation in the circuit as a whole is greatly simplified. This arrangement can, therefore, be satis-

factorily used for long circuits where two-wire operation might be impracticable, and examples would be such circuits as New York-Pittsburgh or New York-Chicago.

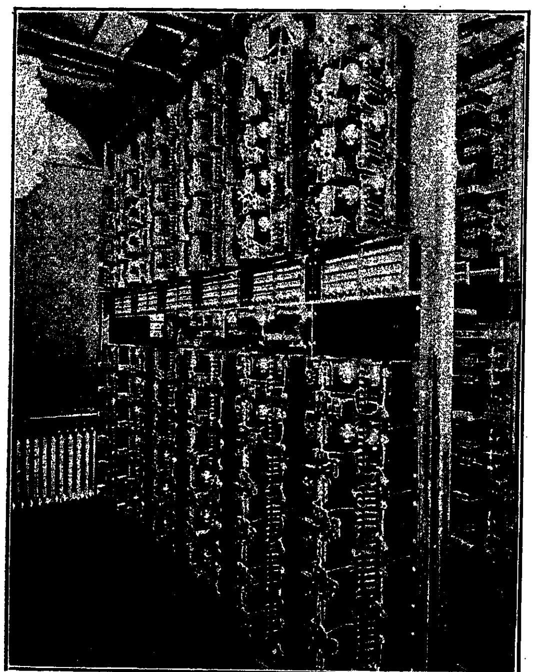

Fig. 24—Group of Repeaters at Reading, Pa.

Both of these types of circuits may be operated on No. 19 A. W. G. four-wire facilities which may be either physical or phantom circuits.

Fig. 24 shows a group of repeaters installed in the office at Reading, Pa., and Fig. 25 shows one of the four-wire repeater units in somewhat greater detail.

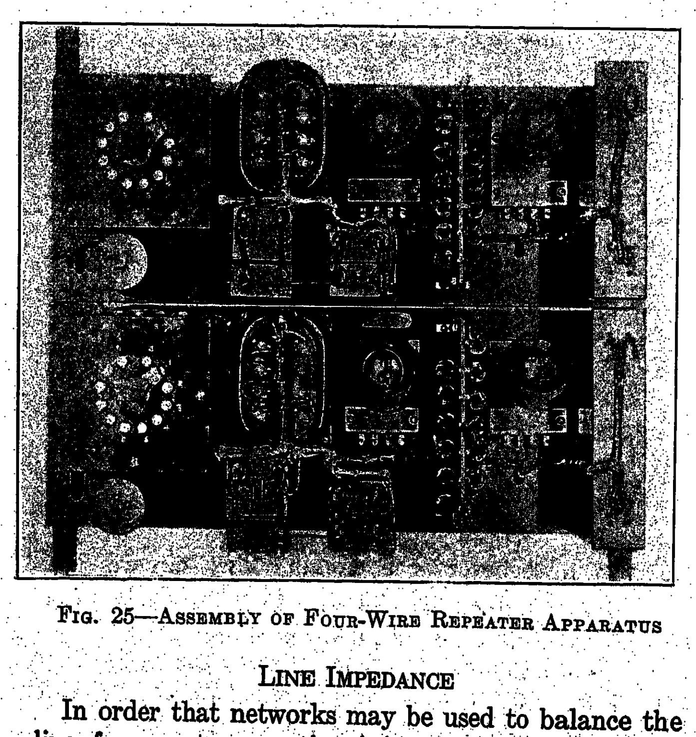

Fig. 25—Assembly of Four-Wire Repeater Apparatus

Line Impedance

In order that networks may be used to balance the lines for repeater operation, it is necessary as a practical proposition that the impedance characteristics of the lines be fairly uniform over the range of telephone frequencies. The solid line in Fig. 26 shows the resistance component of the impedance of a No. 19 loaded cable circuit with all loading coils in place. The solid line in Fig. 27 shows the resistance component found in impedance measurements on the same circuit with one coil omitted at the thirteenth loading point from the end at which the tests were made. It will be noted that in the latter case the characteristics of the circuits vary greatly with frequency. It would therefore be very difficult as a practical proposition to build up a network that would balance lines in this condition, and such variations in the electrical characteristics of a circuit impair the quality of telephone transmission, as the currents of different frequencies are differently affected. The necessity for careful maintenance work in promptly replacing loading coils which may become defective or preventing other irregularities from creeping into the plant will therefore be clear.

Transmission Regulation

The resistance of small-gage cable conductors is one of the important factors that determine the transmission losses of a circuit. The resistance of a No. 19 A. W. G. pair is about 88 ohms per mile so that in a long

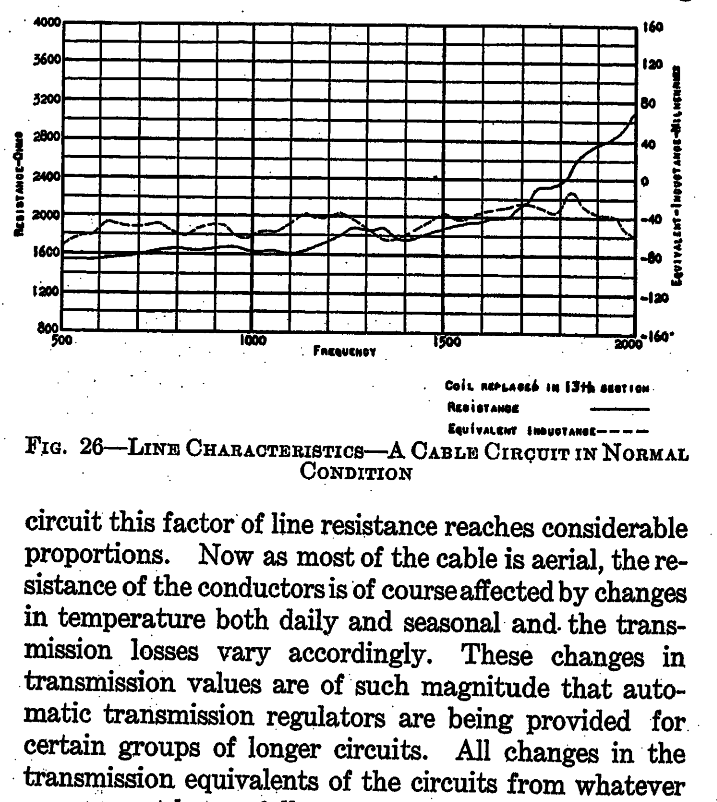

Fig. 26—Line Characteristics—A Cable Circuit in Normal Condition

circuit this factor of line resistance reaches considerable proportions. Now as most of the cable is aerial, the resistance of the conductors is of course affected by changes in temperature both daily and seasonal and the transmission losses vary accordingly. These changes in transmission values are of such magnitude that automatic transmission regulators are being provided for certain groups of longer circuits. All changes in the transmission equivalents of the circuits from whatever causes must be carefully watched and necessary adjustments made or the service will be seriously affected.

Telegraph

In the section between Philadelphia and Pittsburgh practically all of the existing long aerial wire circuits are composited, that is, they are arranged for simultaneous telephone and telegraph operation. The telegraph circuits thus obtained are generally used in furnishing what is sometimes called "leased wire" service. The ground return system providing either full duplex or single-line operation is used and the

line currents average about 75 milliamperes. This grounded telegraph system cannot be used where simultaneous telephone and telegraph service is desired on loaded cable circuits of the length involved in this

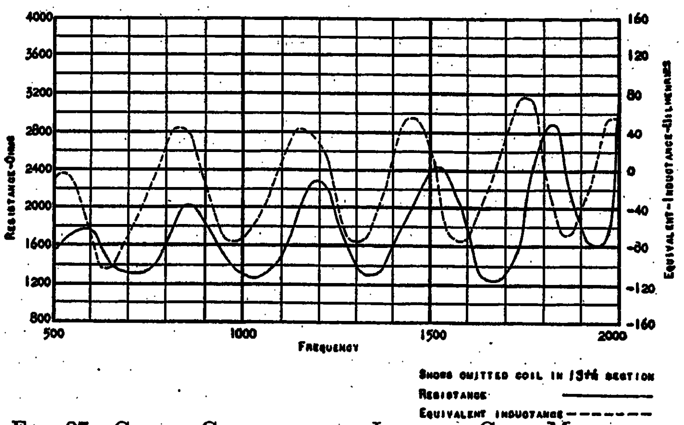

FIG. 27—CABLE CIRCUIT WITH LOADING COIL MISSING AT THIRTEENTH LOADING POINT FROM TERMINAL

cable, and as a part of the work of carrying out the comprehensive toll cable plans of the Bell system, a new telegraph system had to be developed. It was found preferable to use a metallic return circuit and to limit the line current to a value between 3 and 5 milliamperes in order to prevent serious interference to the telephone circuits due to the "flutter effect,"[2] Morse thump, and mutual interference between telegraph circuits. Morse thump results when the composite sets, that is, the apparatus used for separating the telephone and telegraph currents, do not completely prevent the latter from entering the telephone circuit, thus causing interference. The telegraph repeaters are located at about 100-mile intervals on the No. 19

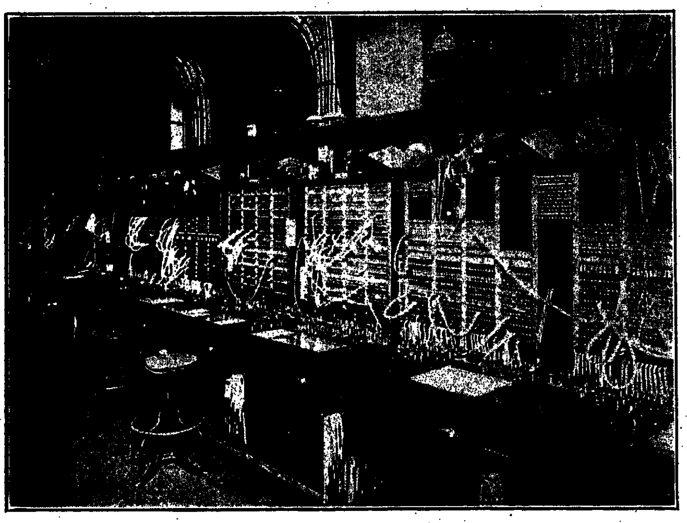

FIG. 28—TEST BOARDS

circuits and at somewhat less frequent intervals on No. 16 circuits. The telegraph apparatus is of course located in the same buildings that are used to house the telephone repeaters, and on the Philadelphia-Pittsburgh cable telegraph repeaters will be located initially at Philadelphia, Harrisburg, Bedford and Pittsburgh.

TEST BOARDS

All of the conductors in the cables are carried into stations located at about 50-mile intervals and apparatus is provided in these stations for making regular tests to ascertain the condition of the cable and to locate trouble quickly. At these offices the different kinds of operating apparatus are also connected to the cable conductors; examples of this apparatus are phantom repeating coils, composite sets to permit simultaneous telephone and telegraph operation, telegraph repeaters, telephone repeaters and associated balancing equipment, signaling apparatus, and where required, the switchboards necessary for making the telephone connnections involved in furnishing service.

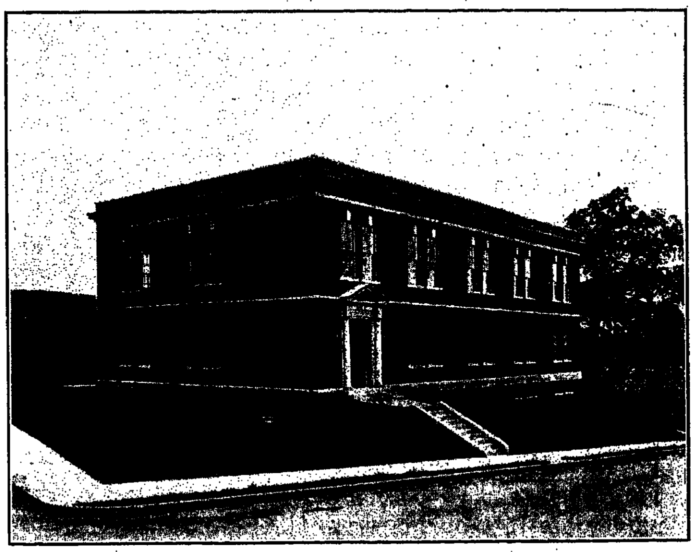

FIG. 29—TEST AND REPEATER STATION AT LIGONIER, PA.

It is necessary that this apparatus which is installed in large quantities be systematically arranged and facilities provided for making quick changes in the circuit arrangement. The circuits are wired through jacks installed in groups in test boards for this purpose and to facilitate testing. One of these boards is illustrated in Fig. 28. This particular board is located in one of the larger offices. The test boards in one of the repeater stations such as Bedford, would consist of a smaller number of positions. A position is three feet in length. In Fig. 28 each position bears a number.

STATIONS AND POWER PLANTS

Telephone repeaters of either the two-wire or four-wire type are connected to the circuits at approximate intervals of either 50 or 100 miles, depending upon the type of facilities which it is economical to use in the different circuits and the kind of service for which a given circuit is intended. As mentioned above, telegraph repeaters are installed at about 100-mile intervals. At some of these points existing offices are used while in a number of cases it was necessary to erect

2. Paper by Martin and Fondiller in JOURNAL of A. I. E. E., February, 1921.

buildings for the sole purpose of housing the repeaters, testing apparatus and other equipment associated with the cable. For example, new buildings of fire-proof construction were erected at Shippensburg, Bedford and Ligonier. Fig. 29 is a view of the building at the latter

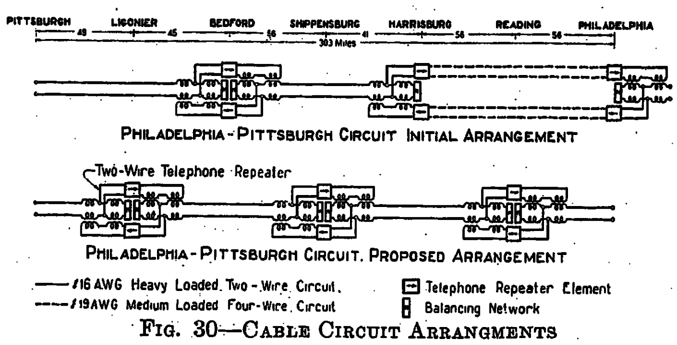

Fig. 30—Cable Circuit Arrangements

point and the other two buildings are similar to this one, the dimensions being about 50 by 80 feet. Power plants are installed in these buildings to furnish current of the proper characteristics for operating the apparatus, and storage batteries are provided to insure uninterrupted service. As an indication of the size of these plants, the 24-volt storage batteries installed for the initial load at Bedford have a capacity of 2240 ampere-hours and this provides about one day's reserve. The capacity can, of course, be increased as repeaters are added from time to time when additional circuits are needed. Storage batteries of smaller sizes supplying current at potentials of 30, 120 and 130 volts are also provided.

Examples of Circuit Arrangements

Fig. 30 shows two possible methods of building up a Philadelphia-Pittsburgh terminal circuit and Fig. 31, a method of building up a New York-Pittsburgh terminal circuit. In all three cases these telephone circuits are intended to have a transmission equivalent of about 12 miles of standard cable. Some Philadelphia-Pittsburgh terminal circuits of the first type have been in everyday operation for several months, but it is not the most economical arrangement that it is possible to obtain for general use in providing this or similar service. It will be noted that No. 19 four-wire facilities are used between Philadelphia and Harrisburg and four-wire repeaters are located at these two points. At Harrisburg the four-wire circuit is connected to a No. 16 two-wire circuit with a two-wire repeater at Bedford. This arrangement was used in order to start service through the cable with the facilities available, but it is intended later on to use the arrangement shown in example No. 2.

In example No. 2, No. 16 heavily loaded conductors are used and two-wire repeaters are located at Reading, Shippensburg and Ligonier. The total transmission equivalent of this circuit without repeaters is about 50 miles of standard cable so that in order to obtain a net equivalent of 12 miles for the circuit each of the three repeaters must give a transmission gain of nearly 13 miles of standard cable. This circuit could not of course be used for telephone purposes without repeaters.

The third example shows how it is expected to operate New York-Pittsburgh circuits intended for business between these two terminals. Four-wire No. 19 loaded cable facilities are used with four-wire telephone repeaters located at New York, Philadelphia, Harrisburg, Bedford and Pittsburgh.

Even with conductors of only two gages in the cable, it is clear that many different combinations of facilities can be built up into telephone circuits and an endeavor is always made to use the most economical arrangement that will furnish the service required over each circuit group. The examples described above are of circuits used for business between the terminals indicated and if these circuits were to be connected to others extending to points considerable distances beyond these terminals different arrangements would be required. The cable conductors used in building up these telephone circuits can be composited and telegraph circuits are thus provided for simultaneous operation with the telephone circuits.

Conclusion

In the above discussion, an effort has been made to furnish some descriptive information regarding a complete cable system recently completed and now in successful operation between Philadelphia and Pittsburgh and designed for long-distance telephone and telegraph service. In one sense this discussion may be considered a report of the present status of the toll cable plant intended to connect Atlantic Seaboard cities with Chicago and other cities, and extensions are now under construction. However, most of the general methods which it is planned to use in these extensions are not expected to differ greatly from those described.

This cable system utilizes many new developments in the communication art and some of these, which have been briefly touched on here on account of their important application, have been described in more detail in previous papers. It is expected that more information regarding other specific developments

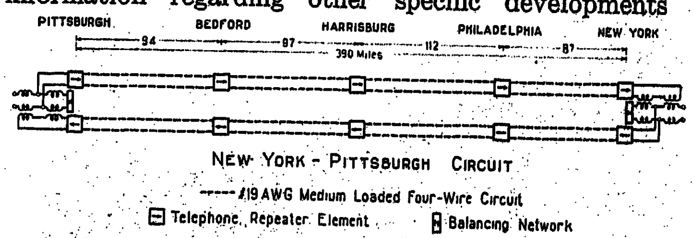

Fig. 31—Cable Circuit Arrangements

which have contributed in an important way to the successful carrying out of this project or which may be utilized later on will be furnished in future papers.

An important feature of this cable project is the fact that while many new developments and practises are utilized, the design of the system as a whole is such as to fit in economically with existing wire and cable systems and proposed extensions.

A Method of Determining Resultant Input from Individual Duty Cycles and of Determining Temperature Rating

BY BASSETT JONES

Member, A. I. E. E.

Consulting Engineer, New York

Review of the Subject.—*Before it is possible to put a group of motors into service, it is necessary to provide means for generating and transmitting the energy which probably will be required to operate them. To select the proper and economical capacity of such generating and transmitting equipment, requires that some reasonably correct estimate be made of the probable amount and probable time distribution of the combined load due to the motors when in service.*

When the motors all operate in a definite sequence on a definite time schedule the problem is simple. But, in the great majority of cases, such as tool, hoist, elevator or traction drive, the motors comprising the group do not in general operate in any such connected sequence. They operate more or less at random.

It is usual to estimate the probable load under such conditions of random, or approximately random, operation by guess work controlled only by experience and by comparison with load records obtained from similar installations already in operation. In general this method of estimating from records is not satisfactory.

In the first place such records, if sufficient for the purpose, are expensive to obtain and are not always available. In the second place, they are generally records of effects and not of causes. Whereas, as is shown in the paper, if the causes are known, the effects can be foretold with surprising accuracy. If certain average duty cycle characteristics of the motor application are known, as they must be known to make an intelligent selection of the motors for the required duty, then, by a simple application of the formulas of probabilities, it is possible to determine the characteristics of the energy input to any group of such motors.

No very great refinement in determining the average duty cycle for the individual motors in the group is required, for, if the number of motors or the number of observations of actual duty cycles be reasonably large, the average deviation from the mean will be small.

It is found that the method proposed gives calculated results that check quite closely with measured results. Not only can the average input, and from this the probable power consumption in kilowatt-hours be determined, but also the r. m. s. or heat generating value of the load as well as the probable amount and frequency of the peaks. Furthermore, data may be obtained for plotting in advance the most probable time distribution of load similar to a graphic instrument record.

The whole method is based on a determination of the average value of the **operating factor** *for the group of motors under consideration. The operating factor is the ratio of the average time any motor is running to the average duty cycle period. The operating factor may be averaged over any group of motors or, its average value may be determined from a graphic instrument record, such as obtained from a graphic wattmeter or ammeter. The value of the average operating factor is a better measure of the variations of load or input to a group of motors than either demand factor or diversity factor. In fact, it is shown that the value of the demand factor is generally meaningless and misleading.*

The value of the operating factor seems to lie within fairly narrow limits over numerous cases of the same kind of motor application. The demand factor does not possess this character.

Having thus established a method of rating the current-carrying and protective devices handling the input to a group of motors, it is necessary to establish a method of similarly rating conductors and protective devices handling the input to individual motors in the group. In other words, it is necessary to determine the heating value of any given intermittent duty cycle in terms of a continuous duty having equal heating value. The ratio between these two duties is found as a ratio of duty cycle factors expressed in terms of the operating factor for the individual duty cycle. In the continuous duty the operating factor is unity, and the duty cycle factor is also unity.

Since current-carrying devices are generally temperature rated in terms of continuous duty, it becomes possible to re-rate all such devices for other than continuous duty by operations performed on the duty cycle factors for the non-continuous or intermittent duty cycles. In this way various time ratings may be established for conductors, fuses, motors, generators, etc.

The resulting calculated time ratings for conductors prove to be very nearly the same as ratings established for the same times by actual tests.

The resulting calculated time ratings for fuses indicate how very narrow is the possible field for fuses as protective devices where continuous heavy overloads are not to be passed without rupture. In general it is impossible to use one set of fuses to protect a motor against more than 25 per cent continuous overload unless the starting peak is almost negligible. The result is quite in accord with general observation and test. It is shown that the underwriter's method of selecting fuses generally introduces a hazard rather than a safeguard.

NEW TERMS. Two new terms have been introduced, the **operating factor** *and the* **duty cycle factor.** *The operating factor not only determines the ratio of average load to total wired load, but also determines the ratio of r. m. s. load to the average load, as well as the amount, duration and frequency of peaks. In a sense, it is also a measure of operating efficiency.*

The duty cycle factor is merely a means of approximating the r. m. s. value of the duty cycle without resorting to the planimeter or to tedious graphical methods.

TABULATED DATA. Tables of values of the various factors entering into the probability formulas used are presented in an appendix, as well as tables for the computation of duty cycle factors.

NEW MATTER. It is believed that this paper presents for the first time an application of the theory of probabilities to the starting and stopping of motors. The theory of probabilities, or of statistics, has many possible applications in engineering which, of necessity, deals largely with statistical averages. The use of the theory in engineering has been strangely neglected.

CONTENTS

Presented at the Annual Convention of the A. I. E. E., Niagara Falls, Ont., June 26-30, 1922.

Preliminary Note

Assuming a group of motors whose individual duty cycles are known, operating at random or nearly so, it is necessary to determine the resultant combined duty cycle in order to select the most suitable capacity of the conductors feeding the group, as well as the rating and type of the generating apparatus supplying the required energy, and of the protective apparatus. The average value and r. m. s. value of the resultant duty cycle are required, as well as the

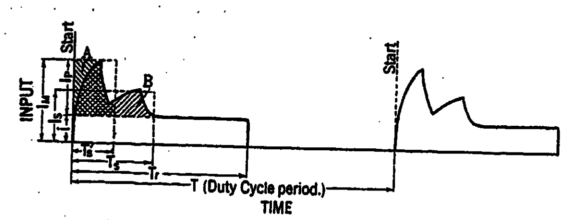

Fig. 1—Individual Duty Cycle
First Approximation.

maximum peaks, their duration and probable frequency of occurrence, together with some knowledge of the probable time distribution of the input. With such information available, even if it be only reasonably approximate, some intelligent selection of generating, distributing and protective equipment is possible. If the heat absorption and heat radiation constants of the current-carrying parts of the equipment are known, then the desirable rating of such parts on a basis of temperature rise may also be determined. Without such information the selection of equipment is largely a matter of guess work, more or less intelligent, depending upon experience and available records.

While the method proposed is worked out in detail for the case of a group of similar motors, all operating at random on the same duty cycle, it is obvious that, with suitable and not very serious complications, it can be applied to groups of dissimilar motors operating

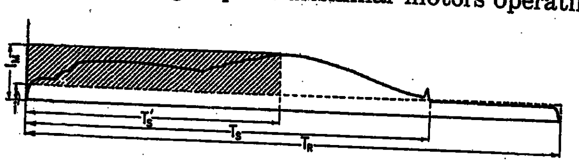

Fig. 2—Oscillogram
Direct-drive, 1 to 1 roping, traction-type elevator.

at random on different duty cycles, such as motors driving diversified machine tools. The method, as given, applies without change to traction systems.

The Individual Duty Cycle

The curve in Fig. 1 represents the average time distribution of the input to all of the individual motors in the group. The average time per cycle or between starts is T. The average time during the cycle when the motor is running is T_r. The average starting period is T_s. The average running input during the time T, omitting the starting peak, is i. The average input during the starting time is I_s. The average starting peak input above i is $I = I_s - i$.

If, in the resultant duty cycle of the group, the maximum value reached by the resultant peaks is of more importance than their duration, the value of I_s is to be changed to I_M, the maximum peak input; in which case $I_P = I_M - i$. As a first approximation, the duration of I_M is then taken at T_s^1 so that the area A between I_M and i is equal to the area B enclosed by the actual curve of peak input and i. Then in both cases, the product of input and time is the same. But, if the actual maximum input is of short duration, the resultant maximum peaks for the group found in this way will be too steep and of too long a duration.

For many cases, such as that shown in Fig. 2, this first approximation will be sufficient. This is an oscillograph of input to a direct-drive, 1 to 1 roping, traction-type elevator hoisting engine on resistance speed control. The error here introduced by considering the starting input to be constant and equal to the

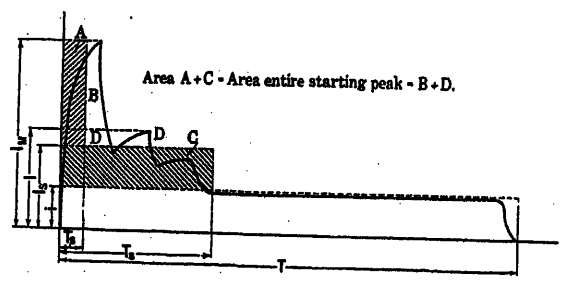

Fig. 3—Individual Duty Cycle
Second Approximation.

maximum input over a reduced starting period is negligible. But in cases like that shown in Fig. 3, a second approximation may be required. In this case the starting peak below I is averaged as I_s over the time T_s and the starting peak I_M above I is drawn of such duration, T_s^1, that the area A enclosed is equal to the area B of the actual peak above I. The total area is then the same as the actual peak area above i.

Obviously some judgment will be required in determining the approximation to be used. But without some such approximation the calculation of the resultant duty cycle becomes too cumbersome for practical use.

Another approximation has been introduced in considering the duty cycle used to be the average duty cycle for the group. If the group is divided into sub-groups in each of which the motors are operating on very different average duty cycles, the calculations must be carried out for each sub-group separately and then combined. This difference may be in the time-distribution of the input during the duty cycle, in the duration of the duty cycle, or in both.

If the motors vary widely in capacity then a second sub-division into groups of motors of approximately the same capacity must be introduced and a separate calculation made for each such sub-group.

When the motors in the group number 20 or more in general no such sub-divisions of average duty cycles or capacities are necessary, unless a few relatively large motors may introduce a periodic large increase in the resultant input. In such special cases the particular motors must be treated as a sub-group.

In special cases it may be advisable to introduce approximations other than those above indicated. Again, if the starting peaks are not material or are relatively short, and particularly where, in such cases, the number of motors is large, it may be sufficient to average the entire input during the duty cycle, including the peak, and to omit from consideration the peaks above this average. If the peaks are of moment then at least two calculations are necessary, one for the average running input, i, and, depending on the order of approximation introduced, one or more for the peaks. The resultant duty cycles, one obtained by each such calculation, are then to be combined to obtain the over-all duty cycle. But in each case the method of calculation is the same, and, as will be seen from the case worked out below, is quite simple.

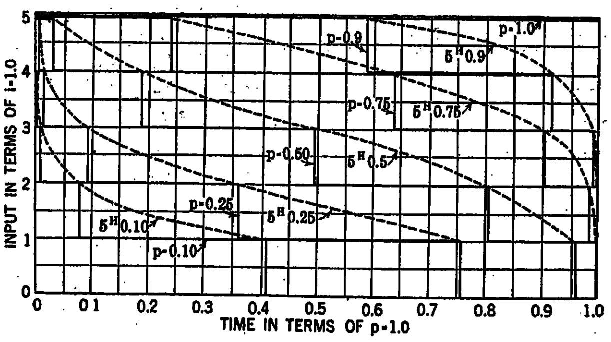

Fig. 3A—Group Duty Cycles
For $N = 5$, $i = 1.0$

Method of Calculation

The method proposed is precisely the same as that used in determining the probable frequency of occurrence of any number of points in any number of throws of a given number of dice. As is well-known, this method very closely approximates to actual experience when the number of throws or trials is sufficiently large.

Let there be N motors in the group (or sub-group), the average duty cycle for which (Fig. 1) has the approximate values T, T_r, i, I_M, and let the duration of I_M be T_s^1. Then, on the average, each motor is running a fraction of the time given as a decimal by

$$T_r/T = p \qquad (1)$$

This is also the average decimal of the total period considered, P, say 15 minutes or one hour as the case may be, during which any one motor in the group is running. If T and P be given in seconds, then P/T is the average number of duty cycles performed by each motor in the group in the time P. Since there are N motors in the group the total number of starts or runs made is

$$P/T \times N = R \qquad (2)$$

The number R corresponds to the number of trials or throws of the dice in the analogous dice problem.

Since, on the average, each motor is running a part of the time P denoted by p, the probability that any one particular motor is running at any particular time is p. But there are N motors in the group. So the relative frequency in the total number of trials or observations, R, that any one motor is running is $N\,p \times R$.

Since, on the average, each motor is running a part of the time P denoted by p, the probability that any motor is running at any particular time is p. The probability that it is standing still at any particular time is $(1 - p)$.

The probability that any particular two motors are running simultaneously at any particular time is p^2. Similarly the probability that any particular set of r motors are running simultaneously at any particular time is p^r. Since there are N motors in the group, the probability that they are all running simultaneously at any particular time is p^N.

The probability that any particular set of r motors are standing still simultaneously is $(1 - p)^r$. The probability that all of the N motors are standing still simultaneously is $(1 - p)^N$.

The probability that any particular set of r motors are running simultaneously, while the remaining $(N-r)$ motors are standing still simultaneously is $p^r . (1 - p)^{N-r}$ But there are ${}^NC_r$ combinations of motors in the group taken either r or $(N - r)$ at a time, so the relative frequency with which the input due to r motors running simultaneously will occur, is

$$P_r = {}^NC_r \,.\, p^r \,.\, (1 - p)^{N-r} * \qquad (3)$$

It is not difficult to compute and tabulate, or chart, values of (3) over a useful range of N, r and p.

In general if $\{ (1 - p) + p \}^N$ be expanded as a binominal thus: $\{ (1 - p) + p \}^N = (1 - p)^N + N\,p\,(1 - p)^{N-1} + {}^NC_2\, p^2 (1 - p)^{N-2} + \ldots + {}^NC_r\, p^r\,(1 - p)^{N-r} + \ldots + p^N$, (4)
the first term is the probability that all the N motors are standing still; the second term is the probability that one motor is running and $(N - 1)$ motors are standing still simultaneously; the third term is the probability that two motors are running simultaneously and $(N - 2)$ motors are standing still simultaneously; . . . .; the last term is the probability that all the N motors are running simultaneously. The sum of the terms in (4) is 1.0.

All of this is quite obvious, of course, to those who are familiar with the elements of the Theory of Probabilities.

Having determined the values of the terms in (4) as

$$* \left({}^NC_r = \frac{N\,(N-1)\,(N-2)\,.\,.\,.\,.\,(N-r+1)}{r\,(r-1)\,(r-2)\,.\,.\,.\,.\,1} \right)$$

P_0, P_1, P_2, . . . , P_r, . . . P_N, they may be taken respectively as the probability that the input to the group at any time may be that due to no motors running or zero input, that due to one motor running, that due to two motors running simultaneously, ..., that due to r motors running simultaneously, ... , that due to all the N motors running simultaneously.

To determine the probable time distribution of the resultant input proceed as follows:

There are R chances in the period P that the input will change (see (2) above). Of these chances the input will be probably that due to no motors running (zero load), $P_0 \times R$ times; the input will be probably that due to one motor running $P_1 \times R$ times; the input will be probably that due to two motors running simultaneously $P_2 \times R$ times; . . . . ; and the input will be probably that due to all the N motors running simultaneously $P_N \times R$ times.

Then, if $P = 1.0$ hour, chances are that $P_0 \times R = F_0$ times per hour the input will reach zero; the chances are that $P_1 \times R = F_1$ times per hour the input will be that due to one motor running; the chances are that $P_2 \times R = F_2$ times per hour the input will be that due to two motors running simultaneously; . . . . ; and the chances are that $P_N \times R = F_N$ times per hour the input will be that due to all the N motors running simultaneously. These results may be changed into time distribution by considering that n times per hour equals every $3600/n$ seconds.

Such calculations having been carried out for the running current, similar calculations are to be made for the starting peaks, repeated twice if two approximations have been introduced as explained above (see Individual Duty Cycle).

In the case of the starting peaks

$$T_s/T = p_s, \text{ and } T_s^1/T = p_s^1 \tag{5}$$

giving the values of p for the two approximations both of which are different from the value of p found for the running current. The corresponding values of ${}^N C_r\, p_s^{\,r}\ (1 - p_s)^{N-r}$, and ${}^N C_r\, p_s^{1r}\,(1 - p_s^1)^{N-r}$ will be different from each other and different from the values of ${}^N C_r\, p^r\,(1 - p)^{N-r}$ found for the running input. In this case, the input per motor is $I_M - i = I_p$ if only one approximation is used (see Fig. 1). If two approximations are necessary the two values are $I_s - i$ for the first approximation, and $I_M - I_s$ for the second (see Fig. 3).

Average Input

The average input over the time P is found as follows; two calculations are necessary, one for the running input and one for the starting input.

First as to the running input:

Of the total time P, zero input exists for the time $P_0 \times P$; the input due to one motor running exists for the time $P_1 \times P$; the input due to two motors running simultaneously exists for the time $P_2 \times P$; . . . . ; and the input due to all N motors running simultaneously exists for the time $P_N \times P$. Each of these results is to be multiplied by their respective values of input o, i, $2\,i$, ... , $N\,i$, and the sum of the products taken. This sum, divided by P, is the average input. It is

$$\frac{(P_0 \times P \times 0) + (P_1 \times P \times i) + (P_2 \times P \times 2\,i) + \ldots + (P_N \times P \times N\,i)}{P}$$
$$= i(P_1 + 2\,P_2 + \ldots + N\,P_N) \tag{6}$$

Similar calculations, using I_p instead of i in (6), must be carried out for the average starting input which is to be added to the average running input to get the total average input.

Simplified Method of Determining the Average Input

If $p\,T \times R$ or $T_r \times R$ is greater than P, so that on the average at least one motor is always running, the average running input A_r may be determined by

$$A_r = i\,N\,p \tag{6a}$$

If $p_s\,T_s \times R$ or $T_s \times R$ is greater than P so that on the average at least one motor is always starting, the average starting input, A_s, may be determined by

$$A_s = I_p\,N\,p_s \tag{6b}$$

For, if at least one motor is running (or starting) and each motor on the average runs (or starts) during that part of the time measured by p then on the average, $N\,p$ motors are running (or $N\,p_s$ motors are starting). Otherwise, in time, either all the motors would be running (or starting) simultaneously, or all the motors would be standing still simultaneously (or no motor would be starting). Since on the average at least one motor is running (or starting) the latter cannot be true.

When the motors all perform one average duty cycle, the determination of A_r or A_s by **(6a)** and **(6b)** respectively is simple. But when the duty cycles vary widely so that the ratings of the motors vary widely, these formulas, like (6), must be applied separately to each group of motors for which an average duty cycle may be taken. (See Average Duty Cycle above).

From the average input thus determined, the approximate power consumption in kilowatt-hours during the period P may be found; determinations of this kind have proved to be within 10 per cent of the actual yearly power consumption of groups of motors in service.

Root-Mean-Square-Input

As in finding the average input, separate calculations for the r. m. s. running input, and for the r. m. s. starting input are necessary.

The values of $P_0 \times P$, $P_1 \times P$, ... , and $P_N \times P$ are determined as above. Then each value is multiplied by the *square* of its respective input. The sum of these products divided by P is the mean-square input, and the square root of this is the root-mean-square input. It is

$$\left\{\frac{(P_0 \times P \times 0) + (P_1 \times P \times i^2) + (P_2 \times P \times 4 i^2) + \ldots + (P_N \times P \times N^2 i^2)}{P}\right\}^{1/2}$$

$$= i\,(P_1 + 4\,P_2 + 9\,P_3 + \ldots + N^2 P_N)^{1/2} \qquad (7)$$

Similar calculations using I_p instead of i in (7), must be carried out for the r. m. s. value of the starting input, and added to the r. m. s. running input to get the total r. m. s. input.

Of course an error is introduced by treating a distributed series of equal load values as if the heating due to the distributed series were the same as a continuous load of the same amount, but lasting a single interval equal to the sum of the separate intervals. This error is not material for values of R equal to or greater than 1000. If R is much less than 1000 then it may be advisable to plot the actual load curve and determine temperature rise from the actual resultant duty cycle thus obtained.

The method assumes that the heating value of the distributed load as shown by curve T in Fig. 5, is the same as the heating value of the curve H shown in this same figure. Curve H is obtained by assembling together in one interval, as expressed by (6), all the separate input intervals that fall within a given range of input for both running and starting. Thus all the separate intervals during which the input lies between 200 and 300 in the curve T have been assembled as a single interval in the curve H. The actual r. m. s. value of both curves is the same, but due to the heat absorption and radiation characteristics of the current-carrying devices or equipment, in general the momentary temperature rise will be different for the assumed duty cycle H and the actual duty cycle T. Generally this difference will be in favor of the actual duty cycle. For instance, a fuse that would blow if subjected to the duty cycle H, would not blow if subjected to the duty cycle T. A fuse subjected successfully to a current of 600 amperes for a second or two at comparatively long intervals would blow if subjected to this same current for 7.2 seconds continuously.

The curve H may be considered as the characteristic frequency curve of input distribution in the particular case for which it has been determined. If curve-drawing instrument charts, giving time distribution of input to any group of motors, is available, the H curve may be determined graphically from the observed input distribution, exactly as it is determined above from the calculated input distribution.

For various values of N and p taking i as 1.0, characteristic H curves may be computed and graphed for comparison with H curves determined by observation. A selection of the appropriate standard H curve for any observed value of N determines the approximate over-all value of p for the group of motors under observation.

Such standard group duty cycles for $N = 5$ and various values of p are shown in Fig. 3A. These curves assume $p_s = 0$, or that the starting peaks are of no material moment. These curves are determined for $P = 1.0$ and $i = 1$.

Method of Plotting Time Distribution of Input

The various possible probable values of input as calculated above, namely, that due to one motor running, that due to two motors running simultaneously, ... , and that due to N motors running simultaneously, may then be spotted on a cross-section sheet taking one border as time and the other as input. These points establish the probable beginning of each change in input. The input remains constant till the next change occurs.

This square topped input curve may then be converted into a curve more resembling an actual curve-drawing instrument record by plotting the resultant input values at equal time intervals, say every two seconds, or five seconds, and by drawing straight lines between these points. If there are two groups or more for which the same calculations have been made, then the resultant input curves should be drawn on the same sheet for each group and their separate values at equal time intervals added to obtain points on the total curve.

A similar, and separate curve is then to be plotted for the peak input, and added to the running curve.

Such curves, plotted from computed probable values of input, may be compared properly with actual curve-drawing instrument records of input only with the understanding in mind that the computed value of the input at any time during the resultant cycle is the most probable value at that time. It should be compared only with the average of the values of the actual input at the same or corresponding intervals. In other words, the form of the computed curve of time distribution of input is the most probable form of the actual record curve.

Frequency of Combined Running and Starting Inputs

Having determined, as explained above, the probable frequencies P_0, P_1, P_2, ... etc. for both running and starting inputs, the frequency with which any combination of running and starting inputs will probably occur can be determined by multiplying together their separate frequencies. Thus, to determine the probable frequency with which the input due to r motors running simultaneously, and the input due to q motors starting simultaneously will occur at the same time, the value of P_r for the running input, and the value of $P\,q$ for the starting input are to be multiplied to get P_{qr}. This may then be converted into terms of "times per hour."

Applications

The method outlined has been applied to actual installations of motors where the calculated results could be checked by comparison with records from curve-drawing and integrating instruments. The com-

puted values always compare very favorably with the actual operating averages. In this, there is nothing strange, for the method of probabilities always leads to results that closely correspond to experience, and experience consists of just such statistical averages.

Example. Consider the case for which $N = 6$, $T = 20$ sec., $T_r = 10$ sec., $P = 3600$ sec., $i = 100$, and, to the first approximation, let $I_M = 200$, for $T_S{}^1 = 5$ sec. Then $p = 10/20 = 0.5$; $p_S = 5/20 = 0.25$; $R = 3600/20 \times 6 = 1080$.

The first step in the calculation is to determine values of ${}^NC_r\, p^r\,(1-p)^{N-r} = P_r$ for $p = 0.5$. They are

1. $P_0 = (1-p)^N = 0.5^6 = 0.015625 = 0.0156$ nearly
$P_1 = {}^6C_1 \times 0.5 \times 0.5^5 = 0.093750 = 0.0938$ "
$P_2 = {}^6C_2 \times 0.5^2 \times 0.5^4 = 0.234375 = 0.2344$ "
$P_3 = {}^6C_3 \times 0.5^3 \times 0.5^3 = 0.312500 = 0.3125$ "
$P_4 = {}^6C_4 \times 0.5^4 \times 0.5^2 = 0.234375 = 0.2344$ "
$P_5 = {}^6C_5 \times 0.5^5 \times 0.5 = 0.093750 = 0.0938$ "
$P_6 = {}^6C_6 \times 0.5^6 = 0.015625 = 0.0156$ "

1.000000

These values of P_0, P_1, P_2, etc. have been plotted in Fig. 4. It will be seen that because $p = 0.5 = (1-p)$ the resulting curve is symmetrical with respect to the maximum value of P_3. The most probable running

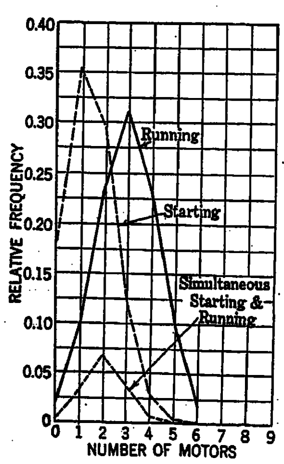

FIG. 4—FREQUENCY CURVES FOR SIX MOTORS
$p = 0.5$, $p_s = 0.25$

input is that due to three motors running simultaneously. In this case it is also the average input.

The next step is to determine values of $P_r \times R = F_r$. They are

2. $F_0 = 0.0156 \times 1080 = 16.85$ times
$F_1 = 0.0938 \times 1080 = 101.30$ "
$F_2 = 0.2344 \times 1080 = 253.05$ "
$F_3 = 0.3125 \times 1080 = 337.50$ "
$F_4 = 0.2344 \times 1080 = 253.05$ "
$F_5 = 0.0938 \times 1080 = 101.30$ "
$F_6 = 0.0156 \times 1080 = 16.85$ "

Now the trials, $R = 1080$ occur in 3600 seconds or 1 hour, so from (2);

3. 16.85 times per hour is equivalent to every 213.6 sec.
101.30 " " " " " " " 35.5 "
253.05 " " " " " " " 14.2 "
337.50 " " " " " " " 10.7 "
253.05 " " " " " " " 14.2 "
101.30 " " " " " " " 35.5 "
16.85 " " " " " " " 213.6 "

Therefore the running input will probably reach that due to no motors running or zero input, every 213.6 sec.; it will probably reach that due to one motor running, or 100 amperes every 35.5 sec.; it will probably reach that due to two motors running simultaneously, or 200 amperes every 14.2 sec.; . . . . ; it will probably reach that due to all six motors running simultaneously, or 600 amperes every 213.6 sec.

It is to be noted that zero input and that due to all the six motors running simultaneously occur with the same frequency. This is also true of the input due to two motors running simultaneously, and the input due to four motors running simultaneously. In such cases either one or the other input is equally likely to occur.

The average running input by (6) is

$$100\,(0.0938 + 2 \times 0.2344 + 3 \times 0.3125 + \ldots + 6 \times 0.0156) = 300 \text{ amperes.}$$

Note that by (6a), $A_R = 100 \times 3 = 300$.

The root-mean-square running input, by (7), is

$$100\,(0.0938 + 4 \times 0.2344 + 9 \times 0.3125 + \ldots + 36 \times 0.0156)^{1/2} = 324 \text{ amperes.}$$

Similar calculations must now be made for the starting peak input. Here $p_S = 0.25$, so the values of ${}^NC_r\, p_S{}^r\,(1-p_S)^{N-r}$ are

4. $P_0 = (1-p_S)^6 = 0.75^6 = 0.1780$
$P_1 = {}^6C_1 \times 0.25 \times 0.75^5 = 0.3564$
$P_2 = {}^6C_2 \times 0.25^2 \times 0.75^4 = 0.2966$
$P_3 = {}^6C_3 \times 0.25^3 \times 0.75^3 = 0.1234$
$P_4 = {}^6C_4 \times 0.25^4 \times 0.75^2 = 0.0308$
$P_5 = {}^6C_5 \times 0.25^5 \times 0.75 = 0.00411$
$P_6 = {}^6C_6 \times 0.25^6 = 0.002285$

These results have also been plotted in Fig. 4. The resulting curve is unsymmetrical (skew) with respect to the most probable value, P_1. The most probable starting input is that due to one motor starting.

The next step is, as before for the running inputs,

2. $F_0 = 0.1780 \times 1080 = 192.24$ times
$F_1 = 0.3564 \times 1080 = 384.91$ "
$F_2 = 0.2966 \times 1080 = 320.33$ "
$F_3 = 0.1234 \times 1080 = 133.27$ "
$F_4 = 0.0308 \times 1080 = 33.26$ "
$F_5 = 0.00411 \times 1080 = 4.44$ "
$F_6 = 0.00229 \times 1080 = 1.57$ "

Then,

3. 192.24 times per hour is equivalent to every 18.7 sec.
384.91 " " " " " " " 9.4 "
320.33 " " " " " " " 11.2 "
133.27 " " " " " " " 28.1 "
33.26 " " " " " " " 108.2 "
4.44 " " " " " " " 812.0 "
1.57 " " " " " " " 2300.0 "

Therefore the starting input will probably reach zero every 18.7 sec.; it will probably reach that due to one motor starting every 9.4 sec.; it will probably reach that due to two motors starting simultaneously every 11.2 sec.; . . . . ; it will probably reach that due to all six motors starting simultaneously every 2300 seconds.

The average starting input, by (**6**) is

$$100\,(0.356 + 2 \times 0.297 + 3 \times 0.123 + \ldots + 6 \times 0.0023) = 148 \text{ amperes}$$

Note that by (**6b**), $A_R = 100 \times 1.5 = 150$.

This is to be added to the average running input of 300 amperes to get the total average. It is 448 amperes.

The root-mean-square starting input, by (**7**), is

$$100\,(0.356 + 4 \times 0.297 + 9 \times 0.123 + \ldots + 36 \times 0.0023)^{1/2} = 183 \text{ amperes.}$$

which is to be added to the r. m. s. running input of 324 amperes to get the total r. m. s. It is 507 amperes.

The kilowatt-hours consumed by the motors in any period during which these conditions hold can be determined from the total average input. It will be found to check very closely with the power consumption of the actual motors in actual service as measured by a watt-hour meter. The conductors feeding the group should be selected on the basis of the total r. m. s. input. The average drop in these conductors will be a function of the total average input.

The periodicity of peaks for this case may be worked out as follows:

The heaviest possible running input of 600 amperes due to six motors running simultaneously occurs every 213.6 seconds, the corresponding value of P_6 is 0.0156. Starting peaks may be added to this. Four motors start simultaneously every 108.2 sec. The corresponding value of P_4 is 0.0308. The probability that both will occur together is the product $0.0156 \times 0.0308 = 0.0048$. This has a probable frequency of $0.0048 \times 1080 = 5.18$ times per hour, or every 695 seconds; which is equivalent to once every 11.6 minutes. Its duration will be less than $T_S{}^1 = 5$ sec.

For six motors running and five motors starting simultaneously, the probable frequency is $0.0156 \times 0.0041 = 0.000064$. This is equivalent to 0.069 times per hour, or once every 52174 sec.; which is equivalent to once every 14 hours and 30 minutes. The corresponding input is 1100 amperes. It is probable that for most purposes this peak can be neglected.

The time distribution of input for this case is shown in Fig. 5. The curve R is the running input. The curve S is the starting input. The curve T is the total input. Greater peaks will appear if the curve is extended, due to the combination of running and starting peaks.

The method of plotting may be illustrated by the curve R. Referring to column *3* in the calculations for running input, it is found that zero input occurs every 213.6 sec. and that the input due to one motor running or 100 amperes occurs every 35.5 sec. The corresponding points $b, b, b,$ . . . . are plotted. Then the load of 200 amperes due to two motors running simultaneously is plotted every 14.2 sec. . . . Since the input every 35.5 sec. is equally likely to be either 100 or 300 amperes, the two values have

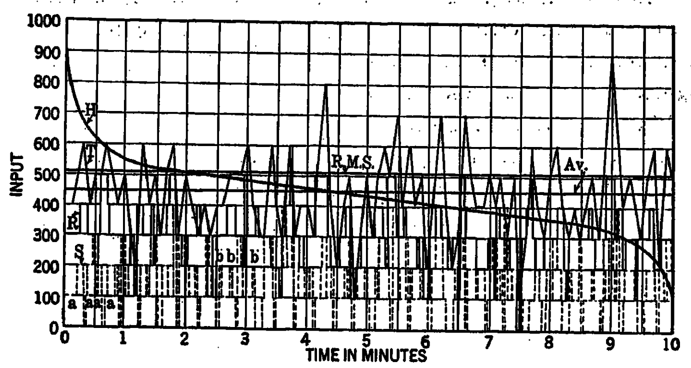

Fig. 5—Time Distribution of Input
$N = 6$, $T = 20$ sec., $T_r = 10$ sec., $T_s = 5$ sec.
$p = 0.5$, $p_s = 0.25$, $i = 100$, $I_p = 100$.
Curve T plotted in 6-sec. intervals.

been plotted alternately. The same is true of the input every 14.2 sec. which is equally likely to be either 200 amperes or 400 amperes.

As explained above (Method of Plotting Time Distribution of Load), the square topped curve R is drawn through these points.

The starting input curve S is plotted and drawn in a similar manner.

Then, at every 6.0-sec. interval ordinates have been drawn and the sum of the input values given by the intercepts of these ordinates with the R and S curves, laid off as the corresponding ordinates of the curve T.

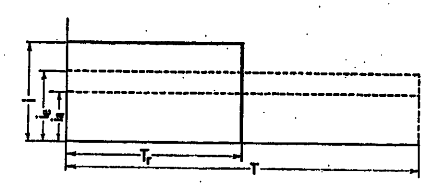

Fig. 6—Constant-Current Duty Cycle

Demand Factor

From the above discussion it will be seen that unless a statement of so called "demand factor" is coupled with a statement of frequency and duration, it means nothing and is more likely to be misleading than helpful.

In the above case, if the motors are rated for temperature rise, as they should be, by the r. m. s. input per motor, their rated input will be 84.5. If they are rated by the average input per motor their rated input will be 74.6, nearly 10 less, and equivalent to a continuous overload of over 13 per cent, involving an increase in temperature of about 23 per cent.

Commonly they will be rated by guess work and will be about twice too big for their work, involving increased annual charges and reduced efficiency.

If the motors are rated at 84.5, their united input

is 507. A demand equal to 507 will probably occur at least every 15 minutes, for which the demand factor is 1.0. But the duration of this demand will be only a few seconds at most.

If the motors are rated by guess work this demand factor may drop to about 0.5 which is not an uncommon value to find with values of p approximating 0.5. A low demand factor should mean a low value of p, not an excessive motor installation.

The probable maximum demand over any period of time, say 15 minutes, may be determined from the curve of time distribution of input. A mere statement of such demand, unless coupled with a statement of frequency, does not determine the character of the input, and is not a logical basis for the determination of rates.

TEMPERATURE RATING

Consider the individual duty cycle shown in Fig. 6. The input i is constant for the time $T_r = p\,T$. The

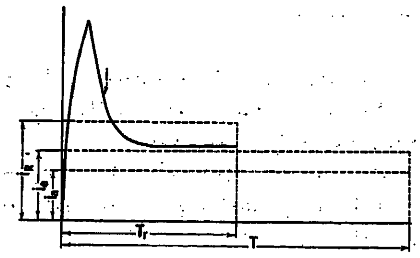

FIG. 7—VARIABLE-CURRENT DUTY CYCLE

equivalent average input for the time T is i_a. The heat liberated by the current i for the time $p\,T$ is $H_i = C\,W\,i^2\,p\,T$, where C is a constant and W the resistance of the circuit. Similarly, the heat liberated by the current i_a flowing for the time T is $H_a = C\,W\,i_a^2\,T$. The ratio of these is

$$H_i/H_a = \frac{i^2\,p}{i_a^2}.$$

But $i_a = p\,i$. Therefore $H_i/H_a = 1/p$.

Obviously more heat is liberated by the current i flowing for the time $p\,T$ than is liberated by the equivalent average current i_a flowing for the longer time T. The smaller is p the greater is this difference.

Assume that it is desired to determine the value of the current flowing for the time T that will liberate the same amount of heat as the current i flowing for the time $p\,T$. Let this desired current be i_e. Then $i^2\,p\,T = i_e^2\,T$, or $i^2/i_e^2 = i/p$. Therefore $i/i_e = (1/p)^{1/2}$

If, as in Fig. 7, the current i is not reasonably constant during the time $p\,T$, find its r. m. s. value i_R. Then $i_R/i_e = (1/p)^{1/2}$.

This is the basis on which conductor temperature rating may be established.

If the current i_e flows in indefinitely, the conductor will reach maximum temperature t_e in the time P_t depending on its radiation constant, etc. If in any case, conductors or fuses, the value of T should be greater than P_t, while $p\,T$ is less than P_t, then a new value of p must be found. It is $p_t = p\,T/P_t$. Then, for equal heat generation, the basis for rating is $i_r/i_{et} = (1/p_t)^{1/2}$, where i_{et} is the equivalent constant current for the time P_t. If $p\,T$ is longer than P_t then i_r is the same as the equivalent constant current. This would be the case for the distribution curve T in Fig. 5. Here the duty cycle period is taken at 15 min. But the input does not reach zero, so the r. m. s. value of input is the required equivalent constant-current rating. Otherwise than as pointed out above, the value of T does not enter into the formulas. It does not matter whether $p\,T$ be 5 seconds, 10 minutes or longer, provided T does not exceed P_t.

When, as in nearly all actual duty cycles, the starting peak is too pronounced to permit figuring it in as a slight increase in i during the time $p\,T$, the heat liberated by the peak must be computed separately. If the r. m. s. of the peak, in addition to the average running current i_a, is I_{pr} for the time $p_s\,T$, where, as above, $p_s = T_s/T$, then the equivalent constant current for the time T is $I_e = p_s^{1/2}\,I_{pr}$. The total equivalent constant current is then $I_{et} = i_e + I_e = i\,p^{1/2} + p_s^{1/2}\,I_{pr}$ (or if necessary, i_R may be used instead of i). The value of I_{pr} may be given in terms of i (or i_R) as $I_{pr} = c\,i$. Then $I_{et} = i\,(p^{1/2} + c\,p_s^{1/2})$. It is proposed to call the term $(p^{1/2} + c\,p_s^{1/2})$ the "duty cycle factor," and write it d. That is $I_{et} = i\,d$, or $i = I_{et}/d$. By taking I_{et} to be the rated constant current given in the N. E. C. Table I in Rule 18-b, then, by giving various values to d the appropriate rating of all such conductors can be determined for the corresponding duty cycles for which the actual running current is i, and the duty cycle factor is d.

It is assumed that in no case does T exceed P_t, or the time required to bring any conductor to its maximum allowable temperature with rated constant current flowing. If T is longer than P_t, new values of p and p_s must be found. If T_r is longer than P_t, then i or i_r is the equivalent running current, but a new value p_{st} must be found for p_s. The duty cycle factor then becomes $d = (1 - c\,p_{st}^{1/2})$.

We may then write down such conductor ratings, giving quite arbitrary values to d. The following table gives the corresponding ratings for a few rubber-covered conductors in conduit.

TABLE I

Size	N. E. C. Rating $d = 1.0$	Ratings for valus of d			
		$d = 0.866$	$d = 0.706$	$d = 0.50$	$d = 0.25$
No. 14	15	17	20	30	60

0.3/0"	275	316	362	550	1100
0.6/0"	450	518	592	900	1800

It is of interest to check these results with time ratings arrived at by test. Assume that $P_t = 30$ minutes. This is a safe assumption particularly for the larger sizes. Assume a duty cycle such as shown in Fig. 6 and let T be equal to P_t. For this duty cycle I_{pr} and p_s vanish, and $d = p^{1/2}$. The time ratings will be given by $i_{et} = i/p^{1/2}$ where i is the N. E. C. rating. The value of p is given by T_r/P_t.

The calculated results marked "Cal." are given below for various values of T_r, together with test results marked "Rep." taken from the Report of the Committee on Demand Factor Western Association of Electrical Inspectors, dated Aug. 20, 1920.

TABLE II

Size	N. E. C. Rating $d = 1.0$	Ratings for values of T_r in minutes							
		Cal. 22.5 min.	Rep. 30.10 min.	Cal. 15 min.	Rep. 15 min.	Cal. 10 min.	Rep. 10 min.	Cal. 5 min.	Rep. 5 min.

0.6/0"	450	518	610	592	750	780	915	1100	1225

The average deviation of the calculated results from the test results in the columns for 15 min., 10 min. and 5 min. respectively are − 29 amperes, + 9 amperes and + 2 amperes. The over-all agreement is remarkably close. Lack of knowledge of the method and refinement of the test referred to in the report mentioned, makes it impossible to compare individual results.

It is evident that the assumption $P_t = 30$ min. is somewhat low and probably too general. If P_t is increased the calculated results for the same values of T_r will be reduced.

It will be seen that if the rated continuous current and the value of P_t for any current-carrying device is given, the proper rating of the device for any other duty cycle for which d is known may be easily determined.

The duty cycle factor may be applied to a motor, thus: If the motor be name-plate rated at A amperes for M minutes, then M is the value of P_t for the motor. Let T, T_r, T_s, i_r and I_{pr} be determined for the duty cycle on which the motor is to operate. Then if T is no longer than P_t, the values of p and p_s may be taken from the duty cycle, and the duty cycle factor d determined. Then if A is no less than i_r/d, the given motor will carry the imposed duty for the time P_t without exceeding its rated temperature. If the duty cycle only is given then $A = i_r/d$ is the required rating for the time P_t of the proper motor for this duty. In general P_t will be taken as the time during which the duty will be imposed and may include a number of successive duty cycles.

If the value of P_t for a given type of motor is determined, the motor will carry the imposed duty cycle for a time P longer than P_t if $A = i_r/d \times P_t/P$ is the motor rating for the time P_t.

The R. M. S. Rating of Fuses

All that has been said above is equally true of the rating of fuses. Thus a fuse rated at 100 amperes constant current will also properly serve to protect a properly rated motor, for which $d = 0.25$ and $I_{et} = 200$ amperes. A larger fuse than this will not properly protect the motor against overheating. Therefore in selecting the proper fuse protection of a motor it is necessary to know not only its rating, but also its probable duty cycle of input and the corresponding value of d. Of course P_t will be different for fuses and for conductors in conduit. It will be different for conductors in conduit and for exposed conductors.

In cases where T is relatively long, it will be found that usually the starting peak has little effect in determining the value of I_{et} and can be neglected. If therefore, the rating of fuses, as now required by the Underwriters' rules, is based rather on the average value of starting peak than upon the value of I_{et} or total equivalent constant current, a fuse will be selected that will not protect the motor against undue temperature rise due to prolonged overloads. Numerous cases of such failure of fuse protection have been noted.

Consider the case in which $p = T_r/T = 0.64$ and $p_s = T_s/T = 0.16$. Determine the average running current i during the time T_r. Assume it to be nearly constant during the time $T_r - T_s$ so its r. m. s. value i_r may be taken equal to i. The equivalent constant current value for the time T is $i_e = p^{1/2}\, i = 0.8\, i$, on which basis a fuse may be selected for the running current only.

Now determine the r. m. s. value of the starting input I_{pr} above i over the time T_s. Its equivalent constant current over the time T is $I_e = p_s^{1/2} I_{pr} = 0.4\, I_{pr}$. Assume that $I_{pr} = 2.0\, i$ (or $I_{pr} = 2.0\, i_u$ if the running input during the time $T_r - T_s$ had been irregular enough to require that i_u be used instead of i). Then $I_e = 0.8\, i$ and the total equivalent constant current I_{et} is $1.6\, i$. Obviously the fuse to be selected would have little if any value during the running period as a protection to the motor against overloads up to 160 per cent of load.

Yet, if a smaller fuse be selected it will not carry the motor over its duty cycle. There are three possible solutions of this difficulty. 1. Let the motor start one set of fuses and run on another set of different rating. Quite generally the proper capacity of the running fuses will be larger than the proper capacity of the starting fuses. 2. Instead of the fuses, use a circuit breaker set to come out only if an excessive overload lasts for a period sufficiently long to overheat the motor. This may be accomplished by the use of time limit relays. The third, and usual, solution is to

use an oversized or underrated motor, capable of standing overloads for sufficient time to bring to rupturing temperature the fuse of the capacity required to carry over the total duty cycle.

The following table gives the equivalent constant current rating of fuses in terms of the average (or r. m. s.) running input i, for various values of the root-mean-square of the starting peak I_{pr} expressed in terms of i as overload, and for various values of P_{st}. It is assumed that T, or the running time of the motor, exceeds P_t, or the time it takes the fuse, rated at i amperes, to reach maximum rated temperature. In other words, so far as the fuse is concerned, after start the motor runs continuously. The rating formula then becomes $I_{et} = i + p_{st}^{1/2} I_{pr}$ or $I_{et} = i + p_{st}^{1/2} c\, i$ where $c\, i = I_{pr}$. Then $I_{et} = i\,(1 + c\, p_{st}^{1/2})$.

TABLE III

p_{st}	Values of $I_{pr} = c\,i$ (overload during start) 0.25 i	0.50 i	0.75 i	1.00 i	1.25 i	1.50 i
0.10	1.08 i	1.16 i	1.24 i	1.32 i	1.39 i	1.48 i
0.20	1.11 i	1.22 i	1.34 i	1.45 i	1.56 i	1.67 i
0.30	1.14 i	1.27 i	1.41 i	1.58 i	1.69 i	1.82 i
0.40	1.16 i	1.32 i	1.47 i	1.63 i	1.79 i	1.95 i
0.50	1.18 i	1.35 i	1.53 i	1.71 i	1.89 i	2.06 i
0.60	1.19 i	1.39 i	1.58 i	1.77 i		
0.70	1.21 i	1.42 i	1.63 i			
0.80	1.22 i	1.45 i				
0.90	1.23 i	1.47 i				
1.00	1.250 i	1.50 i				

Thus, if the r. m. s. starting peak of any motor is 25 per cent overload (in terms of the actual constant running current i) that is, if $I_{pr} = c\, i = 0.25\, i$, and if the duration of this peak, T_s, is $p_{st} = 0.70$ of P_t, then a fuse must be used whose equivalent constant-current rating is $1.21\, i$. That is to say the motor may run continuously at 21 per cent overload (in terms of i) without exceeding the required fuse rating.

The Underwriters' rules permit the marked rating of a fuse to be 80 per cent of its equivalent constant-current rating. In other words the fuse will carry 25 per cent over its marked rating indefinitely. Such equivalent ratings are included above the upper dotted line in the table. A fuse whose marked rating is i will serve in all such cases. It is also understood that approved fuses shall blow instantly at 50 per cent overload. Equivalent ratings less than this are included above the lower dotted line. Thus, for $I_{pr} = 0.75i$ (75 per cent motor overload during start) and $p_{st} = 0.40$ or $T_s = 0.4\, P_t$, a fuse rating must be used that will permit a continuous running overload of 47 per cent. A fuse rated at less than this will not permit the motor to start and run for the time P_t. If, on the other hand, the motor can operate successfully at a continuous reasonable overload, a larger fuse must be selected provided it is concluded that the motor may start and carry this overload for any material part of the time P_t

Assume this overload is $0.10\, i$, then the formula becomes $I_{et} = 1.1\, i + p_{st}^{1/2} I_{pr}$. For $p_{st} = 0.70$, and $I_{pr} = 0.55\, i$, the value of I_{et} is found to be $1.56\, i$. In other words, the fuse will permit the motor to run at 56 per cent overload. In general the r. m. s. value of the starting peak will also increase under such conditions, requiring a fuse still larger than this.

It is probable that for all conditions contained between the broken lines in the table double fuse arrangements should be used; either this or circuit breakers with time limit relays, the latter being always used for cases below the second dotted line.

As an example, consider an induction motor driving a pump. Assume that the running input after the water is in motion at normal velocity is 100 amperes per phase at 80 per cent power factor, therefore, the heating value of the input must be based on $i = 125$ amperes per phase. Let the motor be started by a compensator, or step reactance, so that the r. m. s. starting input will be 250 amperes at an average power factor of 60 per cent. The heating value of this input must be based on 425 amperes. Then, $I_{pr} = 425 - 125 = 300$ amperes. Therefore $I_{pr} = 300/125 = 2.4\, i$, (a value not given in the table). Assume that the duration of the starting period T_s, is 5 seconds. Assume $P_t = 15$ sec. Then $p_{st} = T_s/P_t = 0.33$, and $p_{st}^{1/2} = 0.57$.

The resulting value of $I_{et} = i + p_{st}^{1/2} I_{pr}$, is $125 + 0.57 \times 2.4 \times 125 = 296$ amperes. Therefore a fuse whose actual rating at $P_t = 15$ sec. is 300 amperes, will serve to start the motor and run it, but will also permit 300 amperes, or more than double full-load running input, to flow continuously. If a fused marked at 300 amperes for the same value of P_t were used it would pass 375 amperes continuously. A fuse marked 250 amperes will pass 300 amperes continuously and is probably the best rating to use, if a single set of fuses is required. As a matter of protecting the motor against prolonged over loads, one set of starting fuses rated at $0.57 \times 2.4 \times 125 = 171$ amperes may be used. Actually a fuse marked 150 amperes would serve. For the running side, a fuse marked 125 amperes would be the nearest safe size. Of course, if the name-plate continuous duty rating of the motor exceeds 100 amperes at 80 per cent power factor, larger fuses can be used with safety on both starting and running sides, remembering that since the motor will be operating at fractional load, the power factor during both start and run, under the actual duty conditions, will be lower than those given. If P_t is greater or less than the assumed value of 15 seconds, the value of I_{et} will be altered correspondingly.

All of this assumes that the name-plate rating of a motor means what it says, which generally is not the case.

THE OPERATING FACTOR p

The factor p is here designated as the *operating factor* because it determines that part of the time the motor is actually operating. Similarly $(1-p)$ determines that part of the time the motor is standing still. It is "dead time" when the driven machine is producing nothing. The higher the value of p, the more nearly continuous is the machine operation, the more the machine produces per day, and the less the overhead charges per unit of work accomplished. Every live factory manager spends much of his time in efforts to increase the value of p in his shop. By working the above method of computing resultant duty cycles backward, he can determine the existing average value of p from a curve-drawing instrument chart of input to his shop.

Let us say that $(1-p)$ is a measure of the time when work is being removed from tools and being replaced. It is therefore a measure of man-power hours, just as p is a measure of horse-power hours. Roughly speaking, $p = 0.5$ means that half the time is spent in manual work.

Also the higher the value of p the more nearly constant is the load on the generating plant. Its efficiency is thereby increased. Fewer interruptions due to momentary excessive overloads will occur. The distributing system costs less per kilowatt-hour transmitted.

Appendix

The accompanying tables, giving values of p^r, $(1-p)^{N-r}$ (Tables IV-1 and IV-2), and ${}^NC_r$ for values of N up to 20, (Tables V-1 and V-2), will be useful in applying (4), (6), and (7) from *Method of Calculation*.

For values of N greater than 20 the calculations of resultant duty cycles by the method given above

become quite cumbersome, but in such cases the equivalent duty cycle curve (the H curves in Figs. 5 and 5A) approaches so nearly to a straight line that the demand frequency may be determined with sufficient accuracy by the method given in "Standardized Flexible Distributing Systems in Industrial Plants," *General Electric Review*, Vol. 21, p. 176-285. Indeed, this method may be used for values of N less than 20 if p is sufficiently large, say if $N\,p$ is 10 or more and if R is 1000 or more.

$p_r^{1/2}$ =	0.71	0.74	0.78	0.81	0.84	0.87	0.90	0.92	0.95

TABLE VII - 2.
Duty Cycle Factors

C =	0.25	0.50	0.75	1.00	1.25	1.50
p_s	$c\,p_s^{1/2}$	$c\,p_s^{1/2}$	$c\,p_s^{1/2}$	$c\,p_s^{1/2}$	$c\,p_s^{1/2}$	$c\,p_s^{1/2}$
0.02	0.04	0.07	0.11	0.14	0.18	0.21
0.03	0.04	0.09	0.13	0.18	0.22	0.27
0.04	0.05	0.10	0.15	0.20	0.25	0.30
0.05	0.06	0.11	0.17	0.22	0.28	0.34
0.06	0.06	0.12	0.18	0.25	0.31	0.37
0.07	0.07	0.13	0.20	0.27	0.33	0.40
0.08	0.07	0.14	0.21	0.28	0.35	0.43
0.09	0.08	0.15	0.22	0.30	0.38	0.45
0.10	0.08	0.16	0.24	0.32	0.40	0.48
0.15	0.10	0.19	0.29	0.39	0.49	0.58
0.20	0.11	0.22	0.34	0.45	0.56	0.67
0.25	0.13	0.25	0.38	0.50	0.63	0.75
0.30	0.14	0.28	0.41	0.55	0.69	0.83
0.35	0.15	0.30	0.44	0.59	0.74	0.89
0.40	0.16	0.32	0.47	0.63	0.79	0.95
0.45	0.17	0.34	0.50	0.67	0.84	1.00
0.50	0.18	0.35	0.53	0.71	0.88	1.10

Thus if observation determines the values of p_r = 0.65, c = 0.75, and p_s = 0.15, then in Table VII-1 find $p_r^{1/2}$ = 0.81, and in Table VII-2, opposite p_s = 0.15, and under c = 0.75, find $c\,p_s^{1/2}$ = 0.29. The corresponding duty cycle factor is d = 0.81 + 0.29 = 1.10.

Discussion

V. Karapetoff: Let us take a machine shop, say with thirty identical machines, where thirty operators perform the same operation, for instance, turning a rod to a smaller diameter. Before each machine-tool raw parts are piled up, and when the whistle blows in the morning these men begin operations. Each one takes a piece, fastens it in the lathe, runs the cut, unfastens the piece and puts it back on another tray. Then he takes again another piece and performs the same operation. But all operators do not start at the same instant. Mr. Jones assumes that each machine is driven by an individual motor and as soon as the operation is completed the motor is stopped. Because the men do not start at the same instant, there is some phase displacement in the cycles, and Mr. Jones' problem is to evaluate, by the theory of probabilities, the demand on the power plant under those conditions.

In the case of a very large number of identical machines, the demand on the generating equipment cannot be very different from the average current; that is, if you superimpose those numerous duty cycles, you get practically a horizontal line. So that, in my estimation, with a large number of machines this whole complicated method of probabilities is unnecessary. Look at the tables in the paper. The coefficients in the binomial series are figured out to several places of decimals, to estimate the demand on a power plant. The author performs complete computations for the current, and shows in the end that according to the theory of probabilities the average current is 300 amperes. But the ordinary, common sense average is also exactly 300 amperes. Then, in another example, the difference between the current computed according to the formula of probabilities and the ordinary average is something like 2 amperes. One surely cannot estimate the equipment of an industrial plant down to 2 or 3 amperes.

On the other hand, let us assume that the number of motors is very small, for instance, in an office building with four elevators. Let it be required to estimate the curve of the power demand with any arbitrary time distribution of starting of these elevators. I doubt again, in this extreme case the advisability of applying the theory of probabilities. The theory of probabilities tells you what might happen with a large number of identical objects or events, the most probable combination is very likely to happen; but with only four objects such is not the case. It would not be safe to figure on the most probable curve of power demanded with four elevators starting at random. Now and then at least three of them may start at the same time, and even though this may not happen very often, it may mean an interruption of the service.

What we really want is not the most probable curve, but the danger curve of demand at starting; about this curve the theory of probabilities will give you no information whatever. Your ordinary common sense should tell you what to provide for. Thus, it seems as if we would have to eliminate from the scope of the paper both a large number of motors and a small number of motors.

The theory of probabilities is also not needed to compute the total kw-hr. per year. If I know the duty cycle of a motor, the number of such cycles per hour, and the number of machines, I can readily compute the total demand.

Mr. Jones computes separately the most probable current when a motor is running (with the starting rheostat out) and from it he determines the r. m. s. current for that part of the cycle; that is, the current that will give the same heating in the conductors as the actual current. Then he takes the starting period and figures out the r. m. s. starting current, over and above the running current. Finally he adds arithmetically those two r. m. s. currents; this last procedure is wrong. Since the heating is proportional to the square of the current, one cannot add effective currents arithmetically. It is necessary to take a square root of the sum of the squares. In the author's example, instead of a current of 507 amperes, I got only 372 amperes. However, when the theory of probabilities is used, it is not even permissible to take the sum of the squares; it is necessary to figure out the individual total currents, and to add their squares, each multiplied by the relative duration of time.

F. W. Owens: Mr. Jones' paper is a welcome innovation in the treatment of problems in electrical design. The introduction of new methods of attacking old problems is always stimulating and there is no doubt much more opportunity for the use in engineering practise of the methods of the theory of probabilities which have been of great service in the consideration of problems involving the treatment of mass data.

In applying new methods, however, the early attempts often lose sight of some of the niceties of the methods and may apparently lead to wrong results, or to a misinterpretation of results.

In the present paper of Mr. Jones, the problem considered, in essence, is that of designing the installation of generators and equipment, including protective devices, for furnishing current to a number of machines having regular duty cycles of known character, say a starting period drawing a heavy current, then an ordinary running period drawing less current, followed perhaps by an idle period. These characteristics of an individual machine being known, but the separate machines operating at random, it is necessary to estimate the amount of generating equipment and its character, and the nature and size of the various protective devices.

The *total* demand for current may readily be estimated without

any elaborate methods, since it is simply the product of the average amount drawn by one machine and the number of machines.

More elaborate methods are necessary, however in considering such questions as the total size of generating plant and size of protective devices. Mr. Jones does not treat the first of these questions directly, although the methods of probabilities are very likely to be of much service there.

The most interesting part of Mr. Jones paper rests upon the following assumption which does not seem to be made sufficiently prominent. If a variable current flows in a circuit, the result is the same if the various periods in which the current has a given value are grouped together instead of occurring at different times. Mr. Jones uses this assumption only in regard to total input and heating effects. As far as total current is concerned, the assumption is obviously true. In the case of heating phenomena, it is true as far as the amount of heat produced is concerned, for this is proportional (for a circuit with fixed characteristics) to the square of the current multiplied by the time. However the disposal of this heat is vitally affected by the order in which the various sized currents flow, as well as their magnitudes, particularly if fuses, conduction of heat, etc., are concerned. I do not wish to discuss this phase of the matter, except to make clear the nature of the assumption, but this would have to be considered carefully.

In treating the question of "heat input" as well as total current input, Mr. Jones uses the concept familiar to the actuary as Mathematical Expectation. In applying this to the total input he proceeds correctly, although the complicated process is not necessary, but in his treatment of the heat input, or r. m. s. total input, he makes a serious error of principle, which I shall try to point out. The current input is divided into two parts in his argument, starting current and ordinary running current. These are treated independently, each as if the other were not present, and the results are added numerically. This leads to the correct result for the current itself, but to a wrong result except when only one size current is treated. I will first show this in a very simple problem, then in the illustration Mr. Jones uses in his paper.

Consider two machines each with the following duty cycle. The machine uses 200 amperes for one second, then 100 amperes for three seconds, then is idle for two seconds, then repeats. For each machine, at any time, the probability that it is starting is 1/6, that it is running light is 3/6, and that it is idle is 2/6. Thinking of the starting currents and running currents as distinct, we would say with Mr. Jones that the probability that a machine is running is 4/6, that it is idle is 2/6. We would then have a probability (4/6) (4/6) = 16/36 that both machines are running, 2 (4/6) (2/6) = 16/36 that one machine is running and that the other is idle, (2/6) (2/6) = 4/36 that both machines are idle. The respective currents flowing are 200, 100 and 0 amperes. For the root mean square running current we would have

$$\sqrt{\frac{16}{36}(200)^2 + \frac{16}{36}(100)^2 + \frac{4}{36}(0)} = 149 \text{ amperes}$$

For the starting currents, thought of as extra currents, for each machine the probability of extra current flowing is 1/6, the probability of its not flowing is 5/6. The probability that both machines have extra current flowing is (1/6) (1/6) = 1/36. The probability that extra current is flowing in one machine and no extra current in the other is 2 (1/6) (5/6) = 10/36. The probability that neither machine is drawing extra current is (5/6) (5/6) = 25/36. The total amount of extra current drawn in the three cases is 200, 100 and 0 amperes, respectively. We have then for the r. m. s. of the extra starting current

$$\sqrt{\frac{1}{36}(200)^2 + \frac{10}{36}(100)^2 + \frac{25}{36}(0)} = 62 \text{ amperes}$$

Adding, we would have for total r. m. s. current 149 plus 62 = 211 amperes, which is the result of following Mr. Jones' process.

The correct procedure is as follows, since there is no distinction between ordinary running current and starting currents, and the *sum* should be squared, rather than treating the results separately. There are six different possibilities, according to what the motors are doing. If we use $(a\ b\ c)$ to mean a motors are starting, b motors are running steadily, c motors idle, these cases are (2 0 0), (0 2 0), (0 0 2), (1 1 0), (1 0 1), (0 1 1). The respective probabilities are (1/6) (1/6), (3/6) (3/6), (2/6) (2/6), 2 (1/6) (3/6), 2 (1/6) (2/6), 2 (2/6) (3/6). The respective currents are 400, 200, 0, 300, 200, 100 amperes. Hence for the root mean square input we should have

$$\sqrt{\frac{1}{36}(400)^2 + \frac{9}{36}(200)^2 + \left(\frac{4}{36}\right)(0) + \frac{6}{36}(300)^2 + \frac{4}{36}(200)^2 + \frac{12}{36}(100)^2} = 193 \text{ amperes}$$

instead of the 211 amperes obtained by the wrong process.

In general, if we have N machines, each with a probability p_1 of a current i_1, probability p_2 of a current i_2, . . . probability p_n of a current i_n, the probability of any given combination of k_1 machines drawing a current i_1, k_2 machines drawing current i_2, etc., is obtained from the term containing $p_1^{k1}\, p_2^{k2}\, p_3^{k3} \ldots$ in the expansion of $(p_1 + p_2 + p_3 + \ldots p_n)^n$. (See Hall and Knight, Higher Algebra, or any standard book on Probabilities).

If we apply this to the problem given by Mr. Jones, in which we have six machines each with a duty cycle of 20 seconds, using 200 amperes for 5 seconds, then 100 amperes for 5 seconds, then idle 10 seconds, the work may be tabulated as follows:

Number of motors drawing 200	100	0	$p = 1/4,\ q = 1/4,\ r = 1/2$ Probability π of the combination	Current i / 100	i^2 / 10,000	$4^6 (\pi\, i^2)$ / 10,000
6	0	0	$p^6 = 1/4^6$	12	144	144
5	1	0	$6\,p^5 q = 6/4^6$	11	121	726
4	2	0	$15\,p^4 q^2 = 15/4^6$	10	100	1500
3	3	0	$20\,p^3 q^3 = 20/4^6$	9	81	1620
2	4	0	$15\,p^2 q^4 = 15/4^6$	8	64	960
1	5	0	$6\,p\,q^5 = 6/4^6$	7	49	294
0	6	0	$q^6 = 1/4^6$	6	36	36
5	0	1	$6\,p^5 r = 12/4^6$	10	100	1200
4	1	1	$30\,p^4 q\,r = 60/4^6$	9	81	4860
3	2	1	$60\,p^3 q^2 r = 120/4^6$	8	64	7680
2	3	1	$60\,p^2 q^3 r = 120/4^6$	7	49	5880
1	4	1	$30\,p\,q^4 r = 60/4^6$	6	36	2160
0	5	1	$6\,q^5 r = 12/4^6$	5	25	300
4	0	2	$15\,p^4 r^2 = 60/4^6$	8	64	3840
3	1	2	$60\,p^3 q\,r^2 = 240/4^6$	7	49	11,760
2	2	2	$90\,p^2 q^2 r^2 = 360/4^6$	6	36	12,960
1	3	2	$60\,p\,q^3 r^2 = 240/4^6$	5	25	6000
0	4	2	$15\,q^4 r^2 = 60/4^6$	4	16	960
3	0	3	$20\,p^3 r^3 = 160/4^6$	6	36	5760
2	1	3	$60\,p^2 q\,r^3 = 480/4^6$	5	25	12,000
1	2	3	$60\,p\,q^2 r^3 = 480/4^6$	4	16	7680
0	3	3	$20\,q^3 r^3 = 160/4^6$	3	9	1440
2	0	4	$15\,p^2 r^4 = 240/4^6$	4	16	3840
1	1	4	$30\,p\,q\,r^4 = 480/4^6$	3	9	4320
0	2	4	$15\,p\,q^2 r^4 = 240/4^6$	2	4	960
1	0	5	$6\,p\,r^5 = 192/4^6$	2	4	768
0	1	5	$6\,q\,r^5 = 192/4^6$	1	1	192
0	0	6	$r^6 = 64/4^6$	0	0	0
						99,840

For root-mean-square current we have

$$\sqrt{\left(\frac{99,840}{4^6}\right)(10,000)} = 493. +$$

By Mr. Jones' method, the result was 507 amperes instead of the correct 493—remarkably close for a faulty process.

It is obvious that the numerical computations become rapidly more difficult as the number of machines, or number of different sized currents is increased. The tables in Mr. Jones paper do not help in this as they are of no value when the number of currents not zero is two or more.

It should further be remarked that those unfamiliar with the subject of probabilities should be careful not to understand that Mr. Jones means actually to predict what currents will really flow in the circuits involved at any time, but that the figures are to be understood as averages to be expected. Neither the theory of probabilities nor any thing else can predict the actual happenings, except in this sense of averages, although it can state what is most likely to happen, and the degree of probability of either the most likely, or some other, occurrence.

Bassett Jones: I regret that the error pointed out by V. Karapetoff and F. W. Owens exists in the method. The same error has been recently pointed out to me from two other sources, also with the remark that the error in result is small. As a matter of fact this error has not been picked up in any actual case while the method has been in use during the past several years. In other words, measured results have always compared so closely with calculated results that no reason for doubt developed.

The method has its limits, of course, but a method with limits is better than no method at all. Probabilities is merely a way of guessing intelligently. By its use, guesses have proved to be nearly correct. Without it, the margin of deviation between the guess and the actuality in many cases, has proved to be considerable.

The necessary correction is quite obvious. It is in the approximation used (See Figs. 1 and 2.) The running current i should be taken for the time T_r-T_s'. The starting current, I_m, and *not* $I_P = I_m - i$, should be taken for the time T_s'. In Fig. 3, take i for the time $T_r - T_s$, I_s for the time T_s, and I_m for the time T_s'. In other words, the proper divisions of the duty cycles are vertical, *not* horizontal.

Then, in Fig. 1, $p_r = T_r - T'_s/T$, $p_s = T_s'/T$, and similarly for Figs 2, and 3.

The calculations performed exactly as directed with these changes, give the corrent r. m. s. values. The average values are the same with the correct and the incorrect method.

I am sorry that Mr. Karapetoff's doubts as to the value of the method as a whole are not borne out by actual experience. It has been used to determine the probable average, and probable frequency and amount of peaks for four elevators. We have not heard of any shut-downs due to the wrong selection of either fuses or circuit breakers. It has been used to determine the load distribution for 20 elevators—not all of the same capacity, nor on the same service. Here again, no shutdowns have been reported. And because the method proved useful in this case, the tables were included up to $n = 20$.

I believe the method, as applied to averages, is used in life insurance when n considerably exceeds 20, say a million or more, and many millions of dollars are invested accordingly. Surely the probable starting and stopping of a motor is a certainty compared to the probable period of a man's life.

This does not mean that the method should be used when n is large. Then the more approximate method given by me in "Standardized Flexible Distributing Systems in Industrial Plants" is available, all as pointed out in the paper.

Let me add that the description of the method looks more complicated than it actually turns out to be in practise. Much of it can be graphed for ready reference.

Queenston-Chippewa Development of the Hydro-Electric Power Commission of Ontario

BY F. A. GABY
Fellow, A. I. E. E.
Chief Engineer, Hydro-Electric Power Commission of Ontario

Review of the Subject.*—This paper covers a general description of the entire Queenston-Chippewa development of the Hydro-Electric Power Commission of Ontario, on the Canadian side of the Niagara River, which will have an ultimate capacity approximating 650,000 h. p.*

The general scheme of the development comprises an intake structure in the Niagara River at Chippewa; the utilization, by deepening and widening, of the Welland River as a part of the waterway for 4½ miles; the construction of a canal 8½ miles long from the Welland River to the forebay and screen house on the top of the Niagara escarpment about a mile south of Queenston village; and the construction and equipment of the power house in the gorge immediately below the forebay.

The entire design was carried out with the express object of producing power most efficiently from the available water at the lowest possible cost.

Important features of the waterway are described, covering the special design of intake works to avoid ice troubles; the control gate in the canal; the concrete lined canal channel, and the consideration given the design of canal, forebay, screen house, penstocks and draft tubes to obtain the best hydraulic results.

Of special interest to hydroelectric engineers is the use of the largest capacity turbines and vertical shaft generators that have ever been constructed; the size of the step-up transformers; the design and arrangement of relay systems and of switching equipment to take care of the extremely heavy short-circuit conditions; and features of the design of the power house whereby in every 50-foot length of building all equipment for one 45,000-kv-a. unit, covering penstock, turbine, generator, switching equipment, transformers and outgoing line, is accommodated; the provision of the main floor in the generator room at the top of the generator frame; also the use of a control pedestal on main floor at each unit whereby the turbine and generator may be conveniently operated.

Power for the plant service equipment is obtained from two separate small units, entirely independent of the main units, and 25-cycle current is used exclusively for service equipment motors, including the 300-ton crane equipment and the elevators.

CONTENTS

It is the intent of this paper to give an outline only of the engineering features involved in the undertaking. Under the term "Development" is included only the plant involved in supplying power to the 12-kv. busses, but as the transformer station is combined with the generating station the paper will deal with both features.

Throughout the period of preliminary study of the development and later as the design progressed, continuous use was made of models of the various structures in order that the mathematical analysis might be reinforced by actual demonstrations under the assumed conditions. Such models were made for the studies of the intake, the bends in the canal, the transitions, the diffuser at the mouth of the forebay, and on the draft tubes and station substructure. A calculation table for determining short-circuit conditions was also developed. It is believed that the beneficial result of such studies and of the care taken in the design of what are often considered minor elements of a power development will be demonstrated when complete test results are available.

Such tests as have already been made indicate conclusively that at least as high an over-all efficiency from head water to tailwater has been secured, as has ever before been obtained.

Presented at the Annual Convention of the A. I. E. E. Niagara Falls, Ont., June 26-30, 1922.

True conservation in the use of the waters of the Niagara River for power purposes demands that practically the whole fall of approximately 327 feet between Lake Erie and Lake Ontario be utilized. The various power plants now operating at Niagara Falls vary in

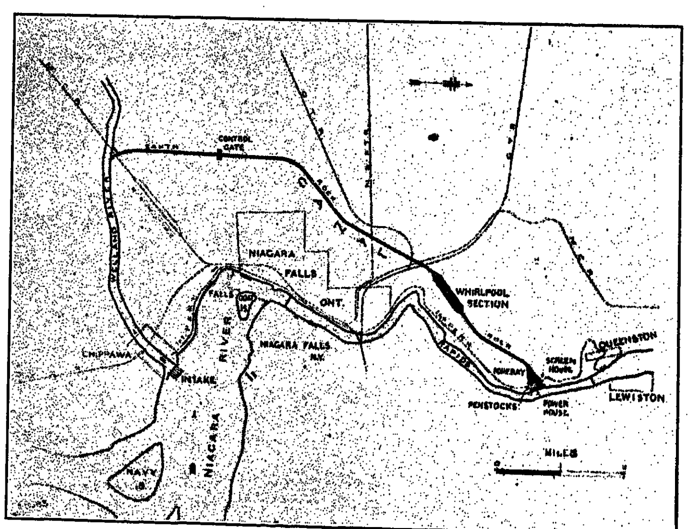

FIG. 1—MAP OF THE DEVELOPMENT

head from 130 feet to 210 feet, and with widely different degrees of efficiency.

The Queenston-Chippewa power development, the first unit of which was operated first in December 1921,

will have a normal operating head of 305 feet when the installation is complete. The conservation of head effected by the reduction of hydraulic losses to a minimum, and by refinements in the design of the various essential elements of the project as a whole, has resulted in the production of a power development which is believed to represent the best in modern engineering practise.

The plant in operation and in course of construction will consist of five 45,000 kv-a., 187.5 rev. per min. units, generating power at 12 kv., three-phase, 25 cycles, which in turn is transformed to 110 kv. for transmission. Ultimately the plant will consist of nine or ten units, with an ultimate capacity of 575,000-650,000 horse power. The subsequent units in all probability will have greater capacity than those being installed at present. Two of the units are now in service developing 110,000 horse power, which is being delivered to the existing 110-kv. system at Niagara Falls for transmission to Toronto, London and Windsor (opposite Detroit), Sarnia and intermediate municipalities.

A glance at the accompanying map, Fig. 1, will indicate the relation of the various works comprising the development. Water is taken from the Niagara River about one mile above the Falls, is conveyed through the improved section of the Welland River, a distance of 4½ miles, thence by a canal 8½ miles long, to the forebay and screen house located on the Niagara River about one mile south of the village of Queenston. From the screen house, steel penstocks encased in concrete carry the water down the cliff to the power house, from which it passes to the Niagara River.

Construction work was carried on almost exclusively by an electrically driven plant, the electrical load at times being in the neighborhood of 20,000 horse power.

Intake

On the Niagara River one of the great obstacles to securing continuity of service is the annual formal tion and flow of ice. Great fields of ice, formed in Lake Erie with its shallow bays and shores, are discharged down the Niagara River every spring, and at frequent intervals during the winter, under the proper coincident wind and temperature conditions. The river itself develops considerable anchor and frazi-ice at times of low temperature, but it never freezes over.

The site of the intake of the Queenston-Chippewa power development, at the mouth of the Welland River is favorable in that floating ice in the Niagara River does not ordinarily follow the shore lines at this point; but the smooth gradient of the river surface and the comparatively shallow water with its low velocity is unfavorable.

The removal of water in large quantities from a river heavily charged with ice is always a difficult problem, but is much simplified when a natural break in the river surface, accompanied by a sudden drop, gives a source of power for the separation of floating ice, and for its continuous disposal. The use of a horizontal diaphragm to skim the surface water with its burden of ice from the lower strata, thus permitting the upper layer to be accelerated and removed clear of the intake without objectionable eddies, while the lower layer clear of all ice is changed in direction and flows through the intake into its new channel, gives a positive and satisfactory solution.

When the natural conditions do not permit such an arrangement, as in the present case, radically different measures must be taken. To confirm certain ideas developed as a result of many years' experience and observation of the Commission's engineers, on the present plants operating on the Niagara River, an extended series of tests and experiments on large-size models were made, these models duplicating to scale the topographical conditions existing at the site of the intake. The result of these experiments contributed to the preparation of a design which, it is

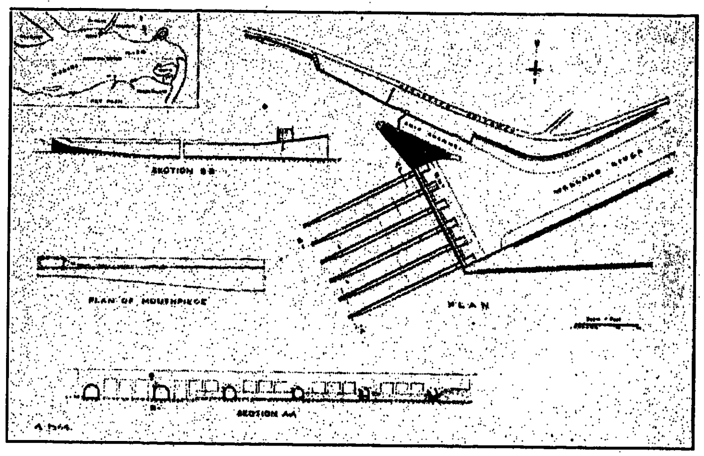

Fig. 2—Intake

confidently expected, will operate in such a way as to keep the plant wholly free of this ice menace.

The illustration of the intake, Fig. 2, shows clearly the physical nature of the design. The complete intake structure is approximately 1100 feet in length and is made up of an entrance with lock gates for navigation, a bulkhead section, and the intake proper, the latter combining two forms of intake; the conventional or surface intake consisting of a concrete barrier or boom with fifteen openings each 18 feet in width, normally having eight feet of submergence, which submergence can be increased however by means of drop gates, to any amount up to the full depth of water or 35 feet; and the submerged intake consisting of gathering tubes or draft distributors, six in number and 675 feet in length. Water enters the tubes along a distance of 500 feet through a slot on their upstream sides. These tubes are controlled by gates similar to those on the surface intake, and comprise an outer tapering section, wherein the velocity is maintained constant, with a longer inner section of twenty-foot

diameter, wherein the velocity regularly increases with respect to distance along its axis. Diffuser sections are situated at the inner end to reduce the velocity to that existing in the Welland River section with as little loss as possible.

The slot on the upstream side of the tubes varies in width from one foot at the shore end to four feet at the outer end, where the slot ends. A restricted section, shaped somewhat like a bathtub, forms a mouthpiece for each tube, its function being to give the required initial impulse to the sucking slot.

The head at any point on the tube, causing flow through the slot, is the resultant of three components (a) the initial loss due to the primer, (b) the total of the induced losses due to the increments of angular flow through the slot, and (c) the total cumulative friction head loss in the tube, including velocity head.

The designed rate of total inflow through each slot is 2500 cubic feet per second along the axis of the tube. The rate of inflow per running foot of slot has not been chosen uniform, however, because the river naturally feeds more water at the outer end of the tubes than nearer the shore. This variation has been chosen in the ratio of four at the outer end to three at the inner end of the slot, which agrees with the natural flow distribution under present river conditions. The total head loss in each gathering tube to the end of the diffuser, with a flow of 2500 cu. ft. per sec. in each tube, will be only three-tenths of a foot.

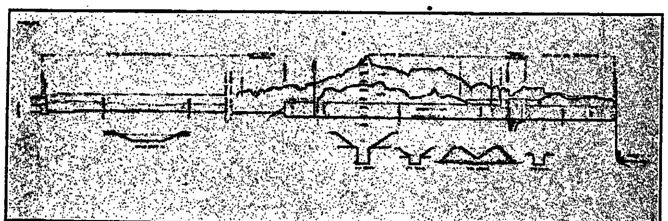

FIG. 3—PROFILE OF CANAL

During the greater part of the year, when no ice is running in the river, the intake gates of both surface and submerged intakes will be open. The navigation channel will also be open and the velocity through the intake at any point will therefore, be very low, so that the head loss under ordinary conditions will be negligible.

THE CANAL

For a great many miles above its mouth the Welland River is a sluggish stream, meandering slightly in a depression that can hardly be called a valley. This stream for four and a half miles forms the first reach of the canal, and its low banks provided a suitable disposal area for much of the material excavated in the process of straightening and deepening the channel. The radius of curvature of some of the bends is increased in the new alinement, but in the main the old channel location is followed. The velocity under full-load conditions will be low, being limited by the scouring velocity for the clay soil through which the improved channel is cut. The canal leaves the river channel near the crossing of the Michigan Central Railway and turning through a deflection of 28 degrees takes a course almost due north for over three miles. The ground surface (Fig. 3) rises fairly uniformly until the crossing of Lundy's Lane is reached. The elevation here is over 660 feet above sea level or 100 feet above the water surface of the intake. The earth overburden is quite heavy (Fig. 4) for the whole of this portion of the canal, the bottom grade of the canal cutting the rock surface one mile from the Welland River. The maximum rock elevation which is 604, is beyond Lundy's Lane and therefore not coincident with the maximum earth surface elevation but the profiles of rock and earth surface are roughly parallel to each other. Just beyond Lundy's Lane there is the maximum bend with a deflection of 51 degrees,

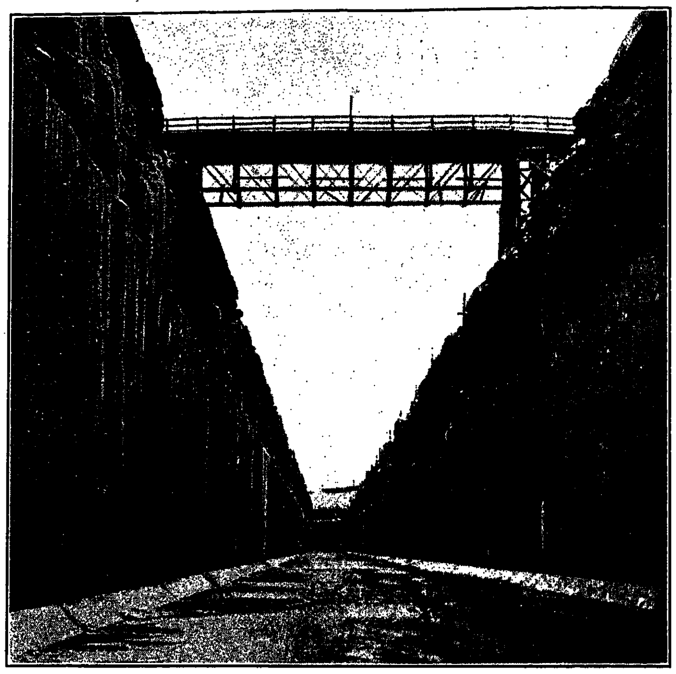

FIG. 4—CANAL IN ROCK SECTION

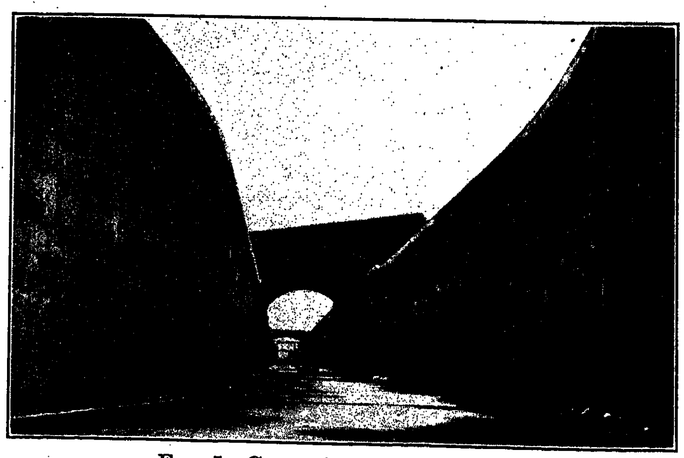

FIG. 5—CANAL SHOWING BRIDGES

and at intervals of a little over a mile each, two other bends of 27 and 31 degrees. The earth over-burden continues fairly uniform (Fig. 5) for three miles beyond Lundy's Lane until Bowman's Ravine is reached.

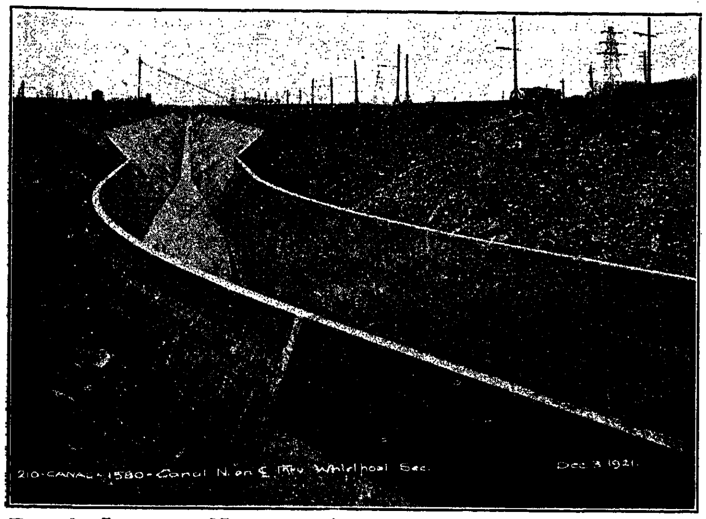

FIG. 6—LOOKING NORTH— CANAL AT WHIRLPOOL SECTION

Here, both rock and earth surfaces fall sharply to an elevation far below the grade of the finished canal. The ravine here is apparently an old river channel through which the Niagara River in preglacial times flowed toward Lake Ontario. At the time the construction started this was the course of a small stream having its outlet at the Whirlpool. The ravine crossing, Fig. 6, is made on a fill and the ravine itself proved a convenient disposal area for about 1,500,000 cubic yards of excavated material.

Where the canal section again enters the rock cutting beyond the ravine, the earth over-burden becomes very light, in some places amounting to only a foot or so. Two deflections are made in the remaining two miles of the canal, one of 33 and one of 47 degrees. A quarter mile beyond the second of these curves the forebay (Fig. 7) is reached.

The Design of the Earth and Rock Sections. Long continued investigations were made of available information on roughness factors for large canals in earth and rock with and without concrete lining. One of the conclusions reached was that Kutter's formula should be used. The roughness factors used in the hydraulic studies were 0.035 for the river section and 0.012 for the concrete lined rock section.

Forty-eight hundred feet from the Welland River the rock surface cuts the bottom grade of the canal. The shape and size of the channel begins to change here, a transition to the rectangular cross-section of the rock section taking place.

A thorough study of excavating machinery and methods that was carried on in 1916 and 1917, indicated the economy of using heavy equipment capable of loading the spoil from the bottom of the cut into cars at the surface. A cut at least forty-eight feet in width was necessary to permit these large shovels to work and economy studies indicated that the saving effected by the large shovels would compensate for any other losses that the wide cut occasioned.

Economy Studies. The procedure in determining the economic proportions of the canal will be outlined briefly. It is essential that the canal should carry full quantity of water required under the lowest conditions of water level in the Niagara River. A series of canals was designed each of forty-eight-foot width and capable of carrying the required supply of water with uniform flow and with low water in the Niagara River at Chippewa. The first of the series was of such a depth that the velocity would be four feet per second and the designed slope of the bottom and water surface was the requisite slope for uniform flow, the others being designed for higher velocities.

The cost of each of these canals was figured and a curve plotted between low water velocity and cost. From this curve the tangents were scaled for various low water velocities. For low velocity the canals will be deep and therefore costly. For very high velocities the canals will be shallow but the slope so steep that the cost will be greater than for moderate velocities, the canal of minimum cost being for a velocity intermediate to the greatest and least investigated. The canal of minimum cost, however, is not necessarily the most economical. Enlargement will reduce the friction loss and consequently increase the head and power output at a cost which up to a certain point is both justifiable and economic. The determination of the economic size is based not on low water but on the mean water conditions. For each of the canals already designed, the profile of the water surface corresponding with mean water level in the Niagara River is computed, thus determining the friction loss

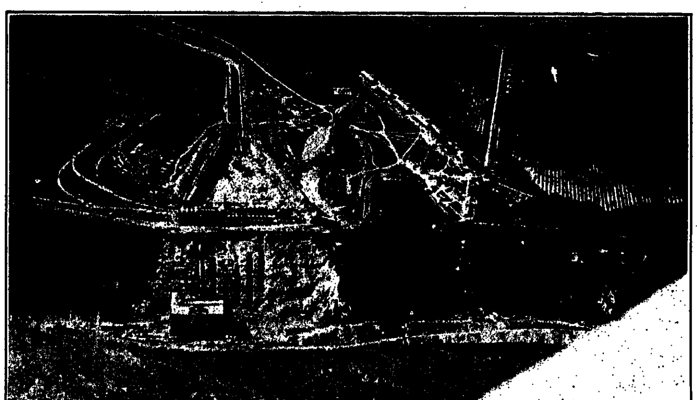

FIG. 7—VIEW OF FOREBAY AND POWER HOUSE

and lost power at mean water. Tangents were scaled from a lost power curve plotted from these results and were divided into the tangents from the lost power curves for each low water velocity. The dividend in each case is the cost in dollars per horse power of

diameter, wherein the velocity regularly increases with respect to distance along its axis. Diffuser sections are situated at the inner end to reduce the velocity to that existing in the Welland River section with as little loss as possible.

The slot on the upstream side of the tubes varies in width from one foot at the shore end to four feet at the outer end, where the slot ends. A restricted section, shaped somewhat like a bathtub, forms a mouthpiece for each tube, its function being to give the required initial impulse to the sucking slot.

The head at any point on the tube, causing flow through the slot, is the resultant of three components (a) the initial loss due to the primer, (b) the total of the induced losses due to the increments of angular flow through the slot, and (c) the total cumulative friction head loss in the tube, including velocity head.

The designed rate of total inflow through each slot is 2500 cubic feet per second along the axis of the tube. The rate of inflow per running foot of slot has not been chosen uniform, however, because the river naturally feeds more water at the outer end of the tubes than nearer the shore. This variation has been chosen in the ratio of four at the outer end to three at the

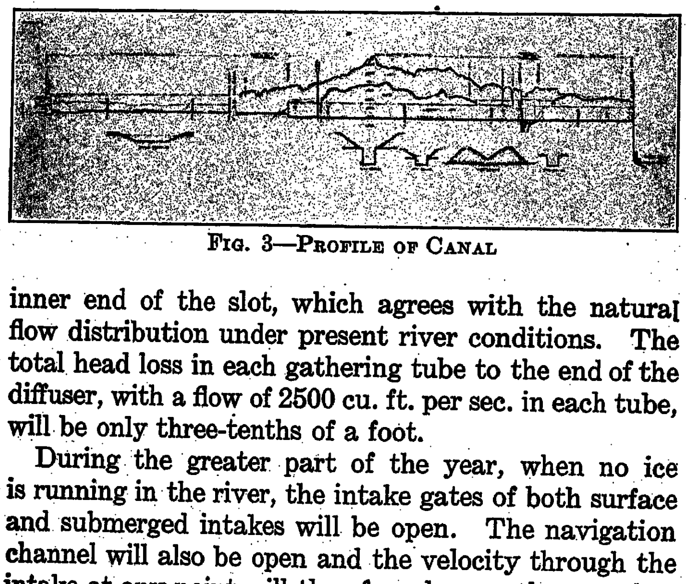

FIG. 3—PROFILE OF CANAL

inner end of the slot, which agrees with the natural flow distribution under present river conditions. The total head loss in each gathering tube to the end of the diffuser, with a flow of 2500 cu. ft. per sec. in each tube, will be only three-tenths of a foot.

During the greater part of the year, when no ice is running in the river, the intake gates of both surface and submerged intakes will be open. The navigation channel will also be open and the velocity through the intake at any point will therefore, be very low, so that the head loss under ordinary conditions will be negligible.

THE CANAL

For a great many miles above its mouth the Welland River is a sluggish stream, meandering slightly in a depression that can hardly be called a valley. This stream for four and a half miles forms the first reach of the canal, and its low banks provided a suitable disposal area for much of the material excavated in the process of straightening and deepening the channel. The radius of curvature of some of the bends is increased in the new alinement, but in the main the old channel location is followed. The velocity under full-load conditions will be low, being limited by the scouring velocity for the clay soil through which the improved channel is cut. The canal leaves the river channel near the crossing of the Michigan Central Railway and

turning through a deflection of 28 degrees takes a course almost due north for over three miles. The ground surface (Fig. 3) rises fairly uniformly until the crossing of Lundy's Lane is reached. The elevation here is over 660 feet above sea level or 100 feet above the water surface of the intake. The earth overburden is quite heavy (Fig. 4) for the whole of this portion of the canal, the bottom grade of the canal cutting the rock surface one mile from the Welland River. The maximum rock elevation which is 604, is beyond Lundy's Lane and therefore not coincident with the maximum earth surface elevation but the

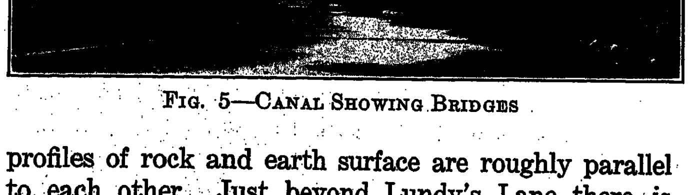

FIG. 5—CANAL SHOWING BRIDGES

profiles of rock and earth surface are roughly parallel to each other. Just beyond Lundy's Lane there is the maximum bend with a deflection of 51 degrees,

and at intervals of a little over a mile each, two other bends of 27 and 31 degrees. The earth over-burden continues fairly uniform (Fig. 5) for three miles beyond Lundy's Lane until Bowman's Ravine is reached.

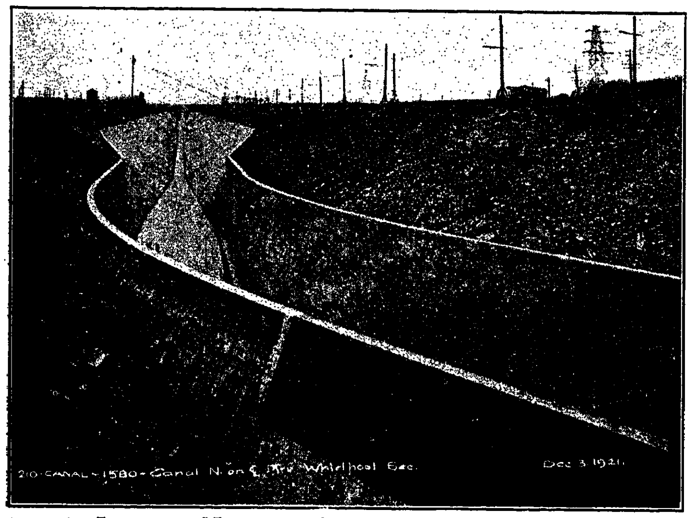

FIG. 6—LOOKING NORTH— CANAL AT WHIRLPOOL SECTION

Here, both rock and earth surfaces fall sharply to an elevation far below the grade of the finished canal. The ravine here is apparently an old river channel through which the Niagara River in preglacial times flowed toward Lake Ontario. At the time the construction started this was the course of a small stream having its outlet at the Whirlpool. The ravine crossing, Fig. 6, is made on a fill and the ravine itself proved a convenient disposal area for about 1,500,000 cubic yards of excavated material.

Where the canal section again enters the rock cutting beyond the ravine, the earth over-burden becomes very light, in some places amounting to only a foot or so. Two deflections are made in the remaining two miles of the canal, one of 33 and one of 47 degrees. A quarter mile beyond the second of these curves the forebay (Fig. 7) is reached.

The Design of the Earth and Rock Sections. Long continued investigations were made of available information on roughness factors for large canals in earth and rock with and without concrete lining. One of the conclusions reached was that Kutter's formula should be used. The roughness factors used in the hydraulic studies were 0.035 for the river section and 0.012 for the concrete lined rock section.

Forty-eight hundred feet from the Welland River the rock surface cuts the bottom grade of the canal. The shape and size of the channel begins to change here, a transition to the rectangular cross-section of the rock section taking place.

A thorough study of excavating machinery and methods that was carried on in 1916 and 1917, indicated the economy of using heavy equipment capable of loading the spoil from the bottom of the cut into cars at the surface. A cut at least forty-eight feet in width was necessary to permit these large shovels to work and economy studies indicated that the saving effected by the large shovels would compensate for any other losses that the wide cut occasioned.

Economy Studies. The procedure in determining the economic proportions of the canal will be outlined briefly. It is essential that the canal should carry full quantity of water required under the lowest conditions of water level in the Niagara River. A series of canals was designed each of forty-eight-foot width and capable of carrying the required supply of water with uniform flow and with low water in the Niagara River at Chippewa. The first of the series was of such a depth that the velocity would be four feet per second and the designed slope of the bottom and water surface was the requisite slope for uniform flow, the others being designed for higher velocities.

The cost of each of these canals was figured and a curve plotted between low water velocity and cost. From this curve the tangents were scaled for various low water velocities. For low velocity the canals will be deep and therefore costly. For very high velocities the canals will be shallow but the slope so steep that the cost will be greater than for moderate velocities, the canal of minimum cost being for a velocity intermediate to the greatest and least investigated. The canal of minimum cost, however, is not necessarily the most economical. Enlargement will reduce the friction loss and consequently increase the head and power output at a cost which up to a certain point is both justifiable and economic. The determination of the economic size is based not on low water but on the mean water conditions. For each of the canals already designed, the profile of the water surface corresponding with mean water level in the Niagara River is computed, thus determining the friction loss

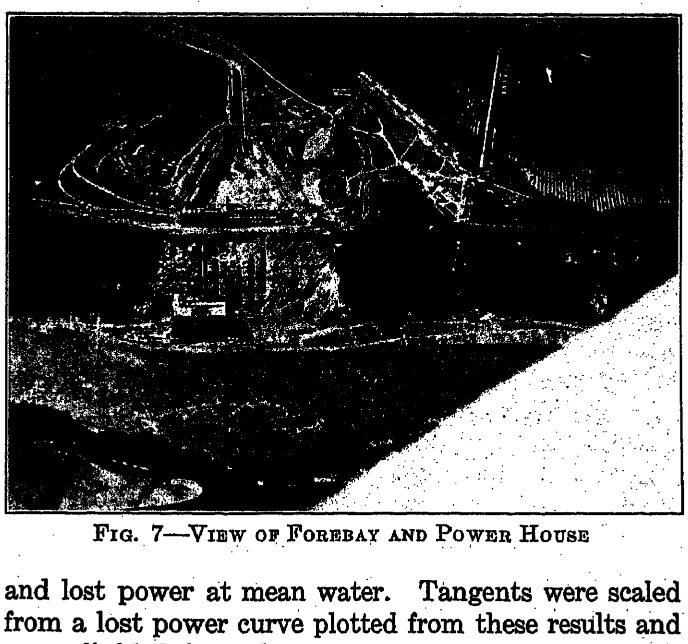

FIG. 7—VIEW OF FOREBAY AND POWER HOUSE

and lost power at mean water. Tangents were scaled from a lost power curve plotted from these results and were divided into the tangents from the lost power curves for each low water velocity. The dividend in each case is the cost in dollars per horse power of

the power gain at the particular velocity to which the result applies. These dividends are now plotted against low water velocity, constituting an "economy curve" from which the economic velocity may be selected.

Slight changes in the head give increases in power without appreciable change in operating or maintenance costs, and the only essential charge against power gained by slight enlargements of the canal is the interest charge on the cost of enlargement. The economic velocity, therefore, is one corresponding with the total cost per horse power on the economy curve considerably higher than the total average cost of the whole development.

Control Works. A control gate (Fig. 8) is located at station 97+00 which is near the beginning of the rock section. This is an electrically operated Stony sluice of forty-eight foot clear span, the full width of the rock section. The use of two gates with a central pier was considered, but the single gate was found to be the most advantageous, as it provided an unobstructed waterway with a consequent reduction in friction losses. The gate, which is supported on steel towers with a concrete substructure, weighs approximately 100 tons, and is provided with two hoisting mechanisms and two counterweights. The gate when at the top of its run is sufficiently above the water surface in the canal to permit a tug to pass beneath.

Fig. 8—Control Gate

Whirlpool Section. Bowman's Ravine west of the whirlpool was crossed on a rock fill, the cross-section of the canal being changed from a forty-eight-foot rectangular section to a trapezoidal section with ten-foot bottom width and side slopes of one vertical and one-half-to-one horizontal. This cross-section was designed to be as large as the rock section at the extreme minimum water level at which operation of the generating station could take place, and of course, the trapezoidal shape gives it greater area than the rectangular for any water surface elevation greater than this. The whirlpool section is lined with concrete, carrying considerable reinforcement to protect the lining, in the event of settlement of the fill. It was also anticipated that should the canal be emptied at any future time, this lining would not withstand the inward pressure of the water with which the supporting rock fill would be saturated, so vents of sufficient size to drain the fill as quickly as the water could be drawn down in the canal, were provided near the top and bottom of the channel. These vents are protected with light wooden covers, which will be dislodged under a comparatively small excess of inward pressure.

Concrete Lining. Economic considerations prompted the lining of the canal with concrete. The height of the lining was fixed slightly lower than the profile of the water surface existing when the load conditions on the plant are a maximum and the Niagara River flow is a minimum. Thus, at all times the lining will be protected by submergence against the action of frost. The thickness of the lining varied with the rock over-break but averaged about 20 inches, and where necessary, steel dowels were used to anchor the concrete lining to the rock face.

It was held that extreme smoothness of surface was not the only determining factor, but that precise alinement is also a most important element in the reduction of hydraulic losses. Great care was taken to obtain a smooth surface by the use of steel forms, and a positive and rigid method of form setting was devised, which insured almost perfect alinement. The results obtained were very excellent, and it is expected that when opportunity offers to test experimentally the efficiency of lined section of the waterway, extremely low roughness factors will be realized.

The Forebay. The kinetic energy of the water at the end of the canal, and at entrance to the forebay was too great to neglect in the design. Necessarily, in the forebay the velocity of the water will be so greatly reduced as to make its velocity head negligible, and some means therefore had to be found to regain the energy in the water as its velocity decreased. The same difficulty is experienced here as in any transition in which velocity is being reduced, namely, that the stream lines tend to follow paths of their own course, unless the design is very carefully worked out and the angle of divergence properly fixed.

A great mass of experimental data on diverging tubes for air and water is available, indicating that a

ten-degree angle of flare is the most efficient. In order to confirm for this particular case the conclusions arrived at from other experiments, a model of the forebay was built in the Hydraulic Laboratory of the University of Toronto, and tried out with nineteen transitions of various angles and lengths. These experiments confirmed the conclusions reached from other available data, and also provided, in their quantitative results, a basis for the economic design of a transition that would cost no more than was justified by the gain in power from reclaimed head. These experiments involved measurements of extremely small differences of water level, necessitating observations to thousandths of an inch as the velocities in the model were quite low—only one-twelfth of the corresponding velocity in the full-size structure. Notwithstanding this condition, the results were, with very few exceptions, quite consistent and resulted in the design of the "diffuser" structure inserted in the forebay transition, providing two entrance passages into the forebay, each with a diverging angle of ten degrees (Fig. 9). It consists of

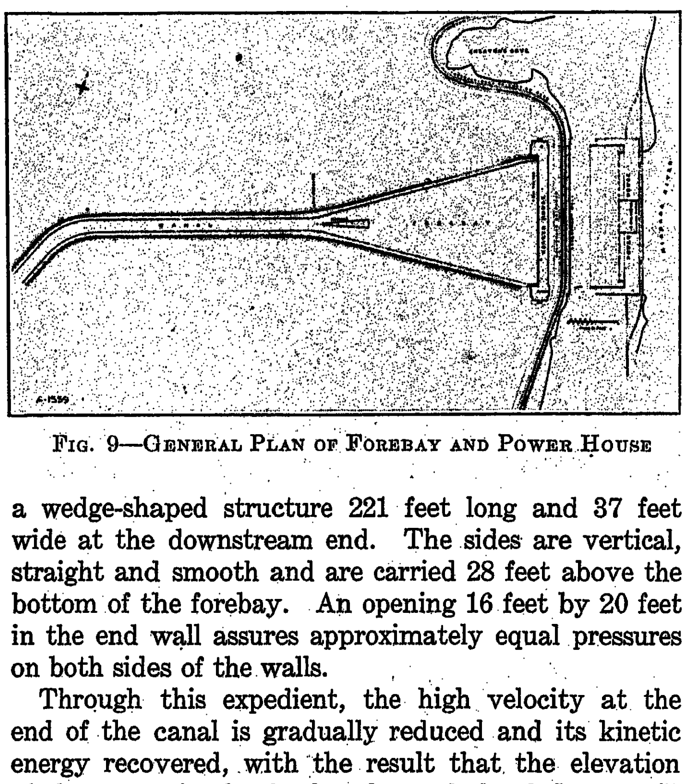

FIG. 9—GENERAL PLAN OF FOREBAY AND POWER HOUSE

a wedge-shaped structure 221 feet long and 37 feet wide at the downstream end. The sides are vertical, straight and smooth and are carried 28 feet above the bottom of the forebay. An opening 16 feet by 20 feet in the end wall assures approximately equal pressures on both sides of the walls.

Through this expedient, the high velocity at the end of the canal is gradually reduced and its kinetic energy recovered, with the result that the elevation of the water in the forebay beyond the deflector will be higher than at the mouth of the canal. For a flow of 15,000 cubic feet per second, and mean water level at Chippewa, the reclaimed head amounts to approximately one foot.

SCREEN HOUSE

At the lower end of the forebay, and serving as a dam for the same, is located the screen house. This structure forms the entrance, and the control, for the penstocks. The entrance to each of the main penstocks is a modified bellmouth consisting of three openings 12 feet 8 inches wide and 29 feet high at the rack supports. These three openings gradually converge into one opening 16 feet in diameter at the point of connection to the penstocks. In designing these water passages particular care was given to the securing of smooth stream lines and consistent changes in velocity. The bell-mouth entrances are sealed by a concrete curtain wall extending down to elevation 542.0 which gives a depth of 28 feet above the floor of the forebay. Immediately behind the curtain wall, steel-lined gate checks are provided to support structural steel gates. These provide a means of unwatering in case it is necessary to get at the lower sections of the racks, or for inspection of the penstocks. The dividing of the intake into three waterways was done in order that the spans for the gates could be made of convenient size and to permit the use of racks of a somewhat new design. The racks, which consist of three-inch by three-eighths-inch bars on edge, at five-inch centers, are fastened rigidly to a structural steel supporting frame held in checks in the concrete walls. The whole of the rack structure is removable and they are split horizontally into two sections for convenience in handling. A specially designed rack follower with an automatic latch arrangement is provided to facilitate the removal of the racks, the bottom section being a considerable distance below the floor of the screen house. The bars and the supporting structure of the racks are designed to withstand a head of 10 feet with a stress of 20,000 pounds to the square inch in the steel. This type of construction removes the danger of a serious shutdown due to the collapse of rack structures, as in the event of blocking by ice or other foreign matter the failure of one section would immediately relieve the others. The broken section can then readily be replaced with a spare one without serious interruption to operation.

A trash trench of liberal dimensions extends across the bottom of the forebay immediately in front of the screen house piers to collect any debris or foreign material which may travel along the bottom of the forebay. The piers dividing the main unit entrances are 6 feet in thickness, while the two intermediate piers in each unit are 3 feet thick. The main dividing piers are designed for full water pressure on each side in order that any unit of the intake may be unwatered while the adjacent units are in operation. An opening in the main floor immediately behind the racks provides a means of disposal of trash into a trough, which empties into the ice chute.

The screen house, as constructed, provides for nine main units, a service unit and an ice chute, and is arranged so that a further unit entrance may be added at the north end.

The entrance to the service unit is similar to the main unit, except that it consists of one bay only, and the entrance to the penstock itself is a true bell-mouth instead of the sectionalized transitions in the main unit entrances. The ice chute bay has a clear width of 25 feet and is provided with a sluice gate of the Stony type, which is lowered to pass surface water

carrying ice. After passing the gate, the water and ice enter a 10-foot diameter concrete pipe and passing down the cliff, out beneath the power house, empty into the Niagara River. Stop log checks are provided ahead of the gate for use in an emergency, or for inspection purposes.

The screen house is located close to the edge of the escarpment, only a narrow ledge of rock being left between it and the gorge. Owing to the disastrous results which would follow a failure, the screen house substructure was designed to resist the full head exerted by the water in the forebay without any assistance from the adjacent rock. The superstructure is built with reinforced concrete walls and roof with a structural steel framework, and is equipped with an electrically operated traveling crane of 25-ton capacity for handling the racks and gates. At the south end of the screen house proper, an enlargement of the building provides for administration offices, and entrance to elevator to the tunnel giving access to the generating station.

Penstocks

From the screen house, the water is carried to the turbines in steel plate penstocks. The main unit penstocks are 16 feet in diameter for approximately two-thirds of their length, and are then reduced by a taper section to a diameter of 14 feet. The accompanying illustrations show the excellent alinement of the penstocks, there being only two bends, one located at the top and one at the bottom. These elbows are held in massive concrete anchor blocks, the one at the upper bend forming a foundation for the piers supporting the sidewalk and roadway along the edge of the escarpment.

Each penstock ring is made up of two plates with longitudinal joints on the horizontal center line. These joints are all double butt joints, varying from double riveted at the top to quadruple riveted at the lower end. The circumferential joints are also single butt, double riveted with the butt strap on the outside. The longitudinal joints are calked on the inside, but the circumferential joints are made water-tight by electric welding. This type of circumferential joint gives a very much better alinement to the inside of the pipe than can be obtained with the usual outside and inside course with lap joints. In designing the penstocks a stress of 12,000 pounds to the square inch was used, this figure being taken to provide for the exigencies of corrosion, fatigue, suddenly applied loads, and other indeterminate or unknown contingencies. The internal pressure, used for design purposes, was taken to be the static head, plus the pressure rise due to a complete closing of the turbine gates in 1½ seconds. This increase in pressure was taken as a maximum at the turbine gates and varying uniformly to zero at the racks.

The thickness of the plates varies from one-half inch at the top section to one and one-quarter inches at the lower section, while the longitudinal butt straps are one-half inch thick with two rows of seven-eighths inch rivets for the lightest joint, and fifteen-sixteenths-inch thick with four rows of one and three-eighths-inch rivets for the heaviest. The efficiency of the longitudinal joints at the heavy section is approximately 85 per cent. In the erection of the penstock, a new departure was initiated in the use of electric rivet heaters; by this method a consistent and close range of temperature was possible so that burnt rivets were very rarely encountered.

The penstocks are covered throughout their entire length with a concrete envelope, having a minimum thickness of 24 inches, which protection will, it is believed, greatly increase the life of the steel pipes.

The penstock for the service units follows the same alinement as the main penstocks and has a diameter of five feet. As friction loss in this pipe was not such an important factor, lap joints and inside and outside courses were used.

Generating and Transformer Station

The generating and transformer station (Fig. 10) is located below the escarpment and close to the River's edge. As will be observed from the cross-section drawing, the station extends about one-half the distance to the top of the escarpment. The structure required to house five main units and the service equipment is 350 feet long, and ultimately this length will be doubled. The substructure is of massive concrete construction carried down to rock foundations, and provides chambers and tunnels for housing and giving access to various kinds of apparatus. The superstructure consists of a structural steel frame work with reinforced concrete floors and roofs, and concrete, brick and tile walls and partitions.

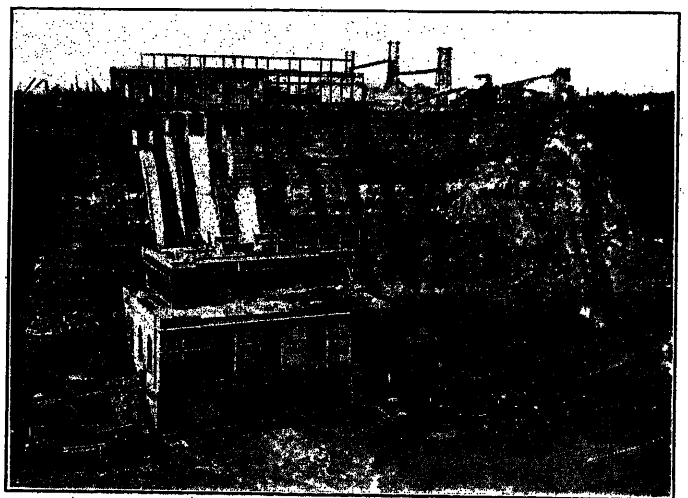

Fig. 10—View of Power House
From American side of river.

The location of the transformer and switching portion of the plant on the top of the escarpment was considered, but owing to the difficulties in carrying the current at 12 kv. from the generators to the transformers up the cliff; and to operating advantages in having a combined station; also to the space between

the generator room and the cliff being sufficient for the purpose, the decision was made to have the building to house the transformers and switching equipment combined with the generator room. It will be noted from the cross-section of the plant (Fig. 10A) that the layout of electrical equipment accommodates itself to the 60-degree slope of the cliff.

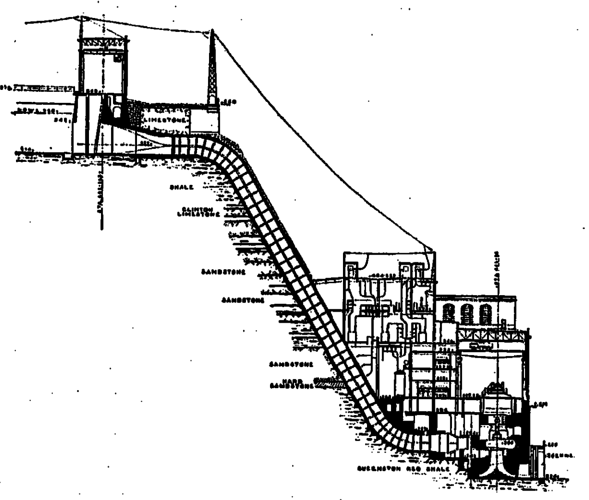

FIG. 10A—CROSS-SECTION OF POWER HOUSE ON CENTER LINE OF MAIN UNIT

The steel columns are spaced longitudinally 26 and 24 feet alternately starting at the south end. The strength of the generator room steel was primarily determined by the necessity of providing cranes to handle the generator rotors which weigh about 300 tons each. The structural steel was so designed that it could be erected and the crane operated before the concrete walls were poured.

To guard against flooding due to the river level rising, the walls are designed to resist water pressure up to elevation 300, which is 16 feet above the base of the generators. No openings which might admit water from the river were permitted below this elevation, although temporarily a railway track is brought in at the south end at elevation 284, and is protected by stop logs.

The illustrations show the general design of the building. Some features which may be mentioned are: the arrangement of the generator cooling air intake ducts, which are carried up in the east wall between the columns to above elevation 300, where openings are provided to admit air either from outdoors, or from the interior of the generator room, an arrangement which takes up no floor space; the location of the generator room main floor at the top of the generator frame, a construction which provides space at small cost for the exhaust air ducts, fans, generator field equipment adjacent to the unit, and still allows a clear space around the generator on the main floor; the large steel sash windows in the generator room which are 21 feet in width by a total height of 38 ft. 4 in.; longitudinal tunnels in the substructure for handling turbine runners, and for piping; a longitudinal room, centrally located, for all conduit runs for control and instrument cable, with a corridor immediately above it the full length of the building; the location of control room over generator room at the center of the completed plant; provision of separate rooms for each 12-kv. oil circuit breaker; and particularly the symmetrical location of all main equipment for each unit—governors, transformers, oil circuit breakers, reactors, fans—in the 50-foot longitudinal space in which the turbine and its generator are situated.

The floor at the top of the generator frame materially reduces the unsupported height of the main crane columns, and does not affect the elevation of the crane rails, as the height of the crane is determined by the height of generator frame and shaft.

Access to the building from the main roadway and the electric railway on the top of the cliff is provided by the elevator in the administration end of the screen house, and a tunnel from the bottom of the elevator shaft to the power house floor on elevation 346 at the south end (Fig. 11).

In general, all plant services are provided in the southerly 75 feet of the station. In this area are located the sump pumps and motors, the air compressor, the service generators, transformers and switchboards, erection space, main station elevator, maintenance shops and stores, lubricating and insulating oil plants, battery rooms, a fully equipped hospital room, also kitchen and dining room and offices. The intention is to duplicate nearly all these services in the extreme north end of the ultimate stations.

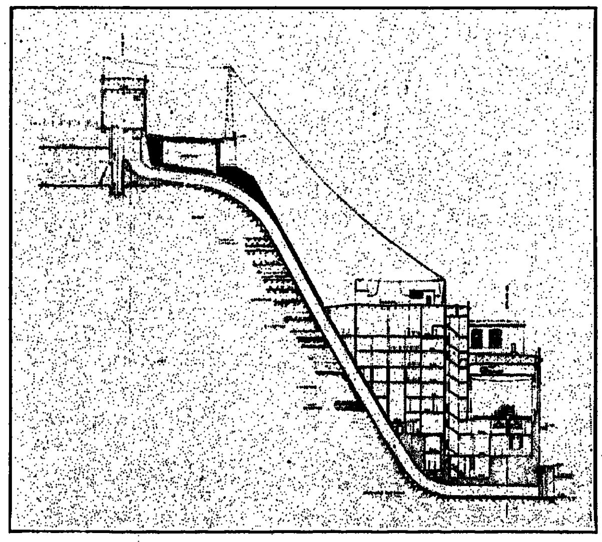

FIG. 11—CROSS-SECTION OF POWER HOUSE NEAR SOUTH END

Permanent railway connections are provided by a track built along the river at the bottom of the cliff from the generating station to the Michigan Central Railway at the village of Queenston. A railway track is carried across the river side of the station building

on an extended portion of the substructure to give access to the area to the south.

A 300-ton crane consisting of two separate units each having a capacity of 150 tons is provided in the generator room for handling generators, transformers and other apparatus. When the crane is to be used in lifting the generator rotor, which is the heaviest piece, an equalizer beam is used. This crane is supplied with a-c. motors and control.

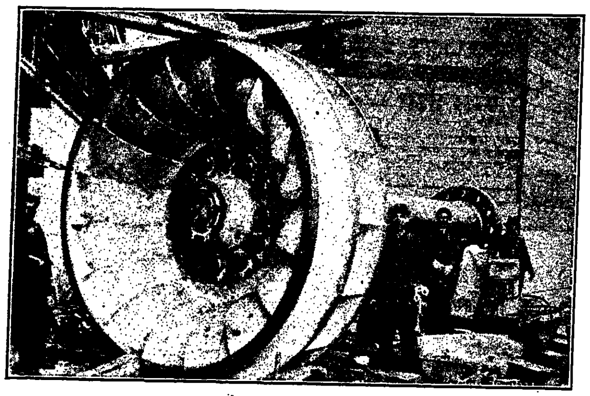

Fig. 12—Turbine Runner

Electric hoists are located throughout the station to facilitate the handling of equipment.

The entrance elevator, from screen house to entrance tunnel, operates at a speed of 450 feet per minute, and is equipped with a 25-cycle, 550-volt, three-phase, variable-speed motor of the commutator type with brush shifting gear. The main elevator in the power house is in the southerly portion of the building and serves all floors. It operates at a speed of 350 feet per minute and is equipped with a two-speed, 25-cycle, 550-volt, three-phase induction motor. An automatic elevator located near the control room for the use of the operators, is also operated by a 25-cycle, 550-volt, three-phase induction motor.

Turbines

Each unit has a capacity of 55,000 brake h. p. under 305-foot head and the section through the power house shows clearly the general arrangement. The draft tube on No. 1 unit is of the common curved type modified at the elbow, while each of the other units is equipped with a Moody spreading tube. In the design of these units care was taken to insure good lubrication for the gate stems and to assure that all wearing surfaces were well greased. The use of labyrinth seals on the runner rims (Fig. 12) cuts down leakage to a minimum. It will be noted on the section that the top portions of the draft tubes are of cast iron and these are so arranged that they can be lowered to facilitate the removal of the runner from below, thus dispensing with the necessity of dismantling of the generator. Owing to the presence of a considerable amount of sand in the water during periods of flood, and by reason of dredging operations in the upper canal, a pressure sand filtering plant has been installed to filter all water supplied to the lignum-vitae bearings to prevent scoring of the turbine shaft. The lignum-vitae bearings themselves are about six feet in length and in order to ensure lubrication over their entire length the water is admitted both at the middle and top of the bearing. A flow meter, with an indicator and an alarm light, is connected to the bearing water supply to guard against any stoppage of the flow continuing long enough to injure the shaft or bearing. The longitudinal passageway on elevation 264 gives access to the turbine bearings, gate stems, servomotors, (Fig. 13), governors and filters.

Air brakes, which act against the underside of the generator rotor, are provided to bring the unit to rest quickly in case of shutdown.

Johnson Valves

The lower end of the main penstock terminates in a 14-foot Johnson valve, the outlet end of which is 10 feet in diameter and connects to the turbine casing by several sections of cast steel pipe. While this type of valve is too well-known to require any description, the method of control is worthy of note. This is accomplished through three 8-inch Johnson valves, which are in turn operated by pistons in cylinders under penstock pressure controlled by a three-way plug valve. When opening the valve to fill the scroll case, it is necessary to build up the pressure in the latter, in order to balance the pressure on the two sides of the plunger. The operation of the valve is so arranged that this is carried out automatically by a series of oscillations of the plunger, as soon as the control handle has been thrown into the opening position. In closing, the motion of the plunger is retarded near the end of the stroke to prevent an excess rise in pressure, due to too sudden closing, and also to protect the plunger seat against shock. The control is so arranged that the valve will close automatically in case of a break in the scroll case, and it is also provided with a remote hand control so that it may be closed, if necessary, from the control pedestal on the main operating floor.

Fig. 13—View of Turbine Deck

Access to the valve is from the floor on elevation 264,

the valve being located in a chamber which provides space for dismantling the valve.

The five-foot service penstock terminates in a steel plate *Y*. The two legs are each equipped with a 36-inch Johnson valve for each service turbine.

Governors

The governor system for the main units uses filtered water containing one per cent of soluble oil. This is supplied to the governor at from 150 to 200-pounds per square inch pressure from two motor-driven centrifugal pumps which feed into an accumulator tank for each unit. The return fluid from the servomotors is carried back through a return main to two concrete tanks so arranged that one tank may be emptied and cleaned while the other is in operation. It had been found in other installations, where a central pumping system capable of handling the completed plant was initially operated to supply only one or two units, that difficulty was experienced owing to the large capacity pumps heating up the small amount of fluid in circulation. To avoid this, a small capacity pump was also installed to supply governor pressure during

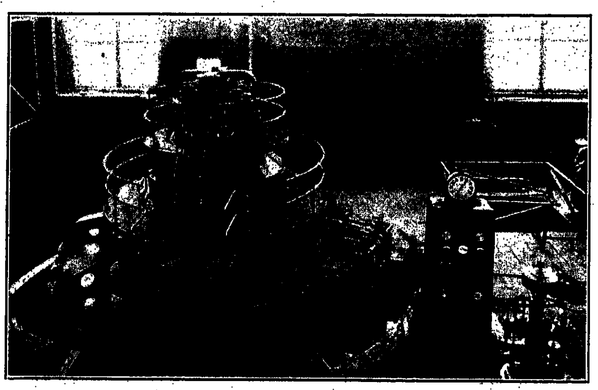

Fig. 14—No. 2 Generator Showing Control Pedestal and Governor Head

the early stages of operation, and to be held afterwards in reserve for an emergency. To guard against a shutdown due to the failure of the governor pumps, an emergency connection has been provided to pass direct penstock pressure into the governor system header. This permits the governors to operate on penstock pressure, at any time that the pumping system is out of service, and has already been called into service since the first two units were placed in operation.

Owing to the very small ratio of length of penstock to head (about $1\frac{1}{4}:1$) and the large flywheel effect of the generator rotors, the regulation of these units is a comparatively simple problem.

Generators

The present five units are each rated at 45,000 kv-a., 80 per cent power factor, 12,000 volts, three-phase, 25 cycles at 187.5 rev. per min. They are capable of being operated continuously at 49,500 kv-a., with either voltage or current 10 per cent in excess of the rated values. The type is vertical (Fig. 14) with direct-connected shunt-field commutating-pole, 250-volt, 150-kw. exciter. The over-all efficiency of the generating units is slightly in excess of 97 per cent at 80 per cent power factor. The thrust bearing is designed to support a load of one million pounds, which is slightly in excess of the weight of the rotor plus the hydraulic thrust imposed by the turbine. Upper and lower guide bearings are provided the latter on account of the length of shaft and to keep the generator a self-contained unit.

The quantity of air required for cooling is 120,000 cu. ft. per minute. It is interesting to note that the weight of air passing through the generator every $2\frac{1}{2}$ hours equals the total weight of the generator, namely 1,400,000 pounds. The units are completely enclosed, the air being drawn either from the outside of the generator room, or from both, and discharged through ducts into the atmosphere or to the different sections of the building for heating purposes. With five units in operation at rated load, there will be available for heating the building 5400 kw., which corresponds to 1.2 kw. per 1000 cubic feet of building contents. This amount of heat should be ample for heating the building at all times.

The maximum observable temperature which any portion of the unit will attain under rated conditions as obtained by thermocouples will not be in excess of 105 deg. cent. with 40 deg. cent ambient air. The temperature as obtained by thermocouples is indicated on the control pedestal adjacent to the generator, and also in the control room.

Units Nos. 1, 2 and 3 are all of the same make, having a rotor with cast steel spider and laminated built-up sheet steel rim, dovetailed to the spider. These three units have upper and lower bearing brackets of cast iron, and are provided with the Kingsbury thrust bearing. Armature windings are insulated in slot portions with sheet mica insulation ironed on, whereas the end portions of the windings are insulated with mica and varnished cambric taping. The stator is divided vertically into four 90-degree sections.

Units Nos. 4 and 5, being made by a different manufacturer, have a rotor made up of seven cast steel sections, five of which carry the pole pieces, the other two, one above and one below, being provided for additional flywheel effect. Upper and lower brackets are of cast steel and a spring supported type of thrust bearing is used. The armature coils are insulated throughout with mica tape. The stator is divided into three 120-degree sections.

The flywheel effect of each unit is 21,500,000 WR^2. The rotors are required to stand an overspeed of 185 per cent of rated speed. Insulation tests of 30,000 volts on armature and of 2500 volts on field and exciter are specified.

The over-all diameter of these units is 25 feet, the diameter of rotor over pole faces being 18 feet

approximately. The shafts are 30 inches in diameter in the guide bearings and are provided with flange at lower end for bolting to corresponding flange on turbine shaft. The shafts are hollow with 8-inch diameter bore and are 30 feet 3 inches in total length. The over-all height of generators above the generator floor (elevation 284) is 26 feet 10 inches, thus above the main floor (elevation 297) only the top of the frame and the upper bracket, thrust bearing housing and exciter are visible (Fig. 15).

The weight of the complete generator is 1,400,000 pounds, that of the rotor 615,000 pounds. The largest piece to be handled by the cranes weighs 600,000 pounds.

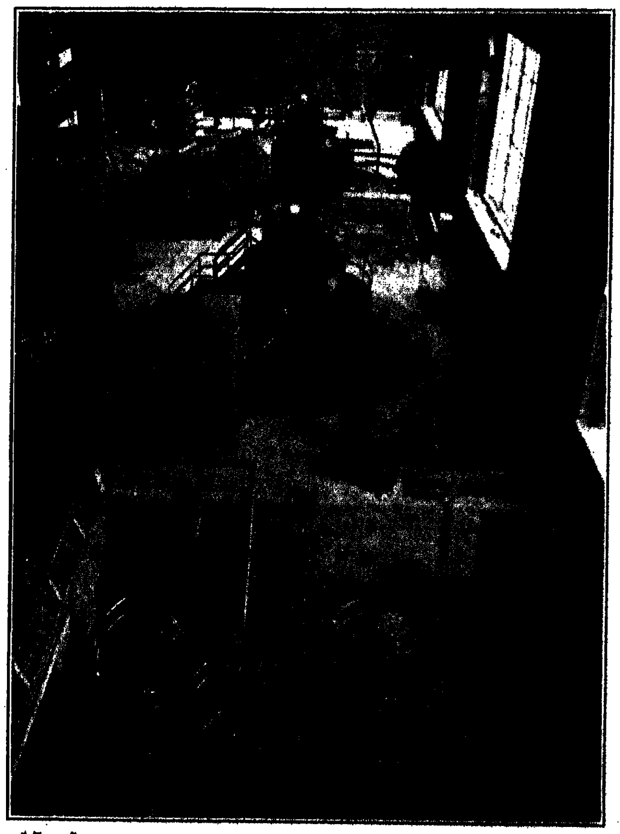

FIG. 15—INTERIOR VIEW OF GENERATOR ROOM LOOKING NORTH

EXCITATION

The principal source of excitation for each unit is the direct-connected exciter mounted above the generator. Each exciter has sufficient capacity to furnish excitation for one 45,000-kv-a. generator, and is rated at 150 kw., 250 volts. It is of the shunt-wound type with commutating poles and is especially designed for service with a generator voltage regulator.

The auxiliary source of excitation consists of a motor-generator set made up of a 250-volt 150-kw. shunt-wound d-c. generator, with commutating poles designed to carry the excitation of any one of the generators, and to work with the voltage regulator belonging to that unit. At present there is one auxiliary exciter set for five units, but in the completed station it is contemplated that there will be additional sets, each acting as a spare exciter for a group of machines. Each spare

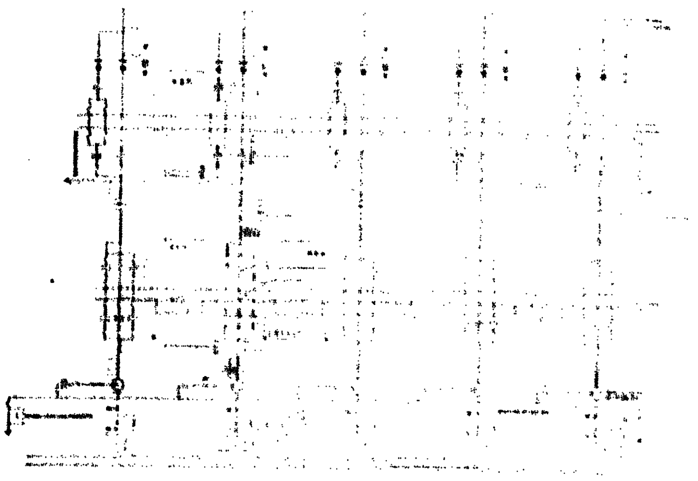

FIG. 16

exciter may be connected to its own bus, to which the field of any generating unit of its group may be connected as shown in the diagram (Fig. 16). The auxiliary motor-generator sets are driven from the 2200-volt station service system.

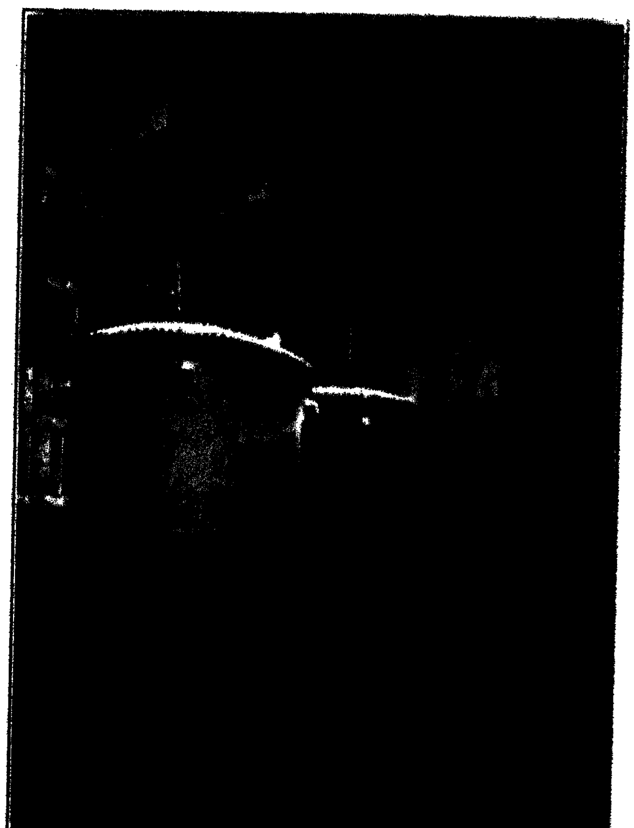

FIG. 17—45,000-KV-A. SINGLE-PHASE TRANSFORMER

A voltage regulator of the vibrating relay type controls the voltage of each generator. This regulator is equipped with compensation to prevent cross currents

when units are in parallel on the 12-kv. bus, also with adjustable compensation for ohmic and inductive drop in transformer banks and lines. Each is provided with a device for maintaining a low maximum of exciter voltage in case of a drop of voltage due to short circuit,

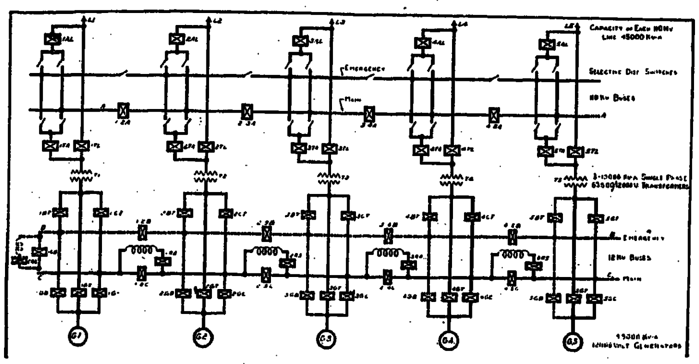

FIG. 18—QUEENSTON GENERATING STATION—WIRING DIAGRAM OF MAIN CONNECTIONS

also with a device for cutting resistance into the exciter field circuit to limit the voltage in case of overvoltage due to overspeed or other causes.

No main generator field rheostats are used.

TRANSFORMERS

These are of the shell type and are individually rated at 15,000 kv-a., 25 cycles, 12,000/63,500/76,200 volts at 80 per cent power factor. There will be five banks of three, connected $\Delta - Y$ to give 110 to 132 kv. at rated load. The guaranteed efficiency at 80 per cent power factor is 98.25 per cent. The quantity of oil required for each transformer with its expansion tank is approximately 6500 Imperial gallons, the weight of the complete transformer is 100 tons. The over-all height is 28½ feet, and diameter of the tank is 9½ feet (Fig. 17).

Maximum observable temperature rise is specified at 50 deg. cent. with an observable temperature rise of 55 deg. cent. under a 10 per cent overload, above ingoing cooling water temperature of 25 deg. cent.

Insulation tests are 280 kv. and 33 kv. on high and low-voltage windings respectively.

The main tanks are of boiler plate with plate bottoms and covers. The tanks are required to withstand an internal pressure of 150 pounds per square inch and also a vacuum equivalent to 24 inches of mercury. The main tanks will be completely filled with oil, the expansions of the oil being provided for in separate tanks, but provision is made in the height of the main tanks so that operation without the expansion tanks will be safe.

The transformers are mounted on roller bearing structural steel trucks set on rails on elevation 297 to the rear of the 12-kv. switching equipment. A track runway throughout the length of the building connects to a cross runway at the south end, which permits moving the transformers to a position under the generator room cranes.

MAIN CONNECTION DIAGRAM AND SHORT-CIRCUIT STUDIES

The main wiring diagram (Fig. 18) shows the electrical arrangement of the main apparatus. A generator, bank of transformers and a line is considered a unit, each with a normal capacity of 45,000 kv-a. It will be impracticable to dispose of the power in blocks of this capacity and grouping of units will be essential. For this purpose 12-kv. and 110-kv. busses are provided. The diagram shows a double 12-kv. bus, only one of which, however, that with reactors, is being installed, but space is being provided for the second or emergency bus, and this may be installed later if conditions warrant.

Extremely interesting studies were carried out to determine the mechanical, magnetic and thermal effects on conductors under normal and abnormal operation with different groupings.

In the analysis practically all possible conditions of operation were considered. A key diagram was prepared with symbols representing groupings of units.

Referring to Figs. 19 and 20, I, II, III or IV indicates that 1, 2, 4 or 8 generators are paralleled on the low-

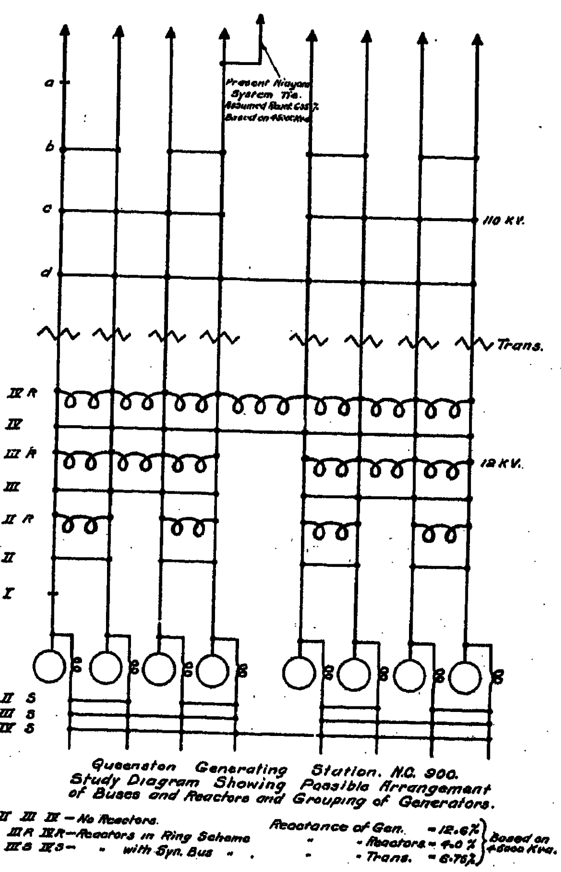

FIG. 19—DIAGRAM FOR SHORT-CIRCUIT STUDIES

voltage bus. If followed by *R* as II *R*, etc. the generators are paralleled through a reactor. If followed by *S* as II *S*, etc. the generators are connected to a synchronizing bus through a reactor. *a*, *b*, *c* or *d* indicates that 1, 2, 4 or 8 generators are paralleled on the high-

voltage bus, so the significance of III $R\ d$ may be readily understood as two groups of four generators each connected through reactors on the low-voltage side and the eight units paralleled on the high-voltage bus.

The short-circuit values are given as the r. m. s. values of the first symmetrical wave of current times the normal voltage times square root of three.

From the studies it was found that the star bus

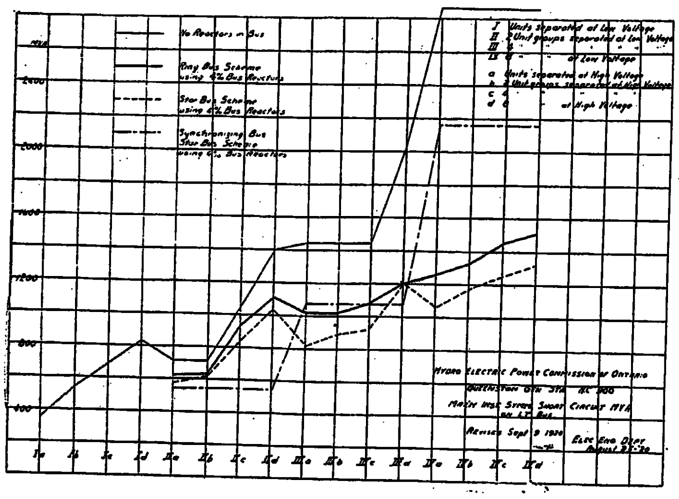

FIG. 20

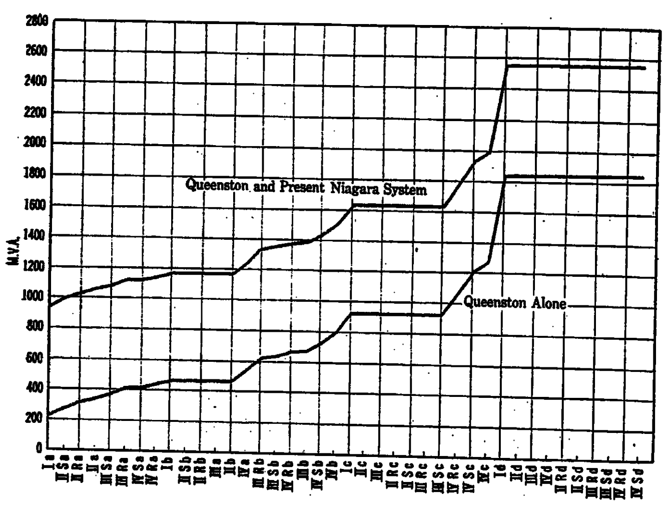

FIG. 20A—MAXIMUM SYMMETRICAL SHORT-CIRCUIT VALUES ON H. T. BUS

scheme had a slight advantage in so far as short-circuit currents are concerned over the ring bus scheme with not more than four generators in parallel, but with more than four generators in parallel the short-circuit currents on the star bus are considerably higher than on the ring bus.

With eight generators operating in parallel on the 12 kv. bus the r. m. s. value of the first wave of the symmetrical short-circuit current may reach a value of 140,000 amperes with no reactors between generators. Using 4 per cent reactance (based on the capacity of a generator, namely 45,000 kv-a.) in bus reactors between the generators in the ring bus scheme 73,000 amperes would obtain and 104,000 amperes in the star bus if that scheme were used.

For the above short-circuit values (140,000, 73,000 and 104,000 amperes) the forces between the busses, spaced two feet apart, would be 5120 lb., 1420 lb. and 2870 lb. respectively per linear foot of bus. Fig. 21 shows the forces between the busses for both 24-inch and 45-inch spacing under different conditions of operation.

From these studies it was decided to install 5 per cent bus reactors between the generators and increase the spacing between the busses to 48 inches in order to reduce the short-circuit currents and mechanical forces to a minimum within the limits of available space. Further increase in the reactance between generators would cause but slight reduction in the short-circuit currents.

These curves were used as a basis in deciding upon the strength of bus supports to use and the rupturing capacity of the oil circuit breakers required. The oil

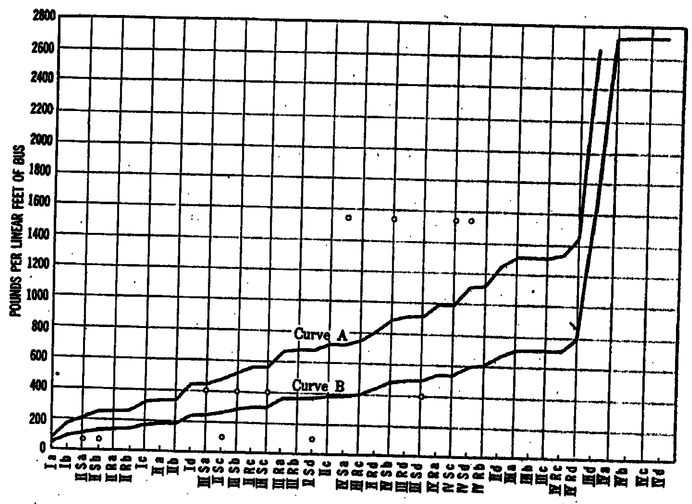

FIG. 21—MAXIMUM STRESSES ON L. T. BUSSES

circuit breakers which are used are suitable for operation under conditions at least as severe as IV $R\ c$.

CONTROL ROOM

The electrical control of the station is centered in the control room which is situated at elevation 361 above the generator room over units 4 to 6. A room approximately nine feet high underneath the whole control room permits control conduits to be brought in from the longitudinal conduit room and distributed to the various switchboards in an accessible and convenient manner. In the control room, the switch controls, indicators and dummy busbars are mounted on bench board sections, arranged in the general form of the arc of a circle. To the rear of the bench board are vertical panels carrying the necessary indicating instruments. Further back are the panels carrying the recording meters and relays, placed face to face. The completed switchboard will consist of bench board and panels for 9 or 10 units.

At each end of the main board is a five-panel board for controlling the main connections of the station service. This consists of bench board, instrument panels, recording meter and relay panels. Beneath each bench board and immediately behind each panel is a slot through the floor into the room below to permit easy installation and tracing of circuits.

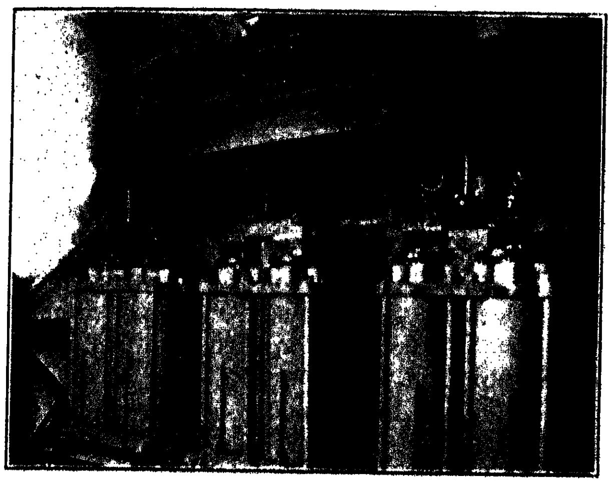

Fig. 22—12-Kv. 3000-Ampere Oil Circuit Breakers Installed in Their Compartments

Control Pedestal

On the main floor, near the governor of each unit (see Fig. 14) is a "control pedestal." This carries necessary hydraulic and electrical meters to enable the attendant to keep in touch with operating conditions affecting the complete generating unit. It also carries a telephone and signal indicators, connected to the control room, and a pull button switch by which the generator oil circuit breakers and field breakers may be tripped in case of emergency.

Signal System

For each unit, a dial-type signal system is installed between the control bench board and the control pedestal near the generator, by which instructions can be transmitted from the operator in charge to the generator attendant. This is supplemented by special telephone connections at each pedestal.

Oil Circuit Breakers

Oil circuit breakers for 12-kv. service (Fig. 22) are rated at 15-kv., 3000-ampere continuous capacity. These are of two types, but the structural steel supports and general dimensions are such that they may be readily interchanged.

Fig. 23—135-Kv. 600-Ampere Oil Circuit Breaker

One type, used principally in units 1 and 2, is solenoid-operated, and has one heavy 36-in. diameter steel tank per pole. Each pole has contacts of inverted brush type with two breaks in series, which can readily be increased to four if necessary. Rupturing capacity is obtained by using large amount and head of oil in a very strong retainer. This breaker is guaranteed to rupture any short-circuit current obtainable with the plant connected in combination IV *R c*. Insulation will withstand 80 kv. for one minute.

The second type, used principally in units 3, 4 and 5, is motor-operated with two grounded tanks per pole. The arc is broken in oil in a very strong explosion chamber surrounding each arcing contact, arranged with baffles to shoot a stream of cool oil under pressure across the path of the arc. The main contacts of the wedge

and finger type are in air. This breaker is guaranteed to rupture any short-circuit currents obtainable under combination IV *R d*. Insulation will withstand a 55-kv. test for one minute.

Oil circuit breakers for 110-kv. service are rated at 135-kv., 600-ampere continuous capacity. They are

FIG. 24—12-KV. BUS INSULATOR

of the solenoid-operated type with one tank per pole of heavy construction. In each pole there are four breaks in series, each break having a special quick break feature to increase the rupturing capacity. Each breaker is guaranteed to rupture any short-circuit current obtainable with combination IV *R c*., and will withstand a test of 280 kv. for one minute. Bushings will withstand 350 kv. for one minute.

The control circuit voltage for operation of all breakers is 250 volts d-c. All breakers have ventilated tanks.

The 12-kv. circuit breakers are installed in individual rooms on two floors between the generator room and the transformers, with the main busses occupying an intermediate floor. These rooms are ventilated to the generator air discharge shaft. The leads from the breakers are carried through the wall at the rear through porcelain bushings, this giving a minimum of connecting material in these rooms.

The 110-kv. breakers (Fig. 23) are located on one floor at elevation 346, the breaker on the direct circuit from transformer bank to transmission line being separated entirely from all other breakers by walls. The breakers for each unit group connecting to the busses are in one room which has walls around all floor openings to prevent spread of oil.

Every switch room is drained into the general drainage system, and the doors to the rooms are provided with master-keyed locks. A designation symbol for every breaker is in use by which each breaker and its position in the connection may be readily identified.

12-KV. BUS AND CONNECTIONS

The results of the short-circuit current study showed that a strong construction would be required for the 12-kv. bus and connections from the generator terminals to the transformer terminals. The combination of the 3000-ampere normal current capacity adopted, with the mechanical strength required, made this bus structure a unique problem. From consideration of this, it was decided that no cable would be used on any of these 12-kv. connections.

The spacing of the phases finally adopted was 48 inches for the main bus, breaker and transformer connections and 37 inches for the generator leads to the bus. These spacings with a calculated short-circuit current having an assymmetrical peak of 170,000 amperes give maximum forces of 485 lb. per foot for 48-inch and 630 lb. per foot for 37-inch spacing.

It was decided that a single-unit bus support to resist a force of 10,000 lb. applied at the bus clamp should be obtained. This would allow a spacing of supports along the bus of about 5 ft. giving a factor

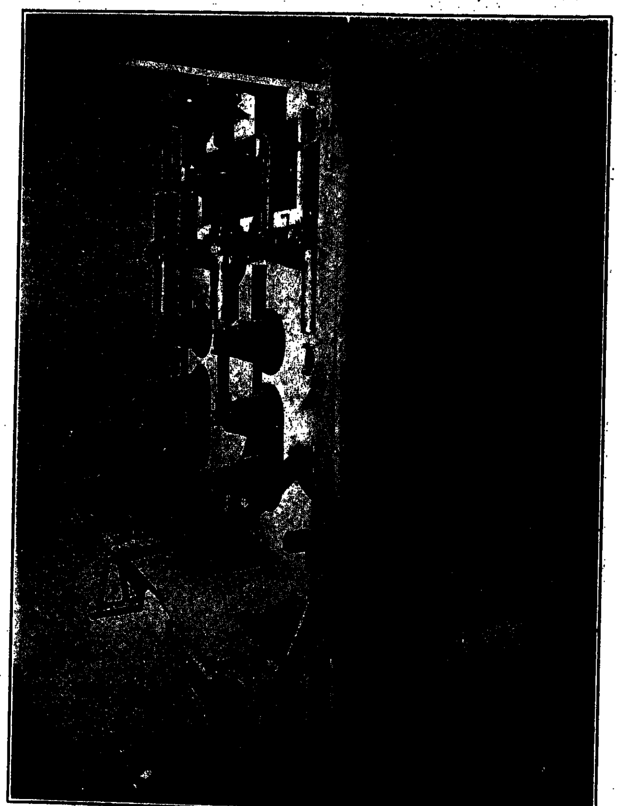

FIG. 25—DISCONNECTING SWITCHES, 3000-AMPERE, 12,000-VOLT, WITH OPERATING MECHANISM

of safety of 3 on the support under maximum load conditions. A single-unit porcelain bus support of smooth surface, with cast iron hardware cemented on, and having an ultimate strength of 10,000 lb. in cantilever (applied at the center of the bus) and an 80,000-volt, 25-cycle, flash-over, was finally obtained (Fig. 24).

The smooth porcelain was adopted with the intention of obtaining every advantage possible in the strength of the porcelain unit and making the cleaning of the units easier.

The bus copper adopted was three bars, 4 inches by ¼ inch, laid flat on the insulator cap. It was decided to mount the bus supports directly on the floors and walls and by the wide spacing of phases dispense with the usual barriers. This arrangement puts the copper into the plane of force in the position of its greatest strength. Tests in the laboratory showed that there is a real danger in using such a spacing of bus supports along the bus that the stresses set up by 25-cycle currents will coincide with the natural period of vibration of the length of copper, thus producing a case of mechanical resonance. On account of the low strength of copper, it is not possible to space the bus supports at the maximum distance considering the short-circuit forces above. The sagging of the copper due to its own weight is a limiting factor in the arrangement adopted.

Fig. 26—Disconnecting Switch, 13-Kv., 600-Ampere

Disconnecting switches of 3000-ampere capacity (Fig. 25) are provided on each side of every oil circuit breaker and are located in separate rooms behind the breakers. They are arranged to be operated in sets of three by a hand-operated mechanism with hand wheel outside of the room in which the disconnecting switches are mounted. These mechanisms are locked in the open or closed position by individual Yale locks with master keys for the station. The blades of the switches are locked in the closed position by the operating mechanism.

Pilot lamps mounted beside the hand-operating mechanism indicate the position of the switches and whether the oil circuit breakers are open or closed. This system was chosen in preference to the added complication of a mechanical or electrical interlock between the circuit breakers and the disconnecting switches.

Motor-operated disconnecting switches were considered but it was decided that the advantages would not warrant the extra expense.

Wherever the copper bars are taken through floors and walls, bushings are installed. They consist of a central porcelain tube mounted in a panel of ebony asbestos. The flash-over value is 80,000 volts at 25 cycles. This design gives a very effective and inexpensive bushing.

It is proposed to have all copper bars covered with flame-proof insulation.

110-Kv. Bus and Connections

A continuous current-carrying capacity of 600 amperes was adopted for all high-voltage circuits, which required the use of one-inch diameter, iron pipe size, copper tubing for all 110-kv. connections. As provision is made for ultimately increasing the potential to 135 kv., a standard 42-inch high, corrugated single-piece porcelain post with cemented-on cast iron hardware was installed. These units have a cantilever and torsion strength of 40,000 inch-lb. and have a dry flash-over value at 25 cycles of 350 kv.

600-ampere, 135-kv. disconnecting switches (Fig. 26) of double break, center rotating post, operated by hand mechanism in gangs of three, were adopted, using the same porcelain post as the bus support. These posts, complete with hardware, are interchangeable with the bus supports.

Relay Protection

The simplicity of the main connections in the plant and especially the absence of 12-kv. feeders makes it possible to use differential relay schemes for protection of apparatus and connections. This allows rapid automatic removal of defective equipment from service with a minimum of disturbance to operation. The apparatus and main connections of each unit are divided into the following groups:

Generator,
Main 12-kv. bus,
Auxiliary 12-kv. bus (when installed),
12-kv. connections of transformer,
Transformer bank,
110-kv. connections of transformer,
110-kv. busses.

Each conductor where it leaves the group carries a current transformer These current transformers are so connected to relays that if the current in each phase leaving the group is not equal to the current entering that phase, the relay will carry the difference in the currents, or in other words the current to a fault. If there is no defect inside the groups, current leaving will be equal to current entering and there will be no relay action, no matter how heavy the through current. To insure correctness of operation, the following precautions have been taken:

1. Current transformers are of special design to give correct ratio even with heavy currents.

2. Impedance in secondary wiring has been kept low by short connections. The only equipment connected is the relays which are in the differential circuit and carry fault current only.

3. Current transformers are placed outside the oil

circuit breakers which would isolate any group so that a defective breaker would be cleared on both sides.

All differential relays are of the instantaneous overload plunger type except for transformer differential which are inverse time overload induction type. Generator differential relays have also a hand reset feature to increase the certainty of operation.

Each differential group of relays is arranged with multiple contact relays to trip the necessary circuit breakers to isolate the defective equipment. In case of the generator differential, the field circuit breakers are also tripped.

In addition to the differential relay groups the following relays have been installed (Fig. 16):

1. A relay in the ground connection of each unit to give an alarm in case of ground current. No switches are tripped.

2. A directional relay on each generator, of the three-element induction wattmeter type restrained by a spring. The principal function of this is to check careless synchronizing. It trips out the generator oil breakers.

3 A ground relay on the 12-kv. connections close to the transformer bank on each unit. It protects this section of the wiring including the transformers 12-kv. bushings which are not included in any of the differential groups. This is an inverse time overload induction type relay.

4. A set of inverse time overload relays of the induction type on each outgoing line. This consists of one relay for each phase and one for grounds.

5. A set of inverse time overload relays in the main 12-kv. bus between units to separate them in case the units drop out of step with each other.

An annunciator is provided with each unit which indicates by a drop and an alarm bell which relay was operated.

Several operations of portions of the relay equipments have shown that they function as intended.

All current transformers on the main circuits are of the bushing type, those for 12-kv. circuits having the core and secondary winding mounted on high-grade condenser bushings placed over the three 4-inch by ¼-inch copper bars. This particular design permits several secondary windings to be mounted on the same bushing.

The 12-kv. potential transformers are of strong construction with an especially high insulation test and are connected through protecting resistors, fuses, and disconnecting switches to the main circuits, the disconnecting switches being in a separate room from the fuses.

Reactors

Reactors are installed only between 12-kv. main bus sections, *i. e.*, between generators. They are of the cast in concrete type with the conductors and the concrete impregnated with varnish. The continuous current-carrying capacity is 2380 amperes with a temperature rise not exceeding 80 deg. cent. above 40 deg. cent. ambient temperature. They will safely carry short-circuit current for 12 seconds. The rating is 12,000 volts, 25 cycles, single-phase 5 per cent reactance based on 2165 amperes, the normal rated current of one 45,000-kv-a. generator. Protective resistors are mounted within the reactor and connected to its terminals.

These reactors are located on the generator floor on elevation 284, below the 12 kv. oil circuit breaker rooms.

Service Apparatus

All services except oil switch control and signal lamps are 25-cycle operated. Power is obtained from two turbine-driven three-phase service generators each rated at 2200 kv-a., 2300 volts, 25 cycles, 500 rev. per min. In addition, power for service is available from a 12-kv. line from the Ontario Power Company.

These service turbines are rated at 2800 h. p. each at 500 rev. per min. under 305 feet head. On these units, the governors, governor pumps, etc., are entirely independent of the main governor system. Oil is used as a medium in these governors, and is supplied by two gear pumps with motors mounted on the same base as the pressure tank.

In general, all motors of 25 h. p. or larger are operated at 2200 volts, whereas smaller three-phase motors are 550 volts.

Generator air exhaust fans, pumps, compressors, shop equipment are electrically operated.

Direct current for operating oil circuit breakers, rheostats and other small motor-driven devices is at 230 volts and is obtained from a 15-kw. motor-generator set. The induction motors are supplied from a 550-volt service feeder. The generator floats on a 230-cell, 154-ampere hour lead storage battery. The generator and battery equipment is in duplicate, so that one generator and battery unit can float on the load at approximately constant voltage while the other battery is being charged. A middle tap is brought from each battery for connection to emergency lighting circuits.

Switchboard indicating and signal lights are supplied from 32-volt d-c. circuits to enable tungsten lamps to be used. Power is obtained from a 4.5-kw., 32-volt generator driven by a d-c. motor from the 230-volt battery, and floating on a 16-cell, 23-ampere-hour lead battery. This unit is in duplicate with one motor-generator and one battery for each 230-volt battery. Better economy is expected from these lamps than from the standard higher-voltage ones.

Arrangement of Service Apparatus. The service electrical circuits are shown in Fig. 27. The principal distributing center called "Section A" is located near the service generators. The two service generators, the incoming feeder from the Ontario Power Company which has been stepped down through a 1500-kv-a., three-phase, 12,000 to 2300-volt transformer, and all service feeders are connected to a main 2300-volt bus

through cell-mounted oil circuit breakers. The generator, incoming feeder and main bus breakers are electrically operated from the main control room. The service feeder breakers are hand-operated. A 2300-volt transfer bus is provided for emergency operation. Power for 550-volt services is obtained from the 2300-volt system through three 300-kv-a. 2300 to 550-volt

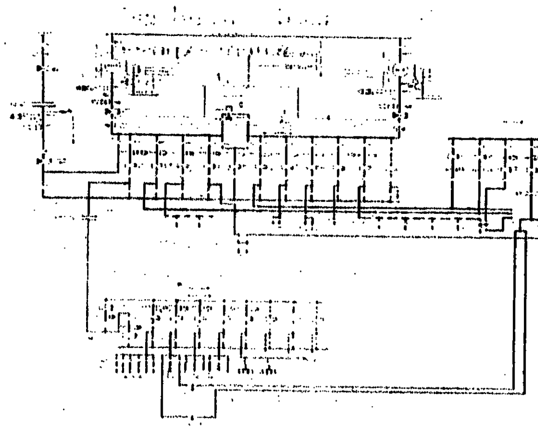

FIG. 27—DIAGRAM OF SERVICE CIRCUITS

transformers to a main and a transfer 550-volt bus. All 550-volt oil circuit breakers are hand-operated and mounted on pipe framework. Section "B" center is located near unit No. 4. It is supplied by two feeders from the 2300-volt bus in Section A. These will eventually be continued to Section C station at the north end of the completed plant, which will be similar to Section A. Section B contains transformers for local services and is a switching center for 2300-volt feeders. The fans and governor pump feeders are arranged as

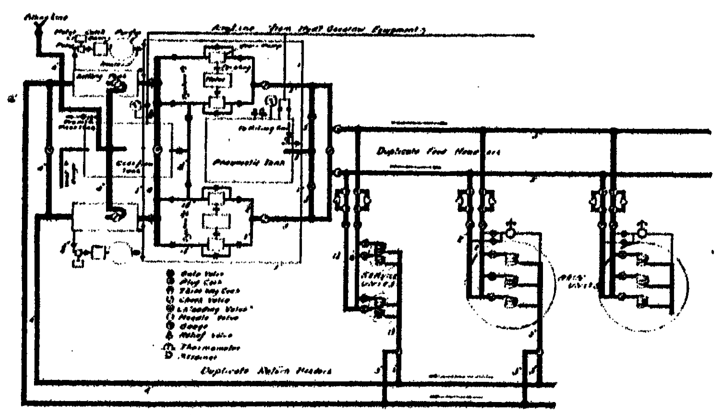

FIG. 28—DIAGRAM OF LUBRICATING OIL SYSTEM

"ring" feeders between Sections A and B so that each has two sources of power. The auxiliary exciter sets are on a ring feeder from Section A to Section C. The generator bearing oil pumps and the governor pressure air compressor have each 550-volt feeders from Sections A and B. The service generators are protected by differential relays and by inverse overload induction-type relays, the latter type being used also for protection of the feeders.

The lubricating oil piping diagram for the main and service generators is shown in Fig. 28. This consists of a central plant of purifying and pumping apparatus with pressure and return headers all in duplicate. Each half of the system is of sufficient capacity for five units. Oil is distributed to the generators by pump pressure and the return oil passes into a settling tank. Any water or sediment settles to the bottom of the tank and passes out to a centrifugal purifier and the purified oil is returned to the system. Each generator requires about ten Imperial gallons per minute of oil. In addition to the duplicate oil pumping equipment, the system is provided with a storage of oil under air pressure suitable for operating the plant for one hour.

The transformer oil system is shown diagrammatically in Fig. 29. Tanks of sufficient capacity to hold all the oil from one bank of transformers are provided and are connected to a "good oil" and a "bad oil" header, which in turn connects with the five banks of transformers. The valves for the storage and purifying equipment are symmetrically arranged and located so that all operations may be performed from one point. The valve arrangement allows the pump and filter press or purifier to be connected with any tank and either header, meanwhile the operator can see at a glance just what connection he is making.

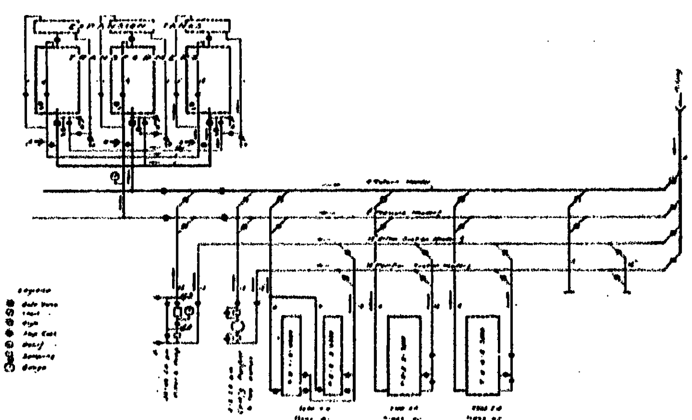

FIG. 29—DIAGRAM OF TRANSFORMER OIL HANDLING SYSTEM

The switch oil apparatus follows the same layout as the transformer oil system, though on a smaller scale. There is no piping connection between the transformer and switch oil systems.

Water for cooling purposes for the transformers and for the generator bearings is obtained from a header connected through valves to the main penstocks, thus eliminating pumping equipment. This header, located in west piping tunnel at elevation 267, is sectionalized by valves between penstocks. Duplicate feeders to each generator and bank of transformers are installed. The house service supply and fire hydrant supply are also obtained from the main header, which also furnishes water through the filters to the turbine bearings.

110-Kv. Outgoing Circuits

The 110-kv. circuit on each unit is brought out of the building through pent houses on the roof by means of compound-filled porcelain bushings. Oxide-film lightning arresters are installed indoors on elevation 375 on each unit.

The single-circuit transmission line for each unit is of 45,000-kv-a. capacity, using steel-cored aluminum cable. The connections of 605,000-cir. mil. cable from bushings to the transmission line are carried on suspension-type insulators, from the tower structure on the roof to special towers on the edge of the roadway at the top of the cliff in front of the screen house, thence to a tower structure on the roof of the screen house, from which the circuits spread out to the standard transmission terminal towers. Two circuits connect to existing transmission lines at Niagara Falls, and additional new circuits under construction extend westwards to connect to more distant existing stations on the 110-kv. system.

Lighting

The lighting of the ultimate plant will be fed from three separate 225-kv-a. banks of 2200/220/110-volt transformers; two banks being installed at present. These banks will feed their respective sections of the building and the distributing boxes are so arranged that in case of failure of any one section, jumpers may be temporarily and quickly installed from adjacent sections. In general, the lighting has been laid out so that all high and low-voltage bus and apparatus, piping, etc., are fully illuminated without undue glare. An automatic transfer switch is installed so that certain circuits may be connected to the 230-volt control battery in case of failure of the a-c. supply.

All feeders from the switchboards are composed of single-conductor rubber-covered double-braided cables. Small wiring from panel boards is of standard rubber-covered double-braided conductor except that in places where excessive moisture is encountered 30 per cent para rubber is used. Rigid galvanized conduit is used throughout and where exposed to moisture shims are used to support the conduit clear of the walls and ceilings.

Telephone Systems

An automatic telephone system is to be installed so that communication may be held between the operators throughout the plant with a code system for emergency conditions. This system will be so designed that it may be connected to the private telephone system of the Commission. Arrangements are being made to install, as a standby for system operation, a wired wireless set.

The engineering and construction work on this development have been carried out under the direction of the commission's staff with Mr. H. G. Acres as chief hydraulic engineer, and Mr. E. T. J. Brandon as chief electrical engineer.

The author wishes to put on record his appreciation of the loyalty and devotion of the entire engineering and construction staffs of the Commission in carrying through the work on this development.

Discussion

For discussion of this paper see p. 507.

Description of the 45,000-kv-a. Queenston Generators

BY B. L. BARNS and F. BOWNESS
Member, A. I. E. E. Associate, A. I. E. E.
Both of the Canadian General Electric Company, Ltd.

Review of the Subject.—Notwithstanding the very large rated capacity of the 45,000-kv-a. generators for the Queenston power house of the Hydro-Electric Power Commission of Ontario, their essential construction features are not different from those of much smaller rated generators. The generators are of the vertical shaft type with two guide bearings, and a thrust bearing. The thrust bearing is located above the stator and carries the weight of the complete rotating elements of the generator and water turbine. Each generator is provided with a direct-connected exciter.

The flywheel effect required for satisfactory speed regulation of the turbines necessitated the use of auxiliary flywheels mounted on the shaft adjacent to the generator rotor. The rotor is constructed with a number of cast steel wheels which together form the rotor spider for carrying the pole pieces. The pole pieces are made of punchings and are attached to the rotor with three dovetails per pole. The coils are made of copper strip wound on edge.

The stator frame is split vertically into three sections to conform with foundry and shipping limitations but the core is built up without being split. The stator windings consist of form-wound, diamond-shaped coils, each slot containing two coil sides. The coils are made of stranded conductor and are insulated with mica tape, which affords more or less flexible insulation. The ends of the coils are braced against the distorting effect of severe short circuits in such a manner as to permit expansion and contraction of the copper without injury to the mica insulation. The armature phase connections are made with bus rings supported from the stator frame, making all connections accessible.

CONTENTS

THE purpose of this paper is to describe briefly a few of the construction features of the 45,000-kv-a. generators manufactured by the Canadian General Electric Company for the Queenston power house of the Hydro-Electric Power Commission of Ontario. Because of the fact that the rated capacity of these generators is greater than that of any generators ever before constructed, there is a tendency to create an impression that their construction would involve radical changes from the more or less familiar types of much smaller generators, but aside from one or two requirements peculiar to this installation, the problems presented in the design of these generators involved no great difficulties or departure from what has been considered standard construction. In fact if our power station engineers should find that larger generators could be used advantageously it is possible to build generators having capacities of 60,000 or 75,000 kv-a. at moderate speed without departing from ordinary methods of construction, or meeting with excessive costs per kv-a.

General Description

These generators are of the vertical shaft type with revolving fields and stationary armatures. They have two guide bearings and a thrust bearing. A substantial base ring supports the stator frame and carries the spider bracket for the lower guide bearing. The thrust bearing is supported by a deck or spider spanning the top of the stator frame and carries the rotating parts of the generator and turbine. There is a direct-connected exciter mounted at the top of the generator. A general view of the complete unit is shown in Fig. 1. The generators are designed to deliver three-phase, 25-cycle current at 12,000 volts, and rotate at a speed of 187½ revolutions per minute. The full-load rating is 45,000 kv-a. at 80 per cent power factor, with a temperature rise not exceeding 65 deg. cent. as observed by detectors imbedded in the slots of the stator core or by resistance measurements of the

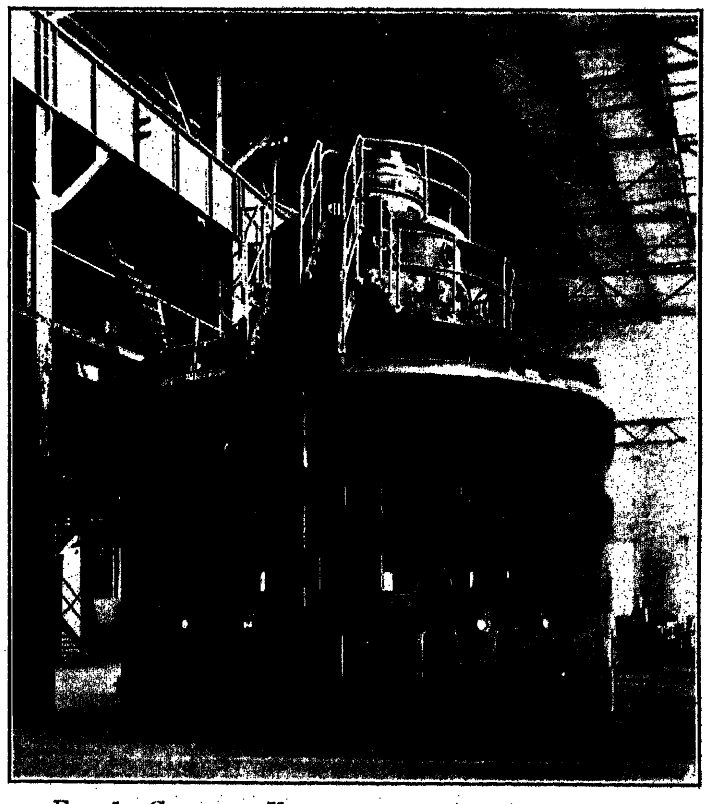

FIG. 1—GENERAL VIEW OF THE ASSEMBLED UNIT

Presented at the A. I. E. E. Annual Convention, Niagara Falls, Ontario, June 26-30, 1922.

stator or rotor windings. The full-load efficiency including all mechanical and electrical losses is guaranteed to be not less than 97¾ per cent at 100 per cent power factor. The exciters are rated 150 kw. at 250 volts.

Stator Frame, Core and Windings

The stator frame is divided into three sections vertically, in order to keep the weight within the foundry capacity and provide sections of a size and weight that could be easily handled in the shop and in transportation. These castings are probably the largest in size and weight ever used for generator construction, the frame being 24½ ft. in diameter by 10 ft high, and weighing, complete, approximately 90 tons. In building the core of such a large generator it is desirable to avoid joints that divide the core into sections because looseness and vibration of the laminations are liable to develop due to the unequal expansion of the frame and core, and the difficulty in arranging clamps capable of exerting sufficient pressure. Therefore it was decided to build up the core in the power station thus

9. Punchings or core.
10. Removable shims to allow taking up settling of core.

obtaining a continuous ring. The slots in the stator core are unusually large for a waterwheel type generator, being as large as those commonly used in the large high-voltage turbo-generators. The stator winding is of the common "Barrel" type with two coil sides per slot. Each turn of the coils is insulated with mica tape applied by hand after the coil has been formed. The coil insulation consists of mica tape put on by hand with a special compound sticker between layers. This process results in a uniform insulation on the full length of the coil and when slightly heated a sufficient flexibility is obtained to permit the removal and assembly of coils without great danger of damage to the

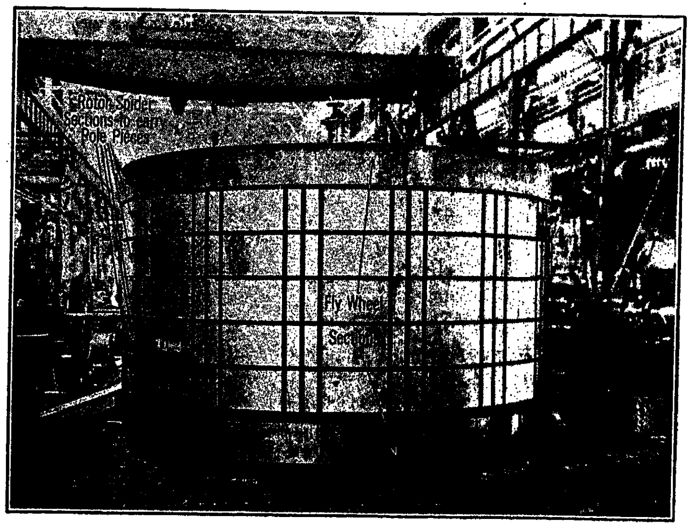

Fig. 3—The Rotor

insulation. The semi-plastic condition of the insulation also permits the expansion and contraction of the copper, due to changes in temperature, with a minimum disintegrating effect on the mica in the insulation.

Stator Coil Supports

The projecting ends of the coils at both the top and bottom are braced against one another by small wooden spacers, placed between the sides of the coils, and the whole winding is supported at each end, against the distorting effect of short circuits by two complete steel rings which are supported from the frame by suitable iron brackets. The windings are bound securely to the supporting rings with treated cord. This method of binding permits of a certain amount of flexibility that is desirable to allow for the expansion and contraction of the coils due to changes in temperature. The bracing rings are covered with insulating material not only for insulating purposes but to act as a cushion for the coils to rest against, and to take the sharp blows resulting from severe short circuits without cutting the coil insulation.

Potential Wave

The stator coils are chorded to take advantage of fractional pitch properties in obtaining a voltage wave form as near as possible to the ideal sine wave, and to eliminate the objectionable harmonics.

Armature Conductor

The section of copper necessary to carry the current in the stator windings being too large to use a single

strand, the conductor was subdivided into a number of strands of small section to facilitate the forming of the conductor in the coils and also to reduce largely the eddy current losses in the copper. The phase connections of the stator winding have been taken care of in a rather unusual manner by the use of a bus ring arrangement supported from the inside of the stator frame. The connections between these bus rings and the windings are made with flexible connections which can be disconnected. This arrangement allows free access to all the connections for cleaning and inspection, and permits the removal of damaged coils without disturbing the connections.

Ventilation

Air for cooling the generator is admitted to the pit beneath it, through ducts from outside the station, or from the generator room, and is drawn into the machine

Fig. 4—Stator Coil

by the blower action of the rotor. The air is expelled through the openings in the stator frame into a chamber surrounding the generator, and is then exhausted by a fan through a ventilating shaft through the roof, or to the different parts of the power house as desired. Because of the large volume of air required (about 120,000 cu. ft. per minute) it was necessary to give special consideration to the ventilation in the construction of the generator and power house. The unique provisions in the design of the power house for the generator ventilation are described in another paper being presented at this meeting.

Flywheel Effect

To meet the requirements of the hydraulic equipment in regard to speed regulation under conditions

of sudden changes in load, the rotor was required to have a much larger flywheel effect than would have been obtained if the rotor were designed with reference only to the strength required. A limited amount of this flywheel effect was available in the pole pieces with their coils, and the balance had to be obtained principally in the rim of the rotor spider. It was found that if the axial length of the rotor spider rim were limited to the length of the pole pieces the radial thickness of the rim would be so great that the air passages between the rim and the hub would be restricted too much to allow sufficient air to reach the upper ends of the rotor and stator coils. Therefore the unusual arrangement was adopted of providing two independent spiders or flywheels mounted on the shaft, one at each end of the rotor spider proper. These flywheels are of the same diameter as the rotor spider in order to allow for the assembly of the pole pieces. The rotor spider is sectionalized into five wheels so that the complete rotor with the flywheels consists

Fig. 6—Upper Guide Bearing

of seven separate wheels which are mounted on the shaft, one above the other. The hubs of these wheels are slightly wider than the rims so that openings are left between the rims to allow air to pass through to the spaces between the pole pieces. The ventilation is further assisted by curved fan blades attached to each end of the rotor and the recirculation of the air is prevented by baffle plates and covers around the ends of the stator windings.

Field Coils

The field coils are probably the largest ever made. Each coil is wound from a continuous strip of copper 1100 feet in length and weighing 2600 pounds. This strip is wound on edge in the usual manner and the adjacent turns are insulated from each other with asbestos and mica. The insulation between the coil and the pole core is of mica sheets while the insulating collars are of asbestos board so that the coils can be subjected to considerable heat without injury. This fire-proof insulation was not thought necessary because of an excessive temperature rise in normal service, but to prevent injury to the coils by a fire in the generator resulting from a failure in the stator winding.

Poles

The pole pieces are of the usual construction having ⅛-inch punchings riveted together between heavy cast steel end plates. Each pole has three parallel *T*-shaped dovetails which are designed to withstand the stresses due to double normal speed, without exceeding half the elastic limit of the material. Each pole with its coil weighs five tons and the peripheral velocity of the pole face at normal speed is over two miles per minute. The flywheel effect of the complete rotor is equivalent to 21,000,000 pounds at one foot radius. The shaft which is 30 inches in diameter in the bearings, has a solid forged coupling. In order to insure ample stiffness of the shaft, the critical speed with the rotor and shaft in a horizontal position was kept well above the run-way speed of the water-wheel. The upper end of the shaft has a groove machined in it to receive a split ring for transmitting the weight of the rotating parts to the thrust collar and spring thrust bearing.

Bearings

The guide bearings are of the usual General Electric construction for this type of large generator. They are provided with a number of small grooves for lubricating purposes.

The thrust bearing is of the spring supported type and is designed to carry a total load of 500 tons. Briefly, the distinctive feature of this type of bearing is that the stationary part consists of a relatively thin steel plate with a babbitted bearing surface which is supported by a large number of coil springs. The slight flexibility of the plate in conjunction with the spring support permits the plate to conform with any slight irregularity either in the supporting structure or the shaft and thrust collar without causing local unit pressures large enough to prevent the maintenance of a film of oil between the bearing surfaces. The thrust bearing operates in a bath of oil which is renewed at a comparatively low rate with clean oil from the station oil system. The heat generated in the bearing is taken up directly by the oil as it passes through and around the bearing plates and is then removed from the oil by water cooling coils immersed in the oil bath.

Bearing Brackets

The upper bearing bracket or bridge-tree for supporting the thrust bearing and exciter, has eight arms and is of cast steel. Because of shipping limitations it is split into halves which are joined together with fitted bolts. The complete bracket was tested at the factory with a load of 1000 tons by means of hydraulic jacks. This test load is double the normal operating load and gave assurance that the castings were sound. Cast steel was used for these brackets not only because

of its greater strength but also to limit the deflection to a value that would not interfere with the adjustment of the bearings or other parts of the generator and turbine. The calculated deflection of 47 mils was reasonably consistent with the observed value of 35 mils. The castings were slightly thicker than the drawing dimensions which fact probably accounts for the difference between the two values.

The openings between the arms are closed with sheet steel covers. Manholes of generous dimensions in these covers permit ready access to the upper part of the rotor and stator for cleaning and inspection.

In view of the fact that this power development is public enterprise and therefore will be open to public inspection, much attention has been paid to the design of the thrust bearing bracket, exciter and platforms, and railing, to obtain graceful proportions, and at the same time present an impression of strength and massiveness in keeping with the great power capacity of the generator and station. Two platforms are provided the lower one for inspection of the thrust bearing and the upper one for the inspection of the exciter and collector rings. The exciter armature is mounted on a short shaft with a forged coupling which is bolted to the top of the generator shaft. The collector rings are mounted on the generator shaft just below the exciter coupling and in case the exciter armature is removed for repairs it is not necessary to disturb the generator collector rings and the generator can be kept in service while the exciter armature is being repaired.

The lower guide bearing bracket is supported on the inner projection of the base ring. The opening for the guide bearing is large enough to pass the coupling on the shaft. The guide bearing shell is made as light as is consistent with good construction to facilitate removal, and is supported in the bearing bracket by the housing. Both the shell and housing are assembled and removed from below the bracket. The arms of this bracket have pads directly beneath the rim of the rotor spider, four of which are for the air brakes. The other four are to be used for lifting jacks for raising and supporting the rotor when assembling and dismantling the thrust bearing. The arms are designed so that four of them have ample strength to support the weight of the rotating parts of the generator and waterwheel.

Dimensions and Weights

In conclusion the following weights and dimensions may assist in formulating a conception of the size and proportions of these generators:

Outside diameter of stator frame.........	24 ft. 6 in.
Over-all height from face of coupling to top of exciter.........................	33 ft. 10 in.
Over-all height from base ring...........	28 ft. 3 in.
Weight of stator with core and windings..	175 tons
" " base ring......................	37 "
Diameter of shaft in rotor...............	32 inches
" " coupling..................	53 "
Length of shaft........................	30 feet
Weight of shaft........................	40 tons
Weight of upper bearing bracket.........	50 "
" " lower " "	12 "
Diameter of thrust bearing..............	69 inches
Load on thrust bearing.................	500 tons
Weight of one pole piece with coil.......	5 "
" " rotor spider (7 sections).......	190 "
Total weight of rotor..................	310 "
" " " generator with exciter....	625 "

65 miles of wire used in one set of stator coils.

450 miles of tape used to insulate one set of stator coils.

110,000 punchings required for stator core.

$3\frac{1}{2}$ miles of copper strip used for one set of pole coils.

4 tons of cooling air required per minute.

Discussion

For discussion on this paper see p. 507.

Design of 45,000-Kv-a. Generators, Queenston Plant

BY R. A. McCARTY and H. U. HART

Associate, A. I. E. E. — Fellow, A. I. E. E.

Westinghouse Electric and Manufacturing Company — Canadian Westinghouse Company

The water power development at Queenston, Ontario, which made use of the combined head of Niagara Falls and the Niagara River Rapids below the Falls, involved the design and construction of, what up to the present time are the largest hydroelectric generators built. Owing to the size limits met in these generators certain interesting design problems were encountered. The more important of these problems dealt with the design of (1) the armature winding, (2) the upper bearing bracket and (3) the rotating spider. The solution of these problems is briefly discussed and a tabulation of major dimensions and weights of the generators is given.

THE initial installation at the Queenston Development of the Hydro-Electric Power Commission of Ontario consists of two vertical shaft type alternating-current generators, each rated at 45,000 kv-a., 12,000 volts, 80 per cent power factor, three-phase, 25 cycles, 187½ rev. per min. nominal, or 49,500 kv-a., 13,200 volts maximum. A third duplicate unit will shortly follow the first two machines.

These units, as far as the records show, are the largest hydroelectric generators yet built and put into service. On account of their size, both in kilovolt-ampere rating and in physical proportions some interesting design problems were raised. These problems were divided into two classes, (1) electrical, and (2) mechanical, with perhaps the latter predominating.

Fig. 1 gives a sectional view of the generator unit. Fig. 2 gives a sectional view of the generator turbine and surrounding structure and indicates the flow of the cooling air through the generator and ducts. Each unit consists of the following component parts:

Stationary armature with base ring.

Upper bearing bracket, which supports the upper guide bearing and the thrust bearing.

Kingsbury thrust bearing.

Revolving field.

Shaft, with one-half coupling forged on the lower end for connection to the turbine shaft.

Lower bearing bracket, which carries the lower guide bearing, brakes and lifting jacks.

Direct-connected exciter.

Design of Armature Winding

The design of the armature winding involved, in addition to the ordinary questions of heating, efficiency, etc., the solutions of four important special problems, namely, (a) to obtain a distribution of the armature coils such as to produce a resultant voltage wave practically free from interference with adjacent telephone lines, (b) to obtain sufficient cross-section of copper in the armature coils to carry successfully the rated current, and at the same time not have the conductors of such proportions as to result in excessive eddy current loss; (c) to insulate the coils with materials that could meet the requirements for high dielectric tests and a high maximum temperature limit, even though the operating temperatures are low; and (d) so to support the end windings as to enable them to resist the enormous stresses that would be set up under short-circuit conditions.

The solutions worked out for these design problems were as follows:

(a) It is a well understood condition in the design of electrical generators that starting with the usual field flux form, the actual resultant wave will more nearly follow the desired law, other factors being the same, provided that the conductors, producing the resultant wave, are distributed at a maximum number of different positions about the armature periphery; *i. e.*, in a maximum number of slots. It was not found possible in these units to use an actual number of slots sufficiently large to insure the desired results. However the same effect was obtained by employing

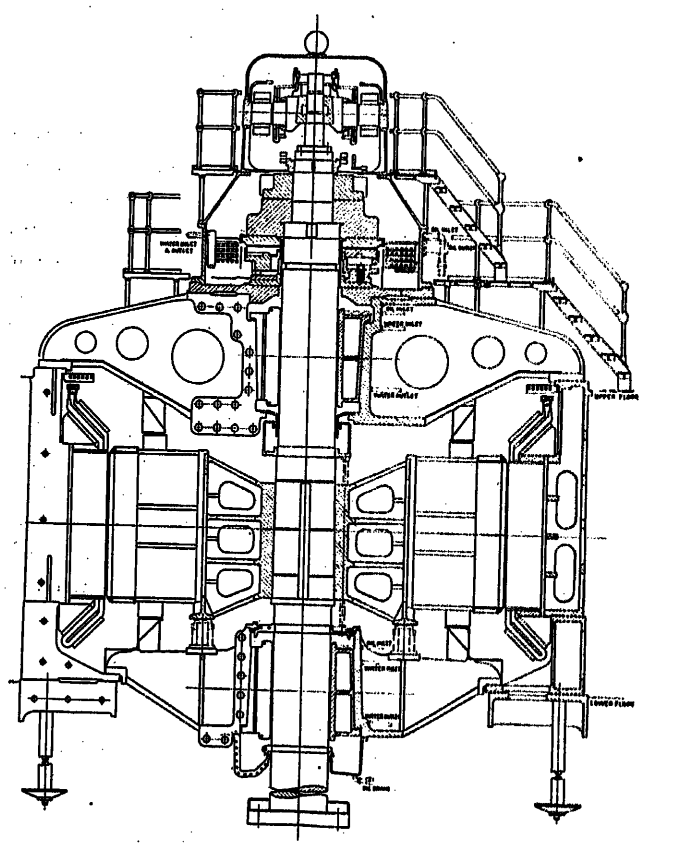

Fig. 1—Cross Section of Generator

Presented at the Annual Convention of the A. I. E. E., Niagara Falls, Ontario, June 26-30, 1922.

instead of the usual whole number of slots per pole a fractional number of slots per pole. The design selected had 19½ slots per pole which gave a distribution of the winding equivalent to 39 slots per pole. Fig. 3 indicates the distribution of the slots in two successive poles. One pole is shown directly above the other to indicate the relative phase position of the slots.

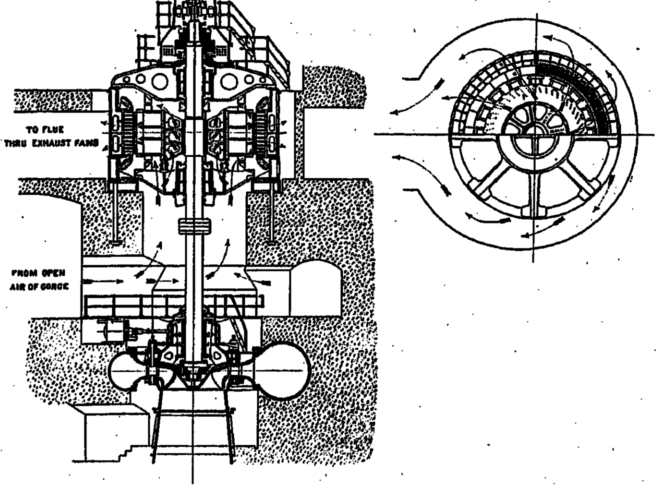

Fig. 2—Showing Flow of Cooling Air

Since the slots per phase in successive poles, in series, are displaced one-half slot pitch with reference to each other, it is apparent that the effect is equivalent to double the actual number of slots per pole.

(b) To minimize the eddy current loss it is necessary (1) to keep the over-all dimensions of the conductors (groups of wires in parallel) small, and (2) to reduce the dimensions, at right angles to the direction of the fluxes, of the individual wires that form the conductors, to relatively small values. To accomplish these results the total copper cross-section per phase was divided into four parallel circuits and the conductor in each of these circuits was subdivided as shown in the slot cross-section, Fig. 4. Each slot contains two coil sides consisting of two conductors each, *i. e.*, four conductors per slot, made up of nine wires in parallel per conductor. Each conductor is divided, depthwise of

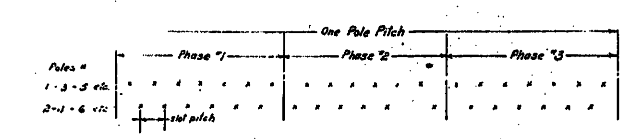

Fig. 3—Armature Winding Distribution
× Represents a slot

the slot, into seven layers, in consideration of the effect of the flux of self-induction. The two layers nearest the air gap were again subdivided into two parts in the width of the slot. The coil was also sunk in the core an additional distance over that ordinarily required for the slot wedge. The latter two features were to minimize the effect of the air gap flux that fringes into the slot.

Each of the wires marked "*A*" in Fig. 4 was insulated throughout its entire length with mica tape to insure positive and permanent separation between the various strands.

Since all the wires are continuous throughout the length of the coil the subdivision, of course, repeats itself in each conductor.

(c) Each group of wires forming a single conductor was insulated with mica tape. The conductors were assembled with mica strips between them to form the coil. The straight section of the coil which is embedded in the armature slot was brushed with bakelite, and then pressed in a hot press to solidify and consolidate the wires. The result of this treatment is a rigid coil in which the wires cannot be disturbed by subsequent insulating and assembling operations.

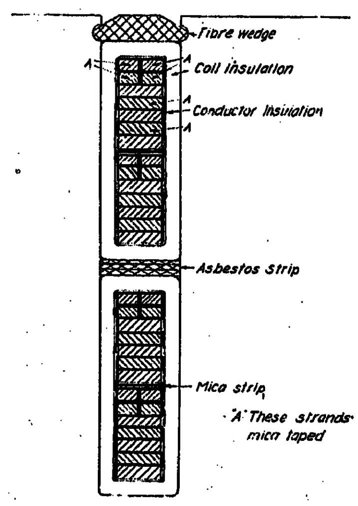

Fig. 4—Section of Armature Slot

The straight coil sides were insulated with a micarta-folium wrapper which consists of mica pasted to a very thin paper to give it the necessary mechanical support during the insulation process. The wrapper was first loosely applied to the coil by hand and then ironed into the finished product by electrically heated irons that revolve around the coil softening the bond and exerting a uniform pressure, thus slipping and tightening the wrapper until the insulation takes on the character of a compact wall of mica. The ends of the coil projecting from the core were insulated with mica tape adjacent to the copper and with varnished cloth outside of the mica tape. Varnished cloth tape on the outside of the coil is preferable since it can be sealed to exclude dirt and oil much better than can mica tape. Insulation in the form of narrow tape was used on these parts in order that the ends be flexible.

This insulation was required to meet successfully a dielectric test to ground, and between phases, of thirty thousand volts for one minute. It was also required

that it safely withstand a maximum total temperature of 150 deg. cent.

(d) The coil ends were bent away from the air gap at an angle of about 45 degrees to provide space below the boreline for the clamping blocks. The coil ends were braced against distortion under short-circuit conditions by clamping them with through bolts between parallel insulating blocks which are bolted to angle-shaped brackets attached to the frame. This construction is shown in the cross-section views of the generator, Figs. 1 and 2. It was required that this bracing be capable of supporting the coil ends, with the generator short-circuited at its terminals under full voltage.

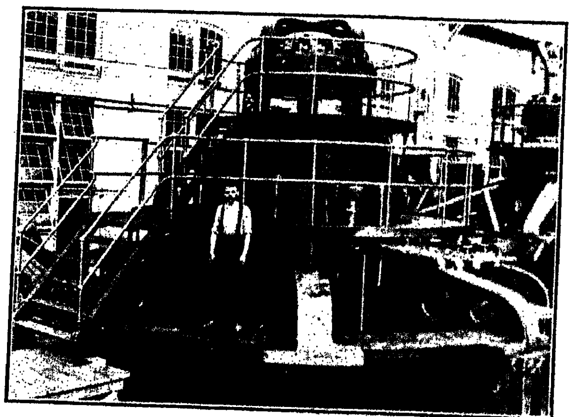

FIG. 5—UPPER BRACKET WITH THRUST BEARING, EXCITER, PLATFORM AND STAIRWAY ASSEMBLED

DESIGN OF UPPER BEARING BRACKET

It was required that this member support the combined loads due to the generator rotor, exciter, turbine runner, shaft and unbalanced water thrust amounting to approximately 1,000,000 pounds. Its design involved the consideration of three principal requirements, namely, (a) the fundamental requirement that it be capable of supporting the load within the safe limits of the material used; (b) that when fully loaded the deflection from the horizontal be less than the clearances between the turbine and generator rotating and stationary parts, and (c) that the character of the material and the design used be such that any vibrations set up by unbalanced conditions in the turbine would not be taken up by the bracket and transmitted to the generator stator.

Obviously these matters are so interwoven that they cannot be considered independently and, therefore, will not be taken up separately.

In designing this supporting member consideration was given to the use of three materials, structural steel, cast steel and cast iron. All factors considered, cast iron seemed the one best suited to the purpose. It was found in considering steel, either structural or cast, that while the requirements of ultimate strength could be readily met, its high degree of flexibility and resilience made it necessary to use sections greatly in excess of the requirement for strength in order to limit the deflection and the possibility of sympathetic vibrations. As the sections required with steel to meet the latter requirements approximated those needed in cast iron for strength, and as cast iron is not as flexible or resilient as steel, the iron was selected.

As the top surface of the upper bracket forms the bottom of the thrust bearing reservoir it is necessary that this casting be impervious to oil leakage. It is very difficult, if not impossible, to obtain steel castings that will entirely meet this requirement whereas there is no difficulty in obtaining cast iron that is perfectly homogeneous and oil tight. As the matter of oil leakage is one of no small importance in the operation of such a unit this was also a deciding factor in determining the selection of the bracket material.

This bracket, Fig. 5, in the finished design used sections approximately 2 inches thick and a maximum height at point of load application of 5½ feet.

DESIGN OF ROTATING SPIDER

Owing to the physical dimensions of the rotating spider the particular problem in the design was to select a construction in which the material throughout would be of uniform quality. On account of the well-known difficulties in making castings of such large sections and of obtaining uniformly homogeneous metal, it was impossible to make the spider of the ordinary "cast wheel" type. The "laminated rim" type of design, Fig. 6, was therefore adopted as the one best suited to meet the requirements.

FIG. 6—ROTATING PART

This design used an inner cast steel spider which consists of a hub and arms but has no rim. The rim

is built up using over-lapping $\frac{1}{16}$-in. rolled steel plates that are dovetailed to the spider arms in a manner similar to that used in attaching the armature punchings to the frame. In addition to being attached to the spider by the dovetails, the rim is clamped between heavy steel end plates by means of through bolts that pass through the entire laminated rim and the end plates. This design results in a rim structure of perfectly uniform material of known quality, to a degree impossible to obtain with castings. In this design the rim was not only self supporting as to radial stresses, entirely neglecting the dovetails, but was also capable of carrying the weight of the poles and field coils when operating at a maximum speed of 347 rev. per min.

The two large vent spaces provided in the central part of the spider were to provide additional cooling air inlets for this part of the unit.

Operating Results

With the generators in regular commercial service and operating under rated load, the maximum temperature rise measured by embedded temperature detector is 55 deg. cent.

General Dimensions and Weights

The principal dimensions and weights of the generators are as follows:

Maximum over-all diameter	25 feet.
Height from floor line to top of frame	13 ft. 8 inches.
Maximum over-all height from floor line	26 ft. 10 inches
Diameter of shaft at coupling	2 ft. 6 inches
Total weight of copper	50,000 lb.
Weight of rotating part	615,000 lb.
Total weight of generator unit	1,400,000 lb.
Load on thrust bearing	1,000,000 lb.
Flywheel effect of rotor	21,500,000 lb-ft.^{2}

Discussion

and

M. E. SKINNER
Member, A. I. E. E.
Formerly of Westinghouse Electric & Mfg. Co., E. Pittsburgh, Pa.

Review of the Subject.—*Interest in the main step-up transformers for the New Queenston generating station of the Hydro-Electric Power Commission of Ontario centers largely about their great physical size and the heavy short-circuit currents to be dealt with. Physically they are the largest single-phase transformers in operation today. In spite of the fact that they are for 25-cycle service, to our knowledge even their kv-a. rating is exceeded by only one bank of single-phase transformers now in operation, namely, the 70,000-kv-a., 60-cycle bank at the Colfax Station of the Duquesne Light Company.*

Figures are given for the weights and dimensions of these transformers and their component parts as well as the performance calculated from test results.

The mechanical forces in 25-cycle transformers are inherently high because of the relatively large number of turns necessary to develop the voltage, and because of their relatively low impedance to the flow of short-circuit currents. As the forces depend upon the square of the ampere-turns, it is evident that both the above conditions contribute materially toward increasing the forces.

To understand the bracing necessary to withstand the electromagnetic forces developed under short-circuit conditions, it is necessary to understand the nature of these forces as well as their magnitude.

The nature and magnitude of the mechanical forces existing between current carrying coils are discussed, (1) for a single turn coil in space, (2) for two single turn coils arranged concentrically and lying in the same plane, (3) for two single turn coils arranged coaxially and lying in parallel planes.

The conclusion is reached that as long as primary and secondary coils are adjacent there is no limit on the shape of the coil from the mechanical point of view, as all stresses acting in the plane of the coils are neutralized and there is therefore no force of any magnitude tending to distort the coils. The conclusions reached when single turns are considered hold equally as well for coils or groups of coils, so that in considering the forces in a transformer these fundamentals must always be kept in mind.

Thus by interleaving the primary and secondary coils, it is possible to overcome completely any limitations which the mechanical forces with other arrangements of coils may dictate and to choose a coil shape which adapts itself most readily to the solution of the other important problems of the design, namely, insulation and ventilation.

The Queenston transformers employ the interleaved type of construction familiarly known as the shell form, with rectangular pancake coils forming the alternating groups of primary and secondary coils.

The distribution of the mechanical forces in these transformers is analyzed in detail. The effects of imperfect distribution of turns and of taps are shown to be very undesirable. All of the required voltages could have been obtained with considerably fewer leads and taps but the reduction in the insulation difficulty through the elimination of extra leads would have been accompanied by an increase in the mechanical forces due to unbalancing conditions on tap connections. In these transformers the maximum stress occurs on the first under voltage tap and has a value equal to 136 per cent of the maximum stress with the full winding.

Having analyzed the various types of forces to be met with in the design of transformers of this type of construction, it will be interesting to examine the mechanical supports which have been provided in these units.

The proper ventilation and insulation of a transformer is equally as important as the adequate mechanical support of the winding. The system of bracing used in these transformers is particularly interesting, in that, in spite of the substantial construction used, the other vital factors of ventilation and insulation have not been impaired in the least.

CONTENTS

INTRODUCTION

In the years 1909 and 1910 there were designed, built, and installed at the Niagara Falls substation of the Hydro-Electric Power Commission of Ontario, the first nine 3000-kv-a. water-cooled transformers, to raise the three-phase power from 12,000 volts to a nominal transmission line potential of 110,000 volts. The data available at that time for designing, building and operating 110,000-volt apparatus were rather meager.

Six years later, in 1916, there were installed in this same substation the first three 7500-kv-a. transformers having the same characteristics. Six years of experience with the original units on the Hydro-Electric Power Commission's system with many data from other sources, made the problem of designing and building the 7500-kv-a. units relatively a much simpler one.

Presented at the Annual Convention of the A. I. E. E., Niagara Falls, Ontario, June 26-30, 1922.

Interest in the main step-up transformers for the new Queenston generating station of the Hydro-Electric Power Commission of Ontario centers largely about their great physical size and the heavy short-circuit currents to be dealt with. Physically they are the largest single-phase transformers in operation today. In spite of the fact that they are for 25-cycle service, to our knowledge, even their kv-a. rating is exceeded by only one bank of single-phase transformers now in operation, namely, the 70,000-kv-a., 60-cycle bank at the Colfax station of the Duquesne Light Company.

The design of transformers of such great capacity requires the solution of many difficult mechanical problems. This phase of the design is particularly difficult when the transformers must be made self-protecting against the short-circuit stresses incident to a 25-cycle system of the magnitude contemplated for this development. Planned for an ultimate capacity of some

fifteen 45,000-kv-a. generators, the Queenston station will be among the largest ever projected.

Physical Dimensions and Weights

A few statistics as to the physical size of these units might be of interest. They have a nominal rating of 15,000-kv-a. output at 80 per cent power factor delivered at 63,500 volts with 12,000 volts impressed. To compensate for the drop through the transformers

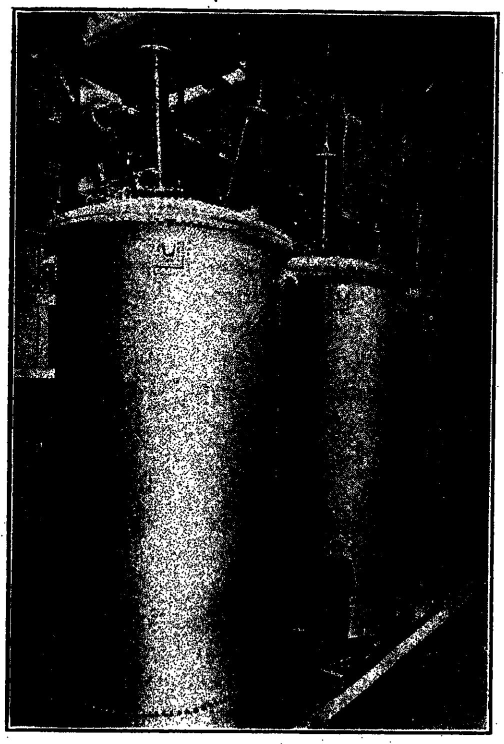

Fig. 1

under the above load condition, the open-circuit voltage is 67,200 volts. They have a maximum rating of 16,500 kv-a. under the same conditions of loading as given above with a guarantee of 55 deg. cent. rise in temperature as measured by change in resistance.

They are operated in banks of three, delta-connected on the low-voltage side, star-connected on the high-voltage side, to step up the generated power from a nominal voltage of 12,000 volts to transmission line potential. Taps are provided on the high-voltage windings so that the line potential may be varied between 110,000 to 132,000 volts.

The windings contain over 11,000 pounds of copper and the magnetic core contains over 60,000 pounds of punchings. The bare transformer weighs 99,000 pounds. The case, cover, base and various accessories weigh 46,500 pounds. Complete, with oil, the unit weighs 205,500 pounds.

Owing to the large dimensions and the great weights of the parts, especially cores and tanks (see Figs. 1 and 18), methods of handling at the manufacturer's plant and at the site of the power house as well as transportation facilities had to be considered in laying out the design.

The case is a cylindrical boiler plate shell, 9 ft. 6 in. outside diameter, and stands 21 feet from the rail to the flange at the top. The height from the rail to the top of the high-voltage terminal is slightly over 28 feet. The great height of the transformer is partly on account of the crowned cover and bottom which were necessary to meet the requirement of 150 lb. per sq. in. pressure, or 24 inches of vacuum, test on the tank. The bare tank with cover weighs 28,000 pounds. The tanks were delivered complete on the power house site.

The heaviest pieces are the transformer cores (Fig. 18). Ready for shipment they measure 7 ft. 2 in. by 7 ft. 4 in. floor space by 12 ft. 4 in. from floor line to top of insulating washers. Each core was shipped complete as shown in Fig. 18, except that the terminal supports were removed. The windings and insulation having been thoroughly dried and treated, the cores were sealed in oil in a special shipping tank. The shipping tank, oil and core weighed 142,000 pounds. At the manufacturer's plant and at Queenston the cores were handled with special lifting rigs by overhead cranes.

At Queenston the transformer cores were transferred directly to the main tanks, and flooded with oil. This procedure obviated the necessity of any drying and treating of the windings or insulation after installation, furthermore it greatly reduced the time required to put the units into actual service.

Rating and Performance

The Hydro-Electric Power Commission of Ontario required these transformers to be rated to develop 63,500 volts when delivering 15,000 kv-a. at 80 per cent power factor, with 12,000 volts applied to the low-voltage terminals at 25 cycles, and further that they

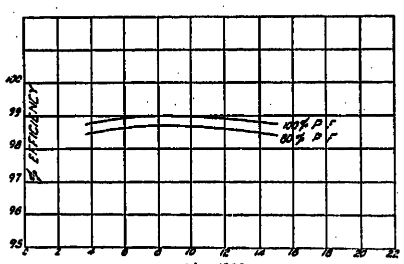

Fig. 2.—Efficiency Curves

would operate successfully with as high as 13,200 volts applied without excessive no-load current and losses.

With the above rating the transformers have a regulation of 5.85 per cent. This gives current rating of the windings as follows: 236 amperes for the high voltage, 1320 amperes for the low voltage. All tests to determine the performance of these units were made with above current values.

Complete tests to determine the no-load and full-load losses, also temperature runs with full-load current and voltage in the windings by the opposition method, have been made at works of the Canadian Westinghouse Company, Limited. All temperatures

of windings were determined by the increase in resistance method. The results obtained from temperature runs indicate that with full kv-a. output under normal voltage and frequency with 45 imperial gallons (54 U. S.) of water per minute through the cooling coils, the temperature of the windings will not exceed 68.5 deg. cent. or a temperature rise of 43.5 deg. cent. above ingoing water at 25 deg. cent.

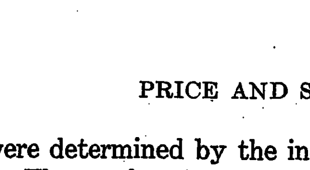

Fig. 3

Fig. 2 indicates the efficiency of these transformers at 100 per cent and 80 per cent power factor, calculated from the measured no-load iron losses and full-load wattmeter copper losses at 75 deg. cent.

Importance of Mechanical Problem

The mechanical forces in 25-cycle transformers are inherently high because of the relatively large number of turns necessary to develop the voltage, and because of their relatively low impedance to the flow of short-circuit currents. As the forces depend upon the square of the ampere-turns, it is evident that both the above conditions contribute materially toward increasing the forces. Frequently the conditions under which a transformer operates are such that external impedance considerably reduces the magnitude of the short-circuit currents which can flow through the transformer. On small systems advantage can frequently be taken of this external impedance to make the transformer good for the conditions under which it has to operate without making it capable of sustaining a short circuit with full voltage maintained. The usual interpretation of the phrase "self-protecting" is to consider the worst case possible, namely with full voltage maintained.

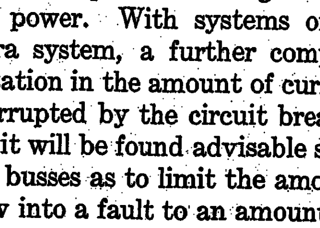

Fig. 4

On large systems only very slight advantage can be taken of external impedance owing to the great concentration of power. With systems of the capacity of the Niagara system, a further complication arises from the limitation in the amount of current which can safely be interrupted by the circuit breakers.

Frequently it will be found advisable so to group the machines and busses as to limit the amount of current which can flow into a fault to an amount which will be within the breaker capacity. This was the case in the layout of the Queenston station so that some slight advantage could be taken of the fact that generators and their respective transformers will never operate in parallel without reactors between the units. The greater the capacity of the individual transformer banks on a system in proportion to the total generating capacity, the greater becomes the difficulty of making them fully self-protecting and the less becomes the necessity for their being made so.

Nature of Forces in Transformer Coils

To understand the bracing necessary to withstand the electromagnetic forces developed under short-circuit conditions, it is necessary to understand the nature of these forces as well as their magnitude. Consider first a single circular turn of wire carrying current. If the leads enter the turn along a radius their effect may be neglected and the forces on this turn are due only to the reaction between the various elements of the turn upon one another; thus as illustrated in Fig. 3, the forces acting are all radially outward from the center of the coil and are equally distributed around the circumference of the coil.

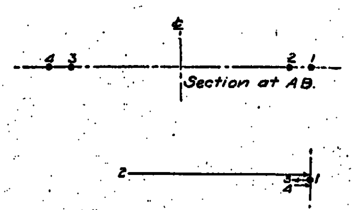

Fig. 5

That the effect of the leads may always be neglected becomes clear when it is remembered that, in the usual case, the coil will consist of a large number of turns instead of a single loop and the forces on portions of the coil will be many times those which can exist between the entering leads. Now consider two concentric circular turns lying in the same plane, and carrying equal currents. The forces are still radial as shown in Fig. 4, with two cases to be considered, first, currents in two turns in phase and second, currents in two turns out of phase. The forces illustrated in Fig. 4 are for the condition of the currents being out of phase by 180 deg. as would be the case between a primary and secondary winding. The forces between the two turns are repulsive and tend to keep them concentric. If the current were in phase in the two coils the forces would become attractive and any eccentricity would tend to increase the force at the point of least separation until the two turns are finally brought into contact.

To analyze this case more closely consider a section $A\ B$ of the two turns shown in Fig. 4. Fig. 5 shows conditions at this point. For convenient reference, the different conductors have been numbered and the direction of flow of current is indicated in the conventional manner. There is a strong repulsion between conductors 1 and 2 due to their proximity and a re-

pulsion of the same order of magnitude between conductors 3 and 4. These are not the only forces acting, however. Conductor 1 is attracted by conductor 3 and repelled by conductor 4. The magnitude of these forces compared with the magnitude of the forces between conductors 1 and 2 is inversely as the distances between

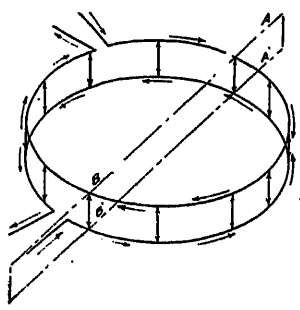

FIG. 6

them. Thus, when the diameter of the circles is great in comparison with their separation the forces on conductor 1 due to conductors 3 and 4 are in opposite directions and of very nearly the same magnitude. The excess of the attraction toward conductor 3 over the repulsion from conductor 4 slightly decreases the repulsion between conductors 1 and 2. By this process of reasoning it may be clearly demonstrated that the only forces which need be considered are those between adjacent coil sides.

The other common grouping of windings employed in transformer construction is the inter-leaved grouping in which all coils are coaxial and primary and secondary groups alternate with one another across the opening in the magnetic core. The mechanical forces between windings arranged in this manner are radically different from what they are with the concentric construction. Refer to Fig. 6, in which the turns are of the same diameter and lie in parallel planes. Fig. 7 shows a cross-section looking in the direction *A B* indicated in Fig. 6. The direction of the various forces acting is shown by the arrows. On any conductor there are three forces acting. For example on conductor 2 there are a strong force of repulsion from conductor 1, a very much weaker force of repulsion from conductor 3,

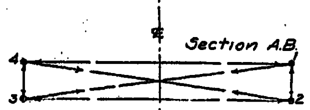

FIG. 7A

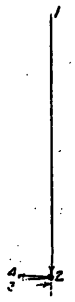

FIG. 7B

and a force of attraction toward conductor 4 of the same order of magnitude as the repulsion from conductor 3. The horizontal component of the attraction 2-4 practically wipes out the repulsion 2-3, and its vertical component detracts only slightly from the repulsion 1-2. The net result is that the only force of magnitude is that between conductors 1 and 2 and all forces acting in the plane of the coils are practically neutralized.

The conclusion is reached that as long as primary and secondary coils are adjacent there is no limit on the shape of the coil from the mechanical point of view, as all stresses acting in the plane of the coils are neutralized and there is therefore no force of any magnitude tending

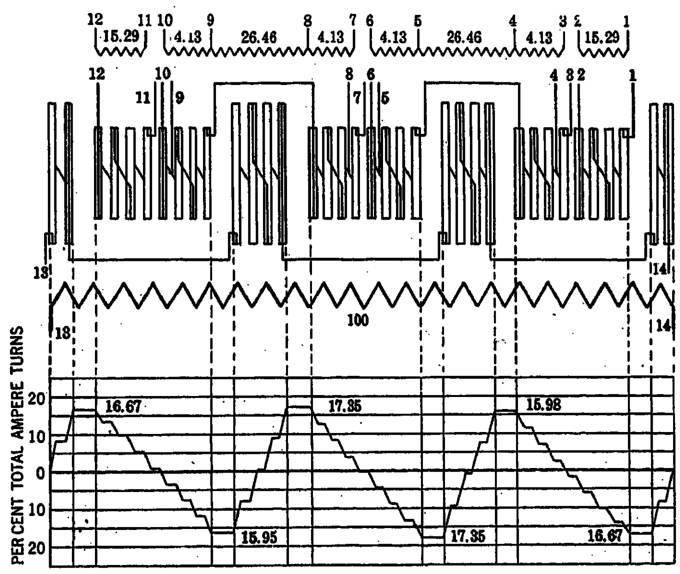

FIG. 8

to distort the coils. The conclusions reached when single turns are considered hold equally as well for coils or groups of coils, so that in considering the forces in a transformer these fundamentals must always be kept in mind. Thus by interleaving the primary and secondary coils, it is possible to overcome completely any limitations which the mechanical forces with other arrangements of coils may dictate and to choose

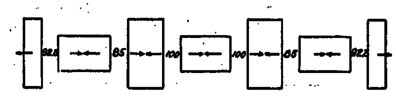

FIG. 9

a coil shape which adapts itself most readily to the solution of the other important problems of the design namely, insulation and ventilation.

DISTRIBUTION OF FORCES IN QUEENSTON TRANSFORMERS

The Queenston transformers employ the interleaved type of construction familiarly known as the shell form, with rectangular pancake coils forming the alternating groups of primary and secondary coils. The interlacing may be indicated symbolically *L H H L-L H H L-L H H L* there being three groups of high-voltage coils with which are associated a group of low-voltage coils on either side. This arrangement is called a 6-*H*-*L* grouping from the number of spaces high to low voltage which occur in the transformer. Fig. 8 shows a view of the top of the transformer, on which are indicated the connections and the develop-

ment of winding. The figures adjacent to the development indicate the percentage of the total series turns in each section. Below the plan view has been plotted a graph of the magnetomotive force causing leakage across the opening between primary and secondary. The flux density will be proportional to the m. m. f. so that the same chart might represent induction just

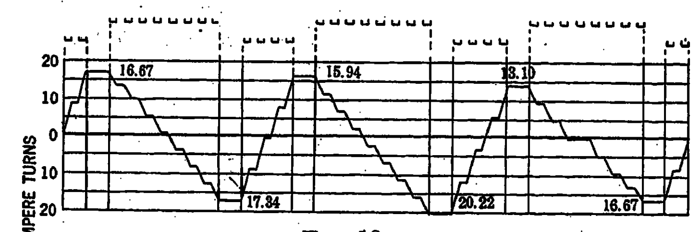

Fig. 10

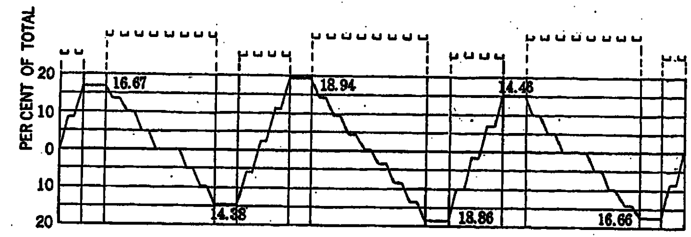

Fig. 11

as well as m. m. f. It will be noted that the flux density rises to a peak value at each H-L space. When it is possible to equalize the ampere turns in all groups the value of all of these peaks will be identical and other conditions being the same, the magnitude of the repulsion at each H-L space will be the same. It is frequently impossible to get an exact balance and in such cases the magnitude of the repulsion at different H-L spaces will differ slightly. For example, refer to Fig. 10 and note the values of the ampere turns across

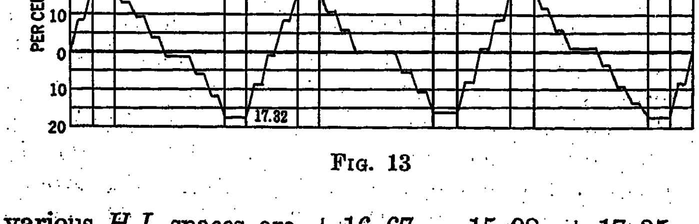

Fig. 12

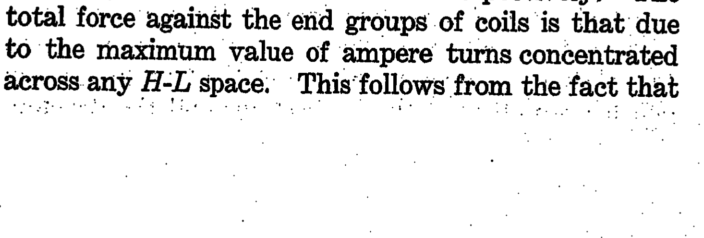

Fig. 13

various H-L spaces are $+16.67$, -15.98, $+17.35$, -17.35, $+15.98$ and -16.67 respectively. The total force against the end groups of coils is that due to the maximum value of ampere turns concentrated across any H-L space. This follows from the fact that each of the internal groups has a force acting against its opposite faces in opposite directions. Since the magnetic centers of all groups lie in the same plane, the resultant of two such forces is the algebraic difference. If there is an excess of one force above the other, it is transmitted to the next group and combines with the forces developed there. Referring to Fig. 9 the force against either face of the middle group of high-voltage coils is due to 17.35 per cent of the total ampere turns. The reaction against the adjacent low-voltage coils is of course of equal magnitude. If we call this force 100 per cent then the force developed in the next H-L space will be $(15.98/17.35)^2 \times 100$ or 85 per cent and in the outermost H-L spaces will be $(16.67/17.35)^2 \times 100$ or 92.3 per cent. Cancelling out opposite forces of equal magnitude it will be seen that the stress of the end group of low-voltage coils against the supports is due to the highest stress in any part of the windings.

100 per cent $-$ 85 per cent = 15 per cent unbalanced force which adds to reaction of 85 per cent against right face of outer high-voltage group giving 100 per cent.

100 per cent $-$ 92.3 per cent = 7.7 per cent unbalanced which adds to reaction of 92.3 per cent against right face of outer low-voltage group giving 100 per cent.

Effect of Taps

Taps always result in unbalanced magnetic conditions unless equal turns are cut out simultaneously from each group. This would lead to a very large number of taps

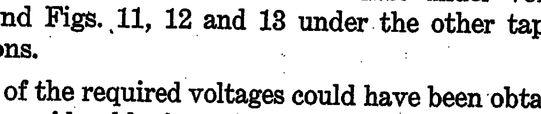

Fig. 14

and leads and in most cases the complication could not be justified. However, it should always be borne in mind that the greater the percentage of the winding tapped, the greater is the possibility of increasing the forces by unbalancing. Fig. 10 shows the magnetomotive force distribution on the first under voltage tap and Figs. 11, 12 and 13 under the other tap conections.

All of the required voltages could have been obtained with considerably fewer leads and taps as for example with the development of winding shown in Fig. 14 but the reduction in the insulation difficulty through the elimination of extra leads would have been accompanied by an increase in the mechanical forces due to unbalancing conditions on tap connections. As will be noted from Figs. 8 and 11 to 13, the maximum stress in the Queenston transformers occurs on the first under voltage tap and has a value of $(20.22/17.35)^2 \times 100 =$ 136 per cent of the maximum with the full winding.

Force on Individual Conductors or Coils

Fig. 15 shows an enlarged section of one portion of Fig. 8. It will be noticed that the individual coils which make up this group do not lie in fields of equal intensity. In fact the field intensity increases almost uniformly from one edge of the group to the other, reaching a maximum value at the edge of the space *H* to *L*. To obtain the total force developed between any two groups the ampere turns in that group must be multiplied by the average flux density through the group. Since the field intensity increases uniformly the average will be one-half the maximum. It is almost self evident that the coils nearest the *H-L* space will develop the greatest repulsion owing to the intense field in which they lie. It is a simple matter to calculate the percentage of the total force developed in a given group, which is concentrated against the face of any particular coil. For example, the number of turns in the high-voltage coil nearest the low-voltage

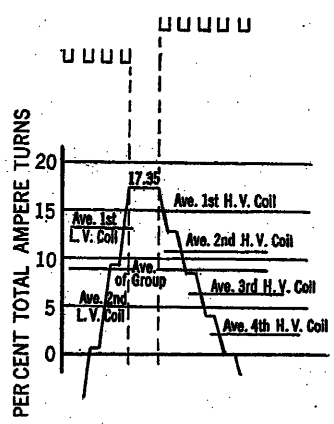

Fig. 15

winding is $4.41/17.35 \times 100 = 25.4$ per cent of the total number of turns in that group. The average field intensity throughout this coil in per cent of the average field intensity for the whole group is

$$\frac{17.35 - \dfrac{4.41}{2}}{8.62} \times 100 = 175.6 \text{ per cent.}$$

The percentage of the total stress developed against the first high-voltage coil will then be $0.254 \times 1.756 \times 100 = 44.6$ per cent. Similarly the second high-voltage coil is subject to

$$\frac{4.41}{17.35} \times \frac{10.735}{8.62} \times 100 = 31.6 \text{ per cent, and the}$$

third high-voltage coil to

$$\frac{4.41}{17.35} \times \frac{6.325}{8.62} \times 100 = 18.6 \text{ per cent, and the}$$

fourth high-voltage coil to

$$\frac{4.13}{17.35} \times \frac{2.065}{8.62} \times 100 = 5.7 \text{ per cent, of the}$$

total force in that group.

In the same way it can be shown that the force against the first and second low-voltage coils is approximately 75 per cent and 25 per cent respectively of the total force developed in the group.

The spacing strips which separate the coils to form the ventilating ducts must give the coils ample support to withstand safely the highest value of stress that can be concentrated against it. The problem resolves itself

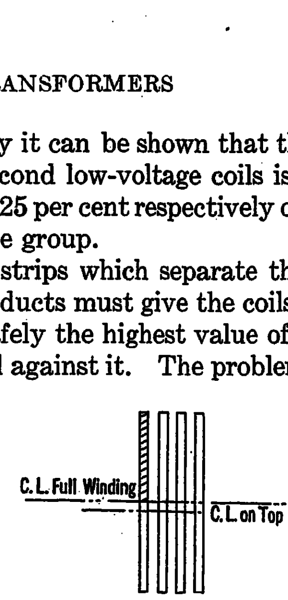

Fig. 16

into a question of supporting each individual turn frequently enough to limit the deflection under short-circuit stress to an amount which the coils can safely stand. This limit is set as much by the amount of bending which the insulation will stand without breaking, as it is by the elastic limit of the copper itself.

Effect of Displaced Electromagnetic Centers

Tapping a coil will always result in locally unbalanced conditions. This applies equally as well, regardless of whether we are speaking from the electrical or the mechanical point of view. From the design point of view, taps are always very undesirable. The mechanical effect of taking a tap out of a group of coils is illustrated in Fig. 16, which shows the worst possible unbalancing due to a single tap in a group of four coils. With one-half of the turns in one coil idle, the shift in electromagnetic center lines would be 3.67 per cent of the width of the coil. Obviously the conditions would be worse with fewer coils in the group, the worst case being a single coil. The ideal arrangement would be where the electromagnetic center lines are maintained coincident under all possible combinations of connec-

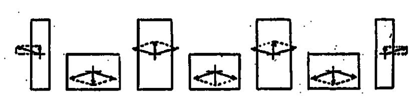

Fig. 17

tions. This ideal condition can be realized even when the design is handicapped by taps, provided the taps can be arranged to come at the connection between coils. Reference to Fig. 8 will show that on these transformers for the Queenston station, this problem has been successfully worked out so that the taps all come from connections between coils. In this way the possible displacement is limited to that obtainable with good manufacturing tolerances.

When a displacement in center lines exists, the total force in the various planes parallel to the face of the coils may be resolved into components parallel and perpendicular to the plane of the coils. Fig. 17 shows

a section through the upper ends of the coils of a transformer in which the displacement has been exaggerated to illustrate the nature of these stresses. With the displacement in the direction assumed the resultant forces are upward at the center of each low-voltage group and downward at the center of each high-voltage group

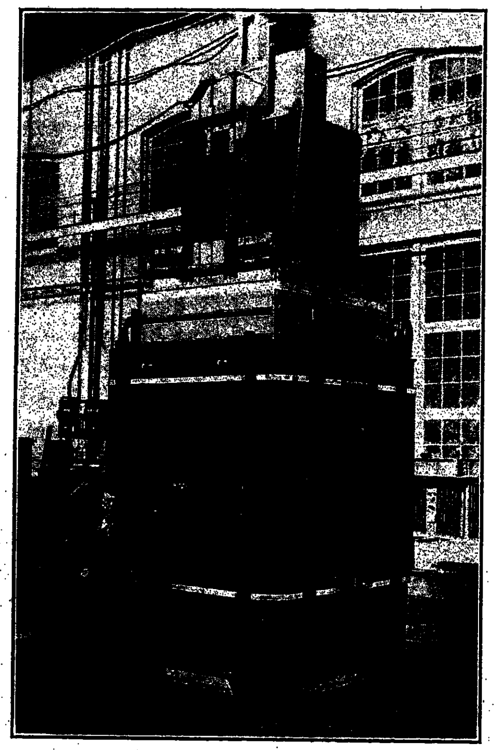

Fig. 18

of coils. Conditions are repeated at the lower ends of the coils so that the total vertical forces will be double those indicated in Fig. 17.

Method of Bracing Employed

Having analyzed the various types of forces to be met with in the design of transformers of this type of contruction, it will be interesting to examine the mechanical supports which have been provided in these units.

First to consider the total horizontal force perpendicular to the faces of the coils. Those portions of the coils which pass through the laminated core are securely held in place against these stresses by the punchings themselves. It is only necessary to supply supports for the portion which projects beyond the iron. Heavy steel plates are placed against the ends of the assembled groups of coils and insulation. By means of tie rods these plates are clamped about the ends of the coils to secure them against possible movement. Fig. 18 shows clearly the steel plates and the tie rods spanning them. Three rods are used on either side, two of the upper and one of the lower being visible in the picture. The others are concealed by the structural steel end frames but the holes provided to tighten these are clearly shown.

The weight of all the coils and insulation is carried on supports which are independent of the stacked up punchings which form the magnetic core. This support consists of two T beams with heavy spreader bolts between. One beam is inserted into each end of

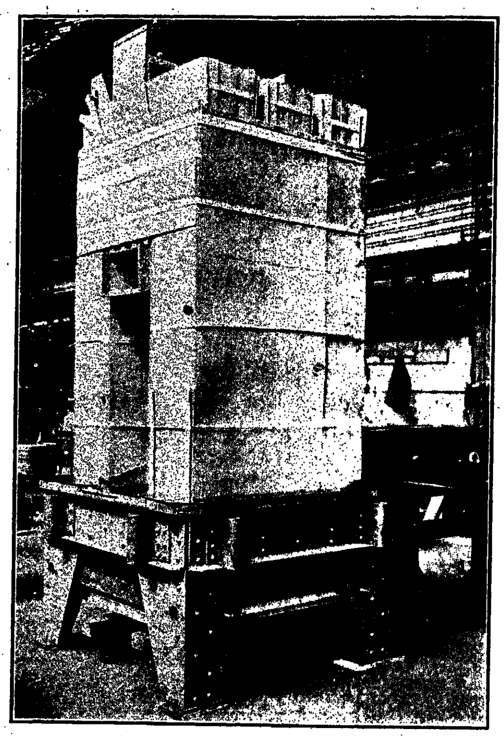

Fig. 19

the opening through the coils. By means of the spreader bolts at each end of the beams they are forced apart until the opening in the coils is solidly blocked, and all the weight transferred to the lower supporting frame. Fig. 19 shows the lower T beam in position ready for the building of the coil, the photograph being

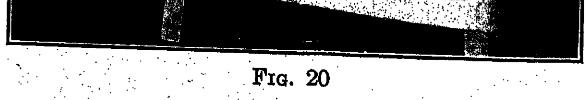

Fig. 20

taken on a unit of slightly different rating and characteristics. The T beams in the case of these transformers are made of phosphor-bronze in order to eliminate stray losses as they parallel a portion of the magnetic circuit. Fig. 18 also shows quite clearly this construction. These T beams also take care of any vertical

stresses due to possible discrepancies in the electromagnetic centers of the primary and secondary coils.

Individual coils are braced by the use of specially designed spacing strips. The vertical portions are supported by "wavy" spacing strips which support each turn at frequent intervals without blanketing any portion of the coil. The group of wavy strips in any duct is cleated together at several places and the cleats dovetail into the channels over the edge of the coils so that the strips cannot shift. The corners and the ends of the coil are braced by means of the ventilated spacers shown in Fig. 20. These spacers are formed of micarta in such a way that a solid piece of material is obtained having ribs at an angle to its length and open spaces between the ribs. The slant of the ribs is sufficient to support every turn crossing the spacer and still allow the free passage of oil through the spacing strip. By properly arranging these spacers they can be made to direct the flow of oil into and out of the ducts along natural stream lines.

The proper ventilation and insulation of a transformer is equally as important as the adequate mechanical support of the winding. The system of bracing used in these transformers is particularly interesting, in that in spite of the substantial construction used, the other vital factors of ventilation and insulation have not been impaired in the least. Over 70 per cent of the area of each coil lies along a vertical duct in which direction the resistance to the flow of oil is a minimum. The velocity of oil flow under these conditions is very high and the swerving oil stream by its vigorous action scours off the stagnant film of oil adjacent to the coil itself, and thereby reduces the temperature difference between the copper and the oil. This temperature drop at the surface of the coil is one of the most important elements of temperature difference going to make up the total difference in temperature between the windings and cooling water. It falls into that division of the temperature rise which responds almost instantly to changes of load and therefore has a most important part in determining the ability of the transformer to carry overloads.

Discussion

QUEENSTON—CHIPPEWA DEVELOPMENT OF THE HYDROELECTRIC POWER COMMISSION OF ONTARIO (Gaby);

DESCRIPTION OF THE 45,000 Kv-a. QUEENSTON GENERATORS (Barns and Bowness);

DESIGN OF 45,000 Kv-a. GENERATORS, QUEENSTON PLANT (McCarty and Hart);

FEATURES OF MAIN POWER HOUSE TRANSFORMERS FOR QUEENSTON PLANT (Price and Skinner).

Niagara Falls, Ontario, June 27, 1922

B. A. Behrend: It is instructive to note in connection with the design and construction of these large water-wheel generators installed as Niagara Falls, that the earliest units, which were rated as 5000-h.p. units, and which operated at 250 rev. per min., installed at the powerhouse of the Cataract Construction Company, as it was then called, were made with externally revolving fields, of the "umbrella" type. The field ring consisted of a large nickel steel forging, against which the solid pole pieces were bolted.

The speed of 250 rev. per min. was retained for all units from the earliest date of installation up to 1907, when the new units installed at the powerhouse of the Niagara Falls Hydraulic Power & Manufacturing Company's plant were projected with a capacity of 7500 kw. at 300 rev. per min.

Following the precedent, the first unit of this type was designed by the speaker with a nickle steel rotor, and a full description of this generator was given in the A. I. E. E. Transactions of June 1908. During the over-speed test, the first generator furnished to the Niagara Falls Hydraulic Power & Manufacturing Company was totally destroyed, the wreck appearing similar to the recent wreck of the 15,000 kw. generator at the Ontario Power Company's plant. The generator which was destroyed at the latter plant was designed and built by another manufacturer, with a cast steel rotor.

A careful examination of the fractures of the nickel steel forgings and exhaustive tests convinced me that large forgings of any kind are unreliable. They are subject to internal stresses, which are unknown, and which could be relieved only by thorough annealing, but the annealing process itself is inimical to the molecular formation of alloyed steels, even if it were possible uniformly to distribute the heat of the annealing furnace through all parts of a large mass of steel. It must be remembered in this connection, that it is customary for pieces to be heat treated to be supplied with holes, if possible, so that uniform penetration of heat can be secured. Such center holes are not practicable in electric generators, as the removal of the metal in the center leads to the doubling of the stress, on account of the redistribution of radial and tangential stresses, resulting in tangential stresses only. This matter was discussed by me in 1917 at Philadelphia, and is recorded in the A. I. E. E. Transactions, Vol. 36, p. 883. The speaker is firmly convinced from vast experience, extending over more than a score of years, that the use of large steel forgings is to be deprecated, and that the safest construction can be obtained by discarding totally these large forgings, and using steel plate construction instead.

The first large generating unit operating at 750 rev. per min.. and generating about 10,000 kw. was designed by the speaker in 1904, and built by the Bullock Electric Manufacturing Company for the Brooklyn Rapid Transit Company. The modern designs of steel plate rotors differ very little from this earliest prototype. Where it is possible to use a shaft, the plates are made with holes, but where it is not possible to use a shaft, the plates are bolted together with through-bolts. The journal ends are fastened to the rotors in a manner first shown to be most effective by Delaval, in his early steam turbines. The construction is now used generally elsewhere, and has been found thoroughly reliable.

The thirteen generators now operating at the powerhouse where the 7500 kw., 300 rev. per min. generator was installed in 1908, have been designed with plate rotors, the plates being made of ordinary open hearth-carbon steel, carefully heat treated, so that the steel is thoroughly ductile. Samples from these plates, which are a little over two inches thick, have been bent cold flat through an angle of 360 deg. without showing seams or fractures on the outside.

B. T. McCormick: About fifteen years ago the companies manufacturing wheel type generators paid very scant attention to the stresses at overspeed and the possibility of the destruction of a machine as a result of a run-away. Suddenly a machine flew to pieces. This was soon followed by a number of similar accidents in different parts of the country and served to awaken the manufacturers to a realization of a serious weakness in their designs and led them to make a close study of the stresses involved, and the suitability of different materials.

The design of a machine to safely stand a run-away involves

two main issues; to determine the stresses accurately, and to obtain a suitable material, the strength of which is definitely known.

The method of calculation must give a true measure of the stresses actually induced. If there is any doubt as to the accuracy of the method, the error should at least be on the safe side. Many of the stresses, on careful consideration, are found to be of a much more complicated nature than was first supposed, and of far greater magnitude. Stresses that at first seemed to be simple tension are really composed of a bending moment, a shear and a tension combined.

The material must be one of uniformly good structure throughout; one that is free from local weaknesses. To know that the material is uniform and to be able to rely on it, is even more important than very high elastic limit.

Rotors built of rolled steel disks of boiler plate mounted on the shaft have been found very satisfactory; also spiders composed of several steel castings side by side. If the castings are properly annealed and enough test pieces are obtained from various parts of the structure, as an index to its strength and uniformity, this construction is very reliable. For uniformity of structure there is no doubt that the laminated field ring is the most reliable. Such a structure is so finely divided that if any weakness exists, it will be so localized that it cannot affect the strength of the ring as a whole. This ring is usually mounted on a cast steel spider and care must be taken that the expansion of the ring at overspeed does not overstress either the arms or the dove-tails of the spider, furthermore, the design must be such that expansion at overspeed does not cause it to become loose on the spider.

W. J. Foster: I agree with Mr. Behrend that it is very important that the castings for the steel forgings be selected and tested carefully. Mr. McCormick has just remarked that about fourteen years ago there was an epidemic of machines flying to pieces. That is rather news to me, although I ought to know about such cases. I do remember happenings in two or three places, one of which our Chairman has referred to. Others occurred on the Pacific Coast, about the same time.

In connection with the idea of the last speaker, who mentioned the fact that the laminations are built up, a great number of them, so that if one is weak, the situation can be saved by its neighbors, I desire to call attention to the fact that the same principle has been carried through the designs of rotors of the multiple wheel type.

I desire to state that certain plate rotors for generators of high centrifugal stresses, involved much study and the testing of a model in the laboratory to guard against such troubles as opening at the shaft on the inner edge of the disk, a trouble which was encountered about that time in the construction of certain steam turbines. In the case of these generators a satisfactory design was obtained by cutting out holes in such manner as to leave material of the proper section to stretch sufficiently to prevent the trouble that would otherwise start at the shaft. The point I wish to make is that there are problems involved in plate construction, as well as in castings, and it is well, as Mr. Behrend has pointed out, to spare no pains to select the proper construction. Often castings should not be used but a plate or laminated rotor.

R. B. Williamson: A prominent feature of the two Queenston generators is the large fly-wheel effect as compared with other machines of comparable size. The fly-wheel effect of 21,000,000 lb. ft.^{2} is much larger relatively than that of the 32,500-kv-a. machines in the No. 3 plant of the Niagara Falls Power Company. The latter generators operate at 150 rev. per min. and have a fly-wheel effect of approximately 10,000,000 to 12,000,000. Thus taking into account the relative outputs and speeds in the two cases the Queenston machines have relatively about twice as much fly-wheel effect as the 32,500-kv-a. units.

The amount of fly-wheel effect to be put into a generator is something that must be determined for each case, taking into account the hydraulic conditions. The fact remains, however, that fly-wheel effects are frequently specified that are very much higher than the normal design of the generator would give. In order to obtain these large fly-wheel effects there has been a tendency in some cases to build generators on a larger diameter of rotor than was necessary from the standpoint of electrical design. This makes it more difficult to take care of overspeed stresses and has a decided bearing on the question of rotor construction.

While it is true that cast steel and forged steel rotors have failed in some instances, it is also true that there have been failures of laminated rotors. Not only must the materials be properly selected for a given case but the mechanical design must be such that the allowable stresses for the given material will not be exceeded. In the case of very large machines, a cast steel rotor has the advantage that it can usually be put together and tested for overspeed at the factory, after which it can be disassembled for shipment. With a large laminated rim this would necessitate stacking and unstacking and the test would be of doubtful value. It is true that there have been some accidents with cast steel and other types of rotor but if care is taken to design the rotor so that the stresses at overspeed are kept to within half the elastic limit of the material and the form of the castings made, in consultation with the steel founder, so that the finished product will be sound, thoroughly annealed and free from shrinkage strains, there is no reason why entirely safe rotors cannot be made; in fact very large numbers of them have been made and have been in successful operation for years.

F. D. Newbury: In two papers describing similar generators it is interesting to observe the differences in design and construction; in other words, how different designers have met the same problem.

The major difference in construction is found in the rotor material. In the generator described by McCarty and Hart, the rotor wheel (to which the poles are attached) consists of a single relatively light steel casting consisting of a hub and arms but without a rim. The rim is built up of 1/16 inch sheet steel punchings. In the generator described by Barns and Bowness the rotating part in made up of seven cast steel wheels placed one over the other on the shaft. It would be impossible to obtain a single satisfactory steel casting for the entire rotor. Barns and Bowness have used steel castings but have subdivided the rotor into as many castings as they considered necessary to secure sound castings. McCarty and Hart have abandoned the cast material entirely (so far as the rim is concerned) and have replaced it by a laminated construction that eliminates the question of unreliability. The laminated rim requires more material (on account of the radial joints in the rim) and more labor, but these are offset, to some extent, by the lower cost of sheet material as compared with castings. In the present case, however, the flywheel effect specified for turbine speed regulation required two additional cast steel sections in the Barns-Bowness design so that in this case, the laminated construction has an advantage, not only in potential reliability, but in rotor cost.

A second difference is found in the type of coil bracing. In one generator the outer layer of coil ends is roped to two rings; in the other, both layers of coils are bolted to cast iron brackets. The generators also differ in type of coil insulation. In the generator described by McCarty and Hart the straight parts of the coils (embedded in the core) are encased in a rigid mica wrapper while the exposed coil ends are insulated with a flexible bond between wires and a flexible tape insulation. The other generator has a flexible tape insulation throughout the entire coil.

In one generator the upper supporting bracket is cast steel and in the other cast iron. The advantage of cast steel is greater strength permitting the use of a relatively shallow structure. However, the necessity for small deflection limits the stress in cast steel to a low value so that full advantage of the greater strength of cast steel cannot be taken. Moreover, cast steel is

more expensive per pound and is considerably more difficult to handle in the foundry. There is more liklihood of defective castings and the greater chance of porosity that will lead to oil leakage from the thrust bearing pot.

O. D. Wood: There is one point in the paper on transformers that is not entirely clear, namely, the bracing of the winding against vertical forces resulting from possible displacement.

It is known that in any coil arrangement, if the magnetic axes do not coincide there exists a force tending to slide one coil or a portion of a coil with respect to the other winding. Thus, if concentric cylindrical coils are not symmetrically arranged, one coil tends to slide with respect to the other, and must be braced against such movement. Bracing is provided to guard against such a movement in concentric windings.

In interleaved windings, if the coils are not symmetrical there will exist a force tending to displace the coils as a whole or portions of the coil with respect to one another.

If the coils are circular this force is resisted by the tensile strength of the conductor because the coil is of circular section.

If the coils are not circular, but rectangular, as in the shell type, this force tends to blow out one coil and to collapse the other coil towards the core. Such a force is resisted by the iron on the coil legs, but if there is no bracing on the coil ends against movement away from the core, this force will tend to cause one of the coils to become semi-circular and to collapse the other on the bracing against the core. It would seem that it is practically impossible to obtain absolute coincidence of magnetic centers even with coils of the same dimensions, but it should be much more difficult in high-voltage transformers of the interleaved style where the primary and secondary coils are usually of different dimension. In fact, it is hard to determine in such unsymmetrical coils where the magnetic center is, so that it can be stated with some degree of assurance that there will always exist a force tending to distort the coils.

Furthermore, in any event where the coils are of different dimensions there exists a force on the wider coil tending to distort it due to the curvature of the leakage flux, *i. e.* the leakage flux is not in the straight line through the leakage gaps, but curves away and some of the flux passes through the outside turns of the coil.

The analysis on page 455 regarding the effect of opposite coil ends, shown in Figures 7A and B, should be influenced by the modifying effect of the core. Under absolute short circuit the full core flux passes through the leakage gaps, yet this flux moves into the core at every coil group, and therefore modifies the condition outlined in these figures.

W. M. Dann: It seems only a few years ago that someone made the prediction that we should have transformer banks with a rating of 50,000 kv-a., and now we have them at Queenston, and they are used on a low frequency which makes them physically much larger than they would be if used on 60 cycles. In Pittsburgh, there are banks of transformers with a rating of 70,000 kv-a. in operation, but they are somewhat smaller than Queenston transformers, because they are used on 60 cycles.

Transformers of this capacity are simply an extension in size over those that have gone before, and the problems of how to insulate them and how to cool them, and how to make them strong enough mechanically to be unharmed by the mechanical forces due to short circuits are bigger problems, but problems of the same kind that have been solved with smaller units.

Insulation troubles in general are rare and generally speaking the manufacturers are ready to insulate their transformers for any possible commercial voltage. The problem of carrying off the heat from the windings in a big transformer is not particularly simple, but it is a problem which is being successfully solved. The efficiency of these Queenston transformers is very high, slightly under 99 per cent at full load, and yet this means losses of about 175 kw. in the transformer. Most of this loss is in the windings. This means that the construction must include an efficient system of ducts to carry this heat away to avoid an abnormal temperature rise at any point. An illustration used in the paper shows a system of ducts which permit the oil to flow vertically upward, which is its natural direction. The curved strips allow the oil to come into contact with every conductor in the coil. The ribbed spacers at the tops of the coils create an open construction which undoubtedly is an important factor in reducing the temperature of the windings at these points which are naturally the hottest parts of the windings.

Perhaps the most important problem with these big transformers is to make them strong enough to withstand the mechanical forces which are present in the windings due to the action of the leakage field on the conductors. There are a good many ampere turns in transformers as big as these, even with only the normal full-load current flowing and the mechanical forces are going to be present as long as we have leakage. The mechanical forces at full load would not be negligible if they were not distributed over quite an area so that the forces in pounds per square inch are low. It is under abnormal conditions such as at the time of short circuit that these mechanical forces become formidable.

This feature of the design of large transformers calls for the greatest care on the part of the designer. As I said before, the mechanical forces are going to be present as long as we have leakage fields cutting current carrying conductors and they will appear as a stress in the materials. This is independent of what kind of construction is used. In a transformer with interleaved coils for instance they will appear, in a shell-type transformer, in the form of bending moments at the tops and bottom of the coils and in a core-type as a crushing force and they must be restrained by the coil bracings.

In a core-type transformer with concentric coils they appear as a tensile strain on the conductors and they must be kept within the tensile strength of the copper.

The vertical components spoken of by the authors depend upon how closely the magnetic centers are made to coincide when the coils are assembled and the tendency for the coils to move if there is a failure to make the centers coincide exactly is present in any type of transformer.

The mechanical forces depend upon ampere-turns and a great deal can be accomplished in reducing them by proportioning the ampere turns per group properly. If the grouping of the coils is done carefully the forces can be kept within bounds and unbalancing among the groups can be minimized by locating taps carefully. If all of these things were not given careful attention, it would be an easy matter to produce a design in which the mechanical forces would exceed the bending and crushing limits of the materials used. The diagrams in the paper show that the coil grouping in the Queenston transformers was carefully worked out and attention was paid to the arrangement of the taps to keep the forces to a minimum under the worst conditions.

The authors have shown in quite a simple way that the forces affecting the coils are practically independent of the shape of the coils because those components which tend to distort them are first of all negligible compared with those which tend to separate the coils from each other, and second they practically neutralize each other leaving effective only those forces which tend to make the coils move as a whole. These forces can be calculated and it is a comparatively easy matter after designing for minimum stresses to apply the bracing necessary to take care of the forces. A section of the paper describes how this bracing is applied.

We are told that the ultimate capacity of the Queenston Station is to be between 600,000 and 700,000 kv-a. This stimulates the imagination to think of the tremendous things that might happen in time of trouble. Even with one generator and one bank of transformers connected and used as a unit, the short-circuit kv-a. capacity could be over a quarter of a million kv-a. and it speaks well for the art that transformers can be

designed and built without any misgivings as to their standing up successfully under the worst short-circuit conditions that can possibly occur.

B. A. Behrend: So far as I am aware, there are no cases on record where machines designed with steel plate rotors have gone to pieces. However, there are numerous cases on record, where steel forgings and steel castings have been wrecked, and it is evident that it is the paramount duty of the designer to eliminate the elements of chance in the design and construction of these large units. The element of chance is greatest, where steel forgings are used, next greatest, where steel castings are used, and the least, where rotors are built up of steel plates. There is no question about the fact that it is possible to construct electric generators with either steel forgings or steel castings, but the fact cannot be denied, that the unknown quantity is greater in this case than it is when dealing with moderately thick plates, the structure of which is thoroughly known, which can contain no blow holes, no piping, no shrinkage stresses, and in which the material is subjected to stress in the direction in which its ductility is a maximum.

R. A. McCarty: From the papers presented and the subsequent discussion, it seems to me to be rather generally recognized among designing engineers that there is a proper field in generator construction for the use of both the built up and the cast steel types of rotor designs. As one speaker pointed out, many satisfactory machines have been built with both constructions. It, therefore, appears that the only important matter on which there is any serious disagreement, relates to the exact location of the dividing line which separates the two classes of machines in which the use of the different types of rotor should be employed. Since, as in all engineering work, the application of either design will vary, depending on the experience of the particular group of engineers concerned, it is not to be expected to find the various manufacturers following a common practise, there being no common experience. While we would not presume to take the position that our machine classification which fixes the type of rotor construction is the only correct one, I do want to emphasize the fact that in following that classification our record, contains no single case of which I am aware, of any machine of either construction going to pieces.

B. L. Barnes: I think that we are greatly indebted to Mr. Behrend for giving us the very interesting review of his experience as a pioneer in the design of large high-speed rotor construction. I think that it is generally accepted that the plate construction whether in thin laminations or boiler plate is preferable to the forged steel construction for large machines, but there is also a legitimate field for the employment of the cast steel construction.

As pointed out by Messrs. McCormick, Foster and Williamson each type of construction must be treated according to its own peculiarities, and while a given type is applicable in some machines, yet due to difficulties in manufacture it is not suitable for other machines. For instance in the case of a large generator the laminated rim construction involves the manufacture of very large sheet segments which are ordinarily made by only one or two punch press operations, limited in number in order to realize the economy peculiar to this type of construction. This involves some very nice problems in the design of the punch and die and the punch press to handle sheets of sufficient thickness to insure ample stiffness, especially in the pole dovetail parts, and it is quite conceivable that in order to use segments of sufficient thickness the number of operations would be increased to such an extent that the economy of cheaper material is more than offset by the increased labor cost. In addition to the advantage mentioned by Mr. Williamson of being able to make overspeed tests on large rotors at the factory the cast steel construction also permits giving each part a careful balance to insure a good running balance of the completed rotor. Nor is there the danger of the balance being disturbed after a long period of operation which might result from the gradual shifting of the punchings to take a permanent set on the through bolts and dowels.

In reference to Mr. Newberry's comparison of the two types of construction as regards the fly-wheel effect, I wish to explain that definite restrictions were placed on us by our customer as regards the diameter of the stator frame, and if we had been permitted to increase the diameter a few inches the desired fly-wheel effect could have been obtained without the use of the extra wheel sections. As Mr. Newberry has mentioned the laminated rim construction has necessitated more material, due to the radial joints which means a greater radial depth and restriction of the air passages through the rotor. Furthermore the stresses in the laminated rim are not relieved by the arms or spokes as in the case of the cast steel construction with the rim, spokes and hub cast as one piece.

In reference to Mr. Newberry's comparison of cast steel and cast iron upper bearing brackets, it should be noticed that the relatively shallow bracket obtained in cast steel has been taken advantage of for draining the oil pan of the upper guide bearing over the top of the stator windings instead of using a rotating pan on the shaft and draining the oil down through the rotor. Furthermore on the basis of a given deflection a bracket can be designed for cast steel of sufficiently smaller weight than for cast iron to overcome the disadvantage of greater cost per pound, and at the same time obtain a much greater factor of safety. We have experienced as much trouble due to porosity in cast iron construction as in cast steel.

Questions Relating to Standards of Rating, with Particular Reference to Large Machines Using Class B Insulation

F. D. NEWBURY
Fellow, A. I. E. E.
Westinghouse Electric and Manufacturing Co., E. Pittsburg, Pa.

FOR the past two years the Standards Committee has been studying the present rules concerning the temperature limits of Class B insulation and the detector method of temperature measurement, as applied to large machines, and related subjects.

The Electric Machinery Committee of the Institute has suggested that an opportunity for general discussion of these questions be given members of the Institute and this meeting devoted to machinery rating and temperature limits is the result.

This paper is intended to bring to the attention of members desiring to contribute to this discussion some of the questions that are before the Standards Committee.

This statement, it should be understood, is unofficial and should be considered only as an individual expression of opinion where any opinion is expressed or preference shown for one proposal over another.

Basic Principle of Rating

The principle employed in the A. I. E. E. Standards for determining the limiting temperature rises as a basis for rating is the so-called hottest-spot principle. The application of this principle in any particular case involves the determination of two quantities or figures; the limiting safe temperature of the insulation employed, and the difference between the hottest-spot temperature and the highest temperature it is possible to measure by the designated commercial method. Both of these figures are difficult to establish and in few, if any, cases can they be established to the satisfaction of everyone. As a matter of fact, agreement on most values of limiting temperature rise in use has been reached by reason of general experience, and current practise, rather than solely by the method set forth in the first chapter of the A. I. E. E. Standards.

There are two methods of approach in arriving at the limiting observable temperature rise: The hottest spot method, that in theory, at least, is scientific in that it is based on the determination of facts; and the direct discussion of temperature rise itself, without the consideration of intermediate steps. This second method is one of negotiation and compromise, and is as far from the usual methods of engineering as are the methods of the "old diplomacy." However, both methods have their advantages and limitations, and probably neither should be used alone. Whichever is considered *the* method, the other should be used to check the reasonableness of the result.

Presented at the Annual Convention of the A. I. E. E., Niagara Falls, Ont., June 26-30, 1922.

It has been suggested that the "hottest-spot" method or principle, as stated in the A. I. E. E. Standards, should be made less rigid in its application.

It has even been suggested that the complete subject matter relating to this principle be eliminated from Chapter I. A less radical suggestion is that the specific figures or values of conventional allowance and limiting observable temperatures and rises be omitted from Sections 1003, 1006 and 1009. This proposal also contemplates the elimination of specific values of conventional allowance from later chapters of the Rules, publishing only the final result—the limiting temperature rises.

A strong argument in favor of this change is the growing appreciation that it is impossible to establish single values of conventional allowance for all values of limiting temperature (for the various insulation classes) and for the various applications of each method of temperature measurement. If values of conventional allowance are to be retained in Chapter I, it will be necessary to give different values for the temperature limits of Class A insulation and Class B insulation, and to make it clear that the stated values are subject to change in specific applications. Under these conditions, the matter becomes more complicated and confusing, and it is more difficult to establish reasonable values, even for purposes of illustration.

This suggestion of omitting figures from Chapter I would work out somewhat as follows:

Section 1003. The specified differences by which the observable temperatures shall be assumed for purposes of standardization to be lower than the hottest-spot temperatures shall be designated the *conventional allowance.*

The conventional allowance depends on the method of temperature measurement, on the structure of the machine or part, on the limiting temperature rise and on a large number of design factors. Values of conventional allowance can be established only when limited to a specific method of measurement, to recommended applications of that method and to a specific value of limiting observable temperature rise.

Section 1006. This paragraph may be omitted, as it seems unnecessary to devote a separate section to the limiting observable temperatures, since they constitute merely an intermediate step in arriving at the limiting observable temperature *rises.*

Section 1009. The limiting observable temperature rises are obtained by subtracting the conventional allowances from the limiting hottest-spot temperatures (to obtain limiting observable temperatures), and by subtracting the standard ambient temperatures of reference from the limiting observable temperatures.

Values of limiting observable temperature rise for specific cases are set forth in later chapters.

It has also been suggested that Chapter I be designated "Introduction" instead of "General Principles," and that the section numbers be omitted. This would emphasize the general nature of this chapter, and still further separate it from the practical or working Rules given in later chapters.

Limiting Temperatures for Class B Insulation

In the present standards, this limit is 125 deg. cent., with the permissive value of 150 deg. cent. as given in Footnote 2, Section 1005:

The Institute recognizes the ability of manufacturers to employ Class B insulation successfully at maximum temperatures of 150 deg. cent., or even higher. However, as sufficient data covering experience over a period of years at such temperatures are at present unavailable the Institute adopts 125 deg. cent. as a conservative limit for this class of insulation, and any increase above this figure should be the subject of special guarantee by the manufacturer.

At its meeting of November 5, 1920, the Rotating Machinery Subcommittee presented to the Standards Committee the following report:

It is the sense of the Subcommittee on Rotating Machinery that the accumulation of data and experience since the present American rules concerning the hottest spot temperature limit of Class B insulation were first adopted warrants it in favorably considering the adoption of a hottest-spot limiting temperature for Class B insulation of approximately 150 deg. to 160 deg., but that a specific recommendation be deferred until investigations now under way and in prospect shall have been completed.

The Standards Committee received this report and circulated it to the members of the Committee for their consideration. At its meeting held January 17th, 1921, the report was accepted and transmitted to the U. S. Committee of the I. E. C. for their information and use abroad. During 1921, the Subcommittee conducted tests (referred to in another paper at this convention) and at the meeting of the Standards Committee, held Feb. 17th, 1922, presented the following definite recommendations, which were forecasted in its preliminary report of Nov. 5, 1920:

The Subcommittee proposes the following temperature limits for large machines with Class B insulation:

Stators: By detectors located between two coil sides:	
Hottest-spot limit	150 deg. cent.
Conventional allowance	20 " "
Total observable temperature	130 " "
Air temperature	40 " "
Limiting temperature rise	90 " "
Rotors: By resistance of the winding:	
Hottest-spot limit	150 deg. cent.
Conventional allowance	10 " "
Total observable temperature	140 " "
Air temperature	40 " "
Limiting temperature rise	100 " "

These recommendations were brought forward at this particular time because of the plans of the I. E. C. to hold a meeting for the discussion of rating in May, 1922.

The Standards Committee adopted its Subcommittee's recommendations, subject to confirmation at its annual May meeting. In response to requests for time for further consideration, the Committee has deferred final action until May 1923.

The recommendations of the Subcommittee for stator temperatures represent a compromise between the lower and higher temperature limits of the present Standards, if observable temperature rises are considered. The present rules provide for a conventional allowance of only 5 deg., while the recommended value is 20 deg. This results in 15 deg. lower value of the rise with the same hottest-spot limit. The limiting temperature rises in the present rules and in accordance with the Subcommittee's recommendation are as follows:

Present Rules:	
With 125 deg. hottest spot limit	80 deg. rise
With 150 deg. hottest spot limit	105 " "
Proposed Rule	90 " "

Separation of Performance Standards from Testing and Operating Instructions

To make the use of the Standards more convenient and to avoid the confusion of fundamentals with less important matter, it has been suggested that the things of first importance—the rules relating to the rating and performance of apparatus—be separated from the less important subject matter relating to testing methods, operation and methods of calculation.

This separation may be accomplished by placing these two kinds of material in different parts of the book or by printing the more important material more prominently.

In this connection, it has been suggested that there be included in each chapter relating to a specific type of machinery or apparatus a concise statement, generally in tabular form, of all values of limiting temperature rise that have been established by the Standards. In connection with rotating machinery, there are a number of sections in the Rules, usually stated as exceptions, that require interpretation before definite values of temperature rise can be arrived at. Table 400 (to be included in Chapter IV) is suggested to cover this proposal in the case of rotating machinery. The addition of this table to Chapter IV makes unnecessary Table 200 in Chapter II.

Other chapters in the present Standards contain similar tables of temperature rises such as, for example, Tables 501 and 502 for railway motors and Table 601 for transformers.

Application of the Embedded Detector Method of Temperature Measurement

The present rules require the use of this method in all machine stators with cores having a width of 50 cm. (20 inches) or over, and in all machines of 5000 volts

TABLE 400—TABLE OF LIMITING OBSERVABLE TEMPERATURE RISES

For machines for operation in locations where the ambient temperature will not exceed 40 deg. cent. for air.[1]

	Designation Number	Items			Method or Methods of Measurement Required	Limiting Observable Temperature Rise Class *O* Insulation	Class *A* Insulation	Class B Insulation
WINDINGS ON STATORS	1	Insulated windings other than 2-3-4	Windings on stators with cores of less than 50 cm. (20 inches) length if voltage is less than 10,000 volts.	Open Type	1	35	50	
					or 2	40	55	
				Enclosed Type	1	40	55	
					or 2	45	60	
			Armature winding on stators with cores of not less than 50 cm. (20 inches) length; also on stators of all machines of 10,000 volts and over.	With two coil sides per slot	3 *a*	No application		
				With only one coil side per slot		No application		
	2	Single layer field windings with exposed surfaces uninsulated and cast copper windings		Open Type	1	45	60	
				Enclosed Type	1	45	60	
	3	Wire field windings		Open Type	1	35	50	
					or 2	40	55	
				Enclosed Type	1	40	55	
					or 2	45	60	
	4	Short-circuited insulated windings			1	45	60	
WINDINGS ON ROTORS	5	Windings in slots such as d-c. armature windings and wound rotors of induction motors		Open Type	1	35	50	
					or 2	40	55	
				Enclosed Type	1	40	55	
					or 2	45	60	
	6	Single-layer field windings with exposed surfaces uninsulated..................			1	40	55	
					or 2	45	60	100
	7	Wire field windings..			1	35	50	
					or 2	40	55	
	8	Field windings of turbine type generators..................................			2	No application		100
	9	Short-circuited insulated windings			1	45	60	

or more, if rated over 500 kv-a. regardless of core width.

It is proposed to retain the 20-inch core limit, but change the voltage limit to 10,000 volts. The exact wording of this proposal is given under Item 1, Table 400.

The investigations of the Rotating Machinery Subcommittee have shown that the differences between winding temperatures, inside and outside the core and inside and outside the insulation of the embedded portion of the coils, are small in machines of less than 20 inches core length and of less then 10,000 volts, as these machines are ordinarily designed. For these machines, therefore, the thermometer or resistance methods of measurement are adequate.

The opinion exists, in some quarters, that the 20 inch core limit is too low. This results in turbo-generators as small as 500 kw. being equipped with embedded temperature detectors, and experience has shown that, in such small machines, there is little, if any, demand on the part of users, for this method of measurement, either for test or for regular operation. Opinion, abroad, is also in favor of a considerably higher limit in size before this method becomes applicable. If a change were made to 40 inches, the 1500-kw. 3600-rev. per min. turbo-generator would be about the smallest generator in which the detector method would be used.

The purpose of this paper is, as stated in the beginning, to stimulate discussion of the general subject and to invite the opinion of Institute members on the proposals that are referred to. It will be of value and of considerable assistance if a large number of written discussions are brought out. Written discussions sent in after the meeting will also be of service to the Standards Committee (if the author may presume to speak for the Committee) in the consideration of these matters during the coming Institute year.

Discussion

For discussion on this paper see p. 529.

Probable Values of Conventional Allowance for A-C. Generator Stator Windings

BY F. D. NEWBURY

Fellow, A. I. E. E.

Manager, Power Engineering Department,
Westinghouse Electric and Manufacturing Co.

THE principle employed in the A.I. E. E. Standards for determining the limiting temperature rises as a basis for rating is the so-called hottest-spot principle. The hottest-spot temperature is the bench mark or original point of reference and the limiting observable temperature is derived from it by subtracting a temperature that represents the difference between this temperature and the highest temperature that it is possible to measure by commercial methods. This difference is known in the A. I. E. E. Standards, as the "conventional allowance."

This basis for determining limiting observable temperatures can scarcely be criticized on theoretical grounds. It has been criticised, however, and with reason, because of the practical difficulties attending the evaluation of the conventional allowance. These practical difficulties have been greatly increased by the conception of the conventional allowance as an attribute of the method of measurement alone, resulting in a single conventional allowance for each recognized method of measurement.

Experience in building up standards under this principle has shown that it is impossible for a single value to satisfy all the practical situations arising. The conventional allowance with a certain method of measurement will vary with the total temperature or temperature rise; this has led to the suggestion that different values of conventional allowance be assigned for the different temperature limits of the different classes of insulation. But, even with a given method of measurement and a given limiting temperature the proper conventional allowance may still vary considerably because of the widely different conditions existing in different applications. For example, a conventional allowance for the thermometer method of measurement (with Class A Insulation temperature limits) may vary considerably in these several applications: A small induction motor stator winding, a large wire-wound shunt field coil, or an air-blast transformer winding. Or, to consider another class, the conventional allowance for the resistance method of measurement (with Class B insulation temperature limits) may vary considerably in a turbine type generator rotor winding and in a relatively small railway motor armature winding.

A consideration of these facts has led many engineers away from the idea of a single value of the conventional allowance applicable to a given method of measurement toward the idea of a conventional allowance associated with a single particular application. The former conception made the values of conventional allowance general in their application and the numerical values naturally became a part of the principle. The latter conception makes the values limited and specific in their use and divorces them from the general principle; this strengthens both the principle and the application of the principle to practical cases.

Presented at the Annual Convention of the A. I. E. E., Niagara Falls, Ontario, June 26-30, 1922.

The work described in this paper has been based on this second conception of the conventional allowance. It has been attempted to determine experimentally the value of the conventional allowance for this particular method of measurement when applied to a given class of alternating-current machine stator windings for given temperature limits.

This experimental work has been of two kinds: First, the measurement in machines of various sizes and voltages of copper temperatures by detectors inside the coil insulation) and of "observable" temperatures (by detectors located between the two coil sides in a slot) thus determining, by direct measurement, the data on which values of conventional allowance can be based; and second, an investigation of the influence of various factors such as insulation thickness, eddy current losses, core length and core temperature on the conventional allowance, by using a small armature model in which these several factors can be varied conveniently.

The tests on generators have been carried out under the direction of the Subcommittee on Rotating Machinery of the Standards Committee and the author acknowledges, with pleasure, his indebtedness to the Committee for permission to publish this information. Mr. C. J. Fechheimer is responsible for the interpretation of the model test results and the development, therefrom, of the formulas for the calculation of values of conventional allowance and top-coil copper temperatures.

Model Tests

In Figs. 1 and 2 are shown the details of a model designed to reproduce the temperature conditions in a radially ventilated armature core.

Thermocouples are distributed throughout the coils and core as indicated, so as to measure the true copper temperature, the temperature between coils and the average tooth temperature.

The several factors whose influence on the conventional allowance it is desired to study were reproduced as follows:

1. In order to imitate the conditions that obtain in a long machine, the coil ends were blocked so that the cooling of the ends by forced convection was very

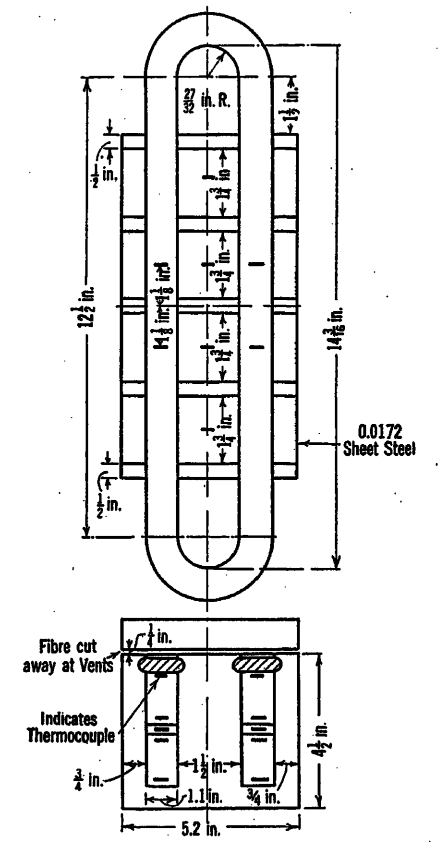

Fig. 1

Two coils, each consisting of eighty turns of 0.095-in. by 0.122-in. d. c. c. arranged 8 by 0.095 in. wide.

small. Thermocouples in the ends then showed nearly the same temperature as the copper in the embedded part, and therefore the longitudinal heat flow was negligible, thus simulating conditions that obtain at

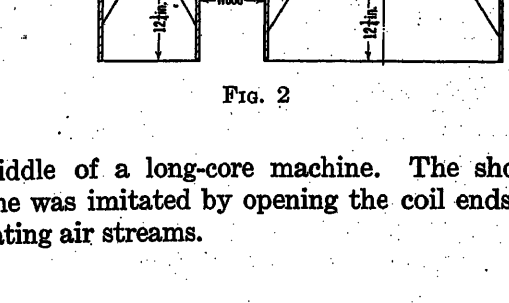

Fig. 2

the middle of a long-core machine. The short-core machine was imitated by opening the coil ends to the ventilating air streams.

2. The temperature of the iron was altered by changing the speed of the blower supplying the cooling air. By this means the iron temperature rise was changed from 10.5 to 70 deg. rise for the long-core, or from 9 to 40 deg. rise for the short-core machine, with the same current in the coils.

3. In all tests, direct current was used in the two coils. In order to imitate the influence of eddy currents the value of current in the upper coil was changed, the current in the lower coil being kept substantially constant throughout the tests.

4. The coil insulation was nominally for 6600 volt wrapper but it was crowded into a smaller space than is ordinarily used for that voltage. The wall thickness was approximately 0.11 in. Extra insulation was placed between coils, as shown in Fig. 3. The extra insulation was about 0.32 in. thick, thus making the equivalent wall thickness $\frac{0.32}{2} + 0.11 = 0.27$ in, or

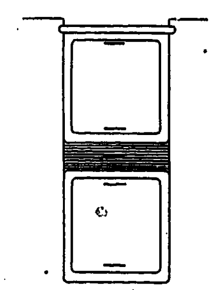

Fig. 3

slightly greater than would be used for 13,200 volts. Tests were made with and without this extra insulation.

Twenty eight different temperature tests were made under various conditions; the first series was equivalent to a 13,200-volt long-core generator with varying eddy current losses (varying loss ratio) and with varying core temperatures; similar series of tests were made for a 6600-volt long-core armature and for 13,200-volt short-core armatures. All temperature tests were continued until steady temperatures were attained. The test results of all runs are summarized in Table I and the results of typical runs are plotted in the accompanying curves.

Fig. 4 shows the variation in temperature rises for different blower speeds, equivalent to different core temperatures, with 20 amperes in each coil and imitating the long-core machine. (The reciprocals of blower speeds are used as abscissas in order that the curves approach straight lines). It will be seen that the maximum copper temperature and iron temperature curves are nearly parallel, indicating that although the iron temperature rise increased from 10.5 deg. to 70 deg. the drop from the copper to the iron changed but little; and this small increase was largely due to the increase in copper temperature with resistance. This relation is to be expected from the fundamentals

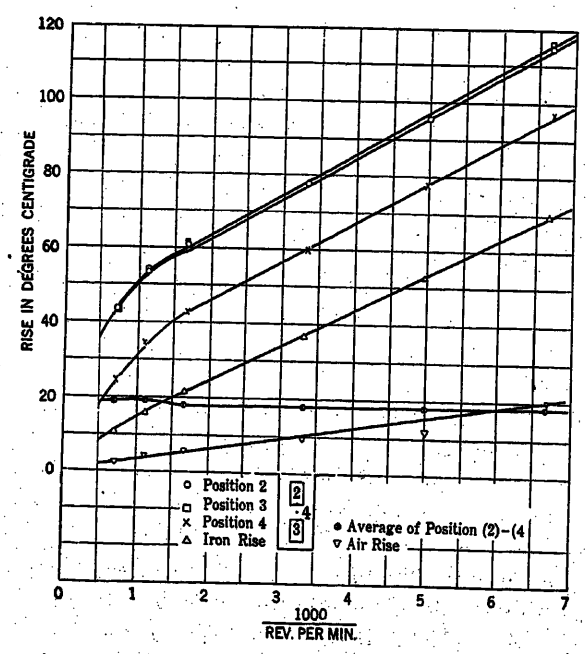

FIG. 4—TEMPERATURE RISE AS A FUNCTION OF RECIPROCAL OF FAN REV. PER MIN.

Twenty amperes d-c in both coils. Ends poorly ventilated. Long core machine. ¾ in. extra insulation between coils.

of heat flow and temperature drop. This is the first important fact to be observed.

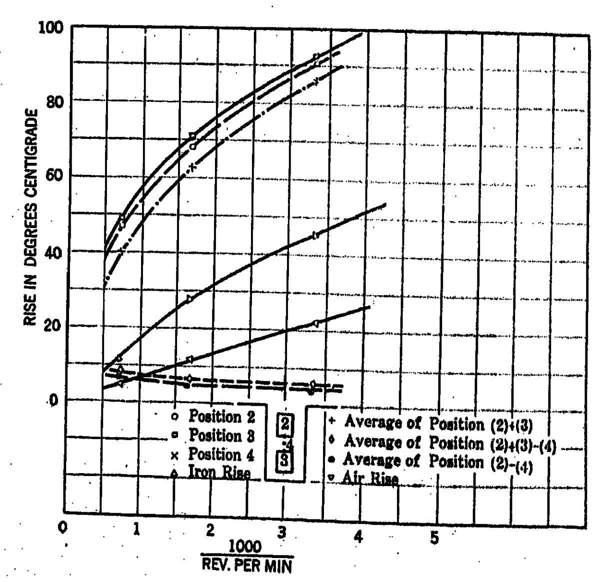

FIG. 5—TEMPERATURE RISE AS A FUNCTION OF RECIPROCAL OF FAN REV. PER MIN.

Twenty amperes d-c. in both coils. Ends poorly ventilated. Long core machine. No extra insulation between coils.

The second important fact may be noted from Figs. 4, 5, and 6 viz., the amount or velocity of cooling air

has no effect upon the total temperature drop through the insulation, or on the difference between copper and observable temperatures, (if allowance is made for the increase in resistance with temperature). It follows,

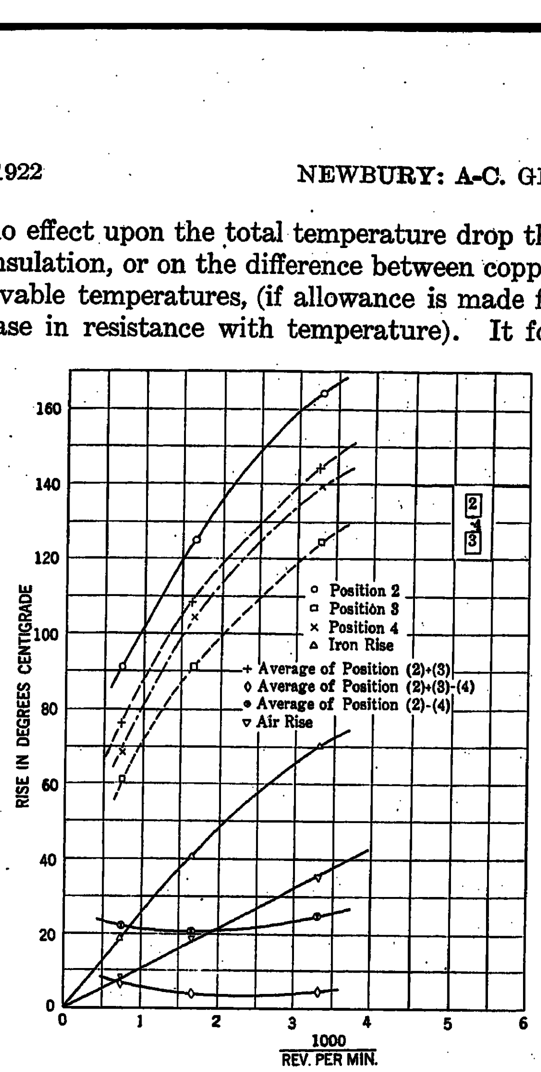

FIG. 6—TEMPERATURE RISE AS A FUNCTION OF RECIPROCAL OF FAN REV. PER MIN.

Twenty amperes d-c. in lower coil. 27.5 amperes d-c. in upper coil. Ends poorly ventilated. Long core machine. No extra insulation between coils.

that changes in armature temperatures caused by changes in ventilation are not accompanied by any changes in conventional allowances.

The third important fact is that there is substantially a constant difference between the mean of the top and bottom coil temperatures and the observable temperature rise (detector between coils,) provided the loss in the bottom coil is not altered and the insulation thickness is fixed. This may be seen to hold with reasonable accuracy whether or not the ventilation (or iron temperature) change through wide limits; whether or not the eddy current loss be materially changed; Figs. 7 and 8; whether the wall of insulation be thin or thick (provided it is not changed during a series of tests); or if the core be long or short. This fact is interesting and of value, and to our knowledge has not been pointed out by any one previous to this investigation. This temperature difference, it should be noted, exists in spite of equal temperatures in top and bottom coils. We have been accustomed to think that under this condition of equal coil temperature, the observable temperature is equal to the copper temperature. Such, however, is not the case because there is heat flow to the slot sides from the adjacent sides of the coils and from this series of tests a measure of the temperature drop caused by this flow was obtained. Thus, (see Table I) this drop for the same current in both coils, was 18 to 19 deg. for iron temperature rises of 10.5 deg. to 70 deg., (with extra insulation between coils); and was 10.5 deg. to 13 deg. for variations in iron temperature rises from 9 deg. to 40 deg. (for no extra insulation between coils). With variations in loss ratio, for a given insulation and core length, the change in this drop is slightly greater, but still can be considered as constant with reasonable accuracy.

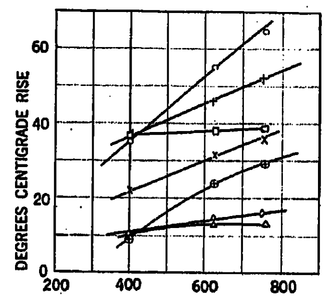
These relations are used in deriving the equations for calculating the conventional allowance. Let

θ_t = the temperature rise of the copper in the top coil

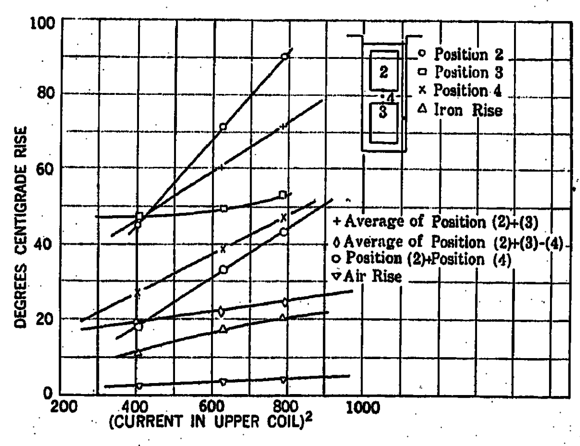
θ_b = the temperature rise of the copper in the bottom coil

θ_m = the temperature rise by detector between coil sides

θ_a = the temperature difference between the means of top and bottom coil temperatures and the temperature by detector between coils. This is equivalent to the drop in temperature due to heat flow to the slot sides (between coils) and is constant under certain conditions.



Tests at 1400 rev. per min. of fan. Twenty amperes d-c. in lower coil in all tests. Temperature rises as a function of square of current in upper coil. ¼ in. extra insulation between coils.



Ends poorly ventilated. Long core machine.

FIG. 7

By definition

$$\theta_a = \frac{\theta_t + \theta_b}{2} - \theta_m \qquad (1)$$

It is reasonable to assume that the temperature rises of the top and bottom coils above the temperature of

the adjacent core teeth is proportional to the losses in these coils; the ratios of these temperature rises will be equal to the ratio of the losses. The loss in each

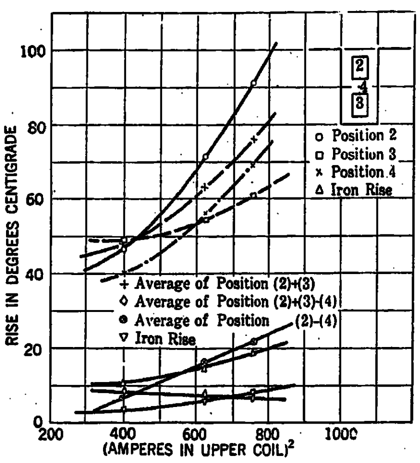


Fig. 8—Temperature Rise as a Function of Square of Current in Upper Coil

Current in lower coil constant equals twenty amperes. Fan speed constant equals 1400 rev. per min. Ends poorly ventilated. Long core machine. No extra insulation between coils.

ratio of coil losses be designated by $L.R.$ and the core tooth temperature by θ_i; then:

$$L.R. = \frac{\theta_t - \theta_i}{\theta_b - \theta_i} \tag{2}$$

In the usual case, θ_i and θ_m are measured, and the constant θ_a, is determined by test on similar apparatus. The loss ratio may be estimated from eddy-current calculations. We then have two equations, and two unknowns, θ_b and θ_t. Solving for them,

$$\theta_b = \frac{2\,(\theta_m + \theta_a) + \theta_i\,(L.R. - 1)}{L.R. + 1} \tag{3}$$

$$\theta_t = \frac{2\,L.R.\,(\theta_m + \theta_a) - \theta_i\,(L.R. - 1)}{L.R. + 1} \tag{4}$$

Also from (1)

$$(\theta_b + \theta_t) = 2\,(\theta_m + \theta_a) \tag{5}$$

The conventional allowance is

$$\theta_c = \theta_t - \theta_m = \frac{(\theta_m - \theta_i)\,(L.R. - 1) + 2\,\theta_a\,L.R.}{L.R. + 1} \tag{6}$$

The difference between the upper and lower coil temperatures is

coil is the $I^2 R$ loss plus the eddy current loss, both of which can be calculated in a given case.[1] Let this

1. See Eddy Current Losses in Armature Conductors. R. E. Gilman, A. I. E. E. Transactions 1920; also article by S. L. Henderson, *Electric Journal*, September 1920, giving principal formulas with examples.

$$(\theta_t - \theta_b) = \frac{2\,(\theta_m + \theta_a - \theta_i)\,(L.R. - 1)}{L.R. + 1} \tag{7}$$

Equation (4) then gives the top coil temperature rise, and equation (6) gives the conventional allowance.

It remains to establish the variation of θ_a with core length, insulation thickness and rate of heat flow. This can be done from the results of the model tests and the

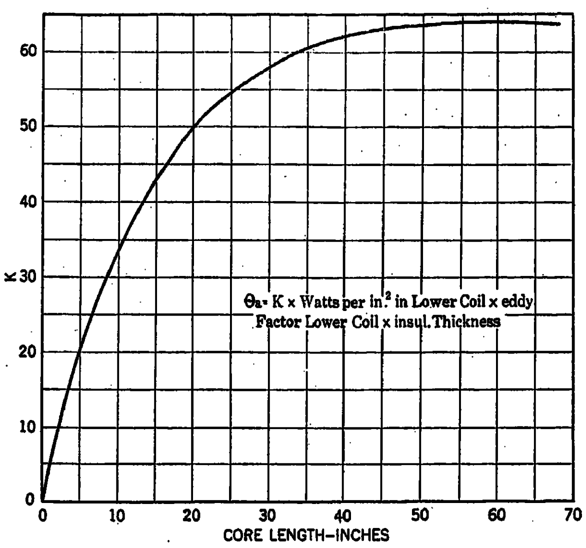

Fig. 9

generator tests described later. It will be noted that the following values were obtained for the conditions tested and were used in obtaining the calculated values given in Table II.

For 13,200-volt insulation and very long core (say in excess of 60 inches).......20 deg.

For 13,200-volt insulation and very short cores (8 1/2 inches)..................13 deg

For 6600-volt insulation and very long core.... 6 deg.

The value θ_a remains constant with varying loss ratios, varying core temperatures and with constant loss in the bottom coil as shown by the model tests.

No tests were made with varying loss in the bottom coil but a little consideration will show that the heat flow to the slot sides (and consequently the value of θ_a) will vary in proportion to the rate of heat flow from the bottom coil (or the watts per square inch of coil surface).

It is also assumed (from the fundamentals of heat flow) that θ_a is proportional to the insulation thickness. We may then write

$$\theta_a = K \times \text{watts per sq. in.} \times \text{insulation thickness} \quad (8)$$

In this expression K varies with core length. In long core machines (say over 60 inches) the heat generated in the copper at the center of the core is transmitted wholly across the insulation wall to the core. As the core length diminishes a greater part of the heat generated in the copper at the center of the core is transmitted along the copper to the external coil ends and the part transmitted across the insulation wall diminishes. The effect of variation in core length, therefore, is to vary the watts per square inch transmitted across the insulation wall. The relations between core length and division of heat flow between

In machines 1-4-5-7-8-13-15-16—10-inch resistance detectors are used; those inside main insulation are in contact with cotton covering of wires; other machines have thermocouples and couples inside insulation are in contact with bare copper. All detectors are located in center of core, lengthwise.

*Temp. affected by flux from field augmenting loss in upper coil.

†Bottom of bottom coil.

the transverse and longitudinal paths are quite complicated, but these have been investigated and the general shape of the curve is known.[2]

The curve, Fig. 9, showing the relation between K and core length has been arrived at from a consideration of these general relations, and the experimental data from both the model tests and the tests on machines. The data from the model tests with extra insulation between coils have not been used (except as an indication of the relative variation of K with core length) because of the known fact that the heat conductivity of laminated insulation varies greatly with and across the laminations.[3] With the extra insulation between coils as used in the model, the layers of the insulation were not rounded, as would be the case with coil insulation, but lay flat. See Fig. 3. Consequently the side flow of heat was greater and the temperature drop was greater than in the usual case.

of the A. I. E. E. arranged to make tests on generators of three different manufacturers to obtain data that would be useful in the revision of the temperature limits of large machines using the embedded temperature detector method of measurement.

Tests were made on sixteen generators ranging in size from 750 kv-a. to 12,000 kv-a. at various voltages from 2300 volts to 15,000 volts and speeds from 150 rev. per min. to 3600 rev. per min. Very large turbine type generators were not included in this program, because another series of tests on such machines had previously been arranged.

The tests conducted by the subcommittee were made in the testing departments of the several manufacturing companies. Each test was supervised by the member of the subcommittee located at the plant. In all of the machines detectors were built into the armature coils to measure the temperature of the copper of the

*Temperature affected by flux from field augmenting loss. Iron temperature at bottom of slot
†Iron temperature assumed, not given from test.
‡On copper of top of upper coil.
Note: Iron temp. not given from tests: The iron temperature rises by thermometer were increased by [illegible] tests on other machines. The iron temperature, as used in formula, has small influence upon the copper temperature [illegible] when the loss ratio is high.

In equation (8) the watts per square inch refer to the bottom coil, the watts being the $I^2 R$ loss at 75 deg. cent., plus the calculated eddy current loss in the bottom coil at the same temperature, and the surface being that of the bare copper, omitting the side adjacent to the top coil. The insulation thickness is taken as one-half the difference between slot width and bare copper width.

Generator Tests

At a meeting held November 4, 1920, the Rotating Machinery Subcommittee of the Standard Committee

top coil and detectors were located between coil sides. In some of the machines detectors were also located inside the insulation of the bottom coil and between the top coil and core tooth.

The essential design information and test results are given in Table III.

A word of caution may be required against using these generator tests *directly* for estimating probable or reasonable limiting values of conventional allowance or measureable temperature rise. The generators selected for test were, in six cases, of shorter core length than the limit set in the Rules for the detector method of measurement; in five cases were for low voltage; in three cases were for low frequency; and in general were of such size and characteristics that low rises and values of conventional allowance should be expected.

2. Longitudinal and Transverse Heat Flow in Slot-Wound Armature Coils. C. J. Fechheimer, JOURNAL, A. I. E. E., March, April and May 1921.

3. The Thermal Conductivity of Insulating and other Materials, T. S. Taylor, *Electric Journal*, December, 1919.

The entire class of large turbo generators was intentionally excluded. But while these tests may not be used directly for determining probable limiting values, they are as good as any for the purpose employed in this paper; viz., for checking the validity of the method of calculation that is developed from the model tests.

The formulas derived from the results of the model tests have been verified by checking values of the top coil temperature and conventional allowance calculated by them against the measured values of the machines tested. The results of this comparison are shown in Table IV. This agreement is sufficiently close to warrant the statement that the conventional allowance can be calculated with a fair degree of accuracy for any machine when the following data are available:

1. Observed temperature rise by detector between coil sides.
2. Observed temperature rise of tooth by detector at side or bottom of slot.
3. Ratio of copper loss to coil surface. (Watts per square inch.)
4. Eddy current losses (loss ratio).
5. Thickness of insulation.
6. Length of core.

As might be expected, some of the test results do not check with the calculated results as closely as others.

The two units No. 4 and No. 5 show practically no difference between the copper temperature and observable temperature. These two machines are among those having ten-inch detectors inside the main coil insulation (in contact with the cotton covering on the wires) instead of thermocouples in contact with the bare copper. With thin insulation (for 2300 volts) low loss ratios and low temperature rise, the conventional allowance will be naturally low and the method of measuring the copper temperature will have a relatively large influence on the measured difference between the copper and observable temperatures.

Unit No. 3 shows a higher measured conventional allowance than can be accounted for. This is a two-pole turbo-generator and the designer explains this discrepancy by the existence of extra losses in the top coil caused by the penetration of main rotor flux into the slot.

As will be evident by considering the method of derivation, the formula for calculating the top coil temperature gives the temperature of that part of the top coil adjacent to the bottom coil. (Position 2, Table III). In generators having small eddy current losses, this is the maximum temperature of the top coil; in generators having larger eddy current losses or in which the main field flux penetrates the slots, thus producing additional eddy current losses, the temperature of that part of the top coil adjacent to the air gap (Position 1, Table III) is the maximum. This is illustrated by the following figures taken from Table III.

Unit No.	L. R.	Position 1 top of upper coil	Position 2 bottom of upper coil	Diff.
3	1.16	68.3	58.9	9.4
9	1.37	78.5	75	3.5
10	1.25	77.5	68.5	9.0
11	1.26	83.8	82.5	1.3
12	1.27	78.3	72.6	5.7

In the comparison between measured and calculated top coil temperatures, the test values given in Table IV are for Position 2 in every case, and this fact should be considered in drawing any conclusions as to the probable range of values of conventional allowance in practise.

Calculation of the Conventional Allowance for Limiting Cases

The only values of the conventional allowance that are of interest from the standpoint of standardization are those that exist at the limiting copper temperatures. In determining the proper value of the conventional allowance for the temperature limit of Class *A* insulation, for example, the values of the conventional allowance that exist when the copper temperature is 105 deg. are the only ones that are of interest. It is possible, then, to assume various sets of conditions (all of which result in 105 deg. copper temperature) and to calculate the conventional allowance, and, in that way, obtain a quantitative idea of the range of values of the conventional allowance at the assumed limiting copper temperature.

TABLE VI

CALCULATED CONVENTIONAL ALLOWANCES.

13200-Volt Insulation—105 deg. Copper Temperature.
Insulation Thickness—0.25 inch
Calculations are based on long core machines.

Top coil temp. rise	65	65	65	65	65	65	65	65	65
Core temp. rise	25	35	45	25	35	45	25	35	45
Temp. drop through ins.	40	30	20	40	30	20	40	30	20
Watts per sq. in., top	0.48	0.36	0.24	0.48	0.36	0.24	0.48	0.36	0.24
Loss ratio	1.10	1.10	1.10	1.20	1.20	1.20	1.40	1.40	1.40
Watts per sq. in., bot.	0.435	0.33	0.22	0.40	0.30	0.20	0.34	0.26	0.17
θ_a	7.0	5.2	3.5	6.5	4.8	3.2	5.5	4.1	2.7
θ_m	56.2	58.4	60.6	55.1	57.7	60.1	53.8	56.6	50.4
Conventional allowance	8.8	6.6	4.4	9.9	7.3	4.9	11.2	8.4	5.6

Tables V and VI show such calculated values of the conventional allowance for 105 deg. total copper temperature and for insulation thickness corresponding to 6600 volts and 13,200 volts. The figures in each table cover a reasonable range in core temperature and in loss ratio (eddy current factors) to fairly represent current design practise.

In Tables V and VI, the values of core temperature and loss ratio are arbitrarily taken so as to cover the range of current design practise. The temperature of the top coil (θ_t) follows from 105 deg. minus 40 deg. air temperature. The temperature drop through the insulation is then 65 deg. minus the core temperature. Knowing this temperature drop, the watts per square inch follows from the thickness of insulation and heat conductivity of the insulation. (This is assumed as 0.003 watts per inch cube per degree). Dividing the watts per square inch of the top coil by the loss ratio gives the watts per square inch of the bottom coil. The constant K and θ_a and the observable temperature rise θ_m can then be calculated and the conventional allowance obviously follows. The measureable temperature rise (θ_m) is calculated from equation (9) which is merely a transposed form of equation (4):

$$\theta_m = \frac{\theta_t + \theta_i}{2} + \frac{\theta_t - \theta_i}{2\,L\,R} - \theta_a \qquad (9)$$

These calculated values are based on long machines, say sixty inches and longer. A little consideration will show that, for a *given copper temperature*, the conventional allowance is practically the same for all core lengths. Generators, as ordinarily designed have the same current density and ratio of loss to coil surface for a considerable range of core lengths. This results in shorter-core machines having lower copper temperatures and smaller conventional allowances, as a rule, than longer-core machines. But, if machines of short core length were designed with higher current densities and smaller cooling surfaces so as to have the same limiting copper temperature as long-core machines, the conventional allowances would be substantially the same. Therefore, for the purpose of establishing reasonable values of conventional allowance, core length need not be considered.

It will be observed from a comparison of corresponding columns in Tables V and VI that while the watts per square inch for 6600 and 13,200 volts are different, the values of θ_a, θ_m and conventional allowance are identical. In other words, the conventional allowance with given copper temperature, core temperature and loss ratio, is independent of insulation thickness. For purposes of standardization, therefore, no distinction need be made between low-voltage and high-voltage generators, within the range of generator sizes for which the detector method is specified. The reason for this will be evident from equation (9). The only term

Watts per sq. in. (top coil)	0.84	0.72	0.60	0.84	0.72	0.60	0.84	0.72	0.60
Loss ratios (assumed)	1.10	1.10	1.10	1.20	1.20	1.20	1.40	1.40	1.40
Watts per sq. in. (bot. coil)	0.76	0.64	0.55	0.70	0.60	0.50	0.60	0.51	0.43
θ_a	12.2	10.2	8.0	11.2	9.6	8	9.6	8	6.9
θ_m	94.8	96.8	98.8	92.8	96.4	97.9	90.4	94.0	95.9
Conventional allowance	15.2	14.2	11	17.2	13.6	12.1	19.6	16.0	14.1

in this equation affected by insulation thickness is θ_a. This term, it will be remembered, is

$\theta_a = K \times$ watts per sq. in. $\times$ insulation thickness (8)

But, for constant copper temperature, the product of watts per square inch and insulation thickness is constant, and therefore, θ_a is constant under the assumed conditions.

Tables VII and VIII give similar values of the conventional allowance for higher copper temperatures. Only one value of voltage and insulation thickness is given for reasons just explained.

The results given in these tables give an idea of the probable range in value of the conventional allowance at the limiting copper temperatures for a wide range in values of design factors. These tables could be extended to cover lower and higher core temperatures, and loss ratios, but it is believed that the values chosen are representative of usual design practise, keeping in mind the assumed condition of a fixed copper temperature.

These results are grouped in curve form in Fig. 10. The limits of the cross-hatched area are the maximum and minimum values for each assumed copper temperature rise from Tables VI, VII and VIII. It represents the range of probable values that may be expected in practise.

There have been two propositions advanced as to suitable values of conventional allowance for use in arriving at limiting values of temperature rise for the A. I. E. E. Standards. The first proposition starts with the value of 5 deg. now in the Rules assigning this to Class A insulation temperature limits and doubling this for Class B insulation temperature limits. The second proposition doubles these figures. These two propositions are shown by the heavy lines in Fig. 10. Obviously, the 5 deg.-10 deg. proposition is not adequate to meet the facts, nor is the 10 deg.-20 deg. proposition unduly conservative when it is remembered that the upper limit of values shown in Fig. 10 would be appreciably increased if: (a) allowance were made for increased top coil temperatures caused by the increased eddy current losses in that part of the top coil nearest the air-gap; and (b) if allowance were made for the probability of higher temperatures existing in the individual case than are discovered.

Discussion

For discussion of this paper see p. 529.

Temperature Limits in Large Machines

BY PHILIP TORCHIO
Fellow, A. I. E. E.
Chief Electrical Engineer, New York Edison Company

Review of the Subject.—*The present Institute standards allow a maximum limit of 105 deg. for fibrous insulation and 125 deg. for mica insulation with an allowance of 150 deg. subject to special guarantees of the manufacturer. In high-voltage machines of large size, the effect of actual copper temperatures higher than 105 deg. may cause softening and disappearance of binding materials, bulging of insulation, and consequent powdering of insulation under periodic pounding of copper on softened material, and ionization at voids so created.*

Operating experience of four large size machines demonstrated the above effects to repeatedly take place in machines operating at copper temperatures of 150 deg. cent. None of these effects were noted in machines operating at copper temperatures of 105 deg. cent. or under. Two machines have safely operated for over three years at maximum copper temperatures of 130 deg. cent. Incorrect conclusions may be made as regards the safe temperature limits by judging the performance of machines unless actual copper temperatures are known. Lower ambient temperatures and fractional loads may reduce the operating temperatures 25 to 35 deg. below the assumed limits.

Machines designed for high temperatures are less efficient than machines designed for cool temperatures, in one instance the difference being as [illegible] at as several hundred kilowatts at all loads.

The calculation of ventilation of large machines is relatively uncertain; it is of importance to aim at a conservative limit rather than set it too near the danger point.

From the standpoint of economy as well as greater safety, it appears that large machines should not be operated at higher copper temperatures than 105 deg. cent. This means that with outside air ventilation seldom exceeding 20 deg., the maximum [illegible] limit with the standard reference of 40 deg. ambient should be 125 deg. equivalent to 85 deg. maximum rise at the copper. In all cases where the room air is close to 40 deg. the maximum copper rise should be limited to 65 deg.

Other correlated and important features discussed incidentally in the paper are the typical proportionality of life at different temperatures for fibrous insulation, and the new tentative conventional allowance for reducing to maximum copper temperature, readings taken outside the insulation.

CONTENTS

Introduction

In response to the request of the Electrical Machinery Committee that I prepare this contribution, I will review the actual temperatures experienced with machines in service and some of the essential features which must be given due weight in the interpretation of such experiences.

The two limits established by the Institute are 105 deg. cent. for fibrous insulation, and 125 deg. cent. or mica insulation, with an allowance of 150 deg. cent. for the latter, subject to special guarantees of the manufacturer. As the established standard ambient temperature is 40 deg. cent., the designer is allowed for his machine a maximum temperature rise at any point on the copper of 65 deg. for fibrous insulation and 85 deg. for mica insulation, with an optional 110 deg. rise, subject to special guarantee.

These are the outstanding and essential bases of A. I. E. E. rating.

In former years, it was the practise to use a double standard of rating, allowing a rise of 50 or 55 deg. for normal loads, and 70 or 75 deg. for overloads, equivalent, for modern machines, to 90 or 95 deg. temperature limit for normal loads and 110 or 115 deg. for overloads.

The writer introduced, fifteen years ago, the method of single rating for turbo-generators which, in the following years, became generally used.[1] In 1914 the Institute adopted the single rating for a larger class of apparatus like motors, transformers, etc., adopting the aforesaid temperature limits for the two classes of insulation.

This was done with the object of simplifying the problem for the manufacturer and the user of apparatus. In substance, the limit of 105 deg. adopted for fibrous insulation was arrived at by striking an approximate average between the two former limits of 90 to 95 deg. for normal loads and 110 to 115 deg. for overloads; the limit of 110 deg. for mica insulation with the optional 150 deg. limit was intended to apply principally to large turbo-generators and large machines.

Considerable objection was raised to the adoption of single rating for commercial motors and in some cases for central station apparatus.

It is not my object here to take any sides in the dispute, which is apparently becoming smoothed out and adjusted.

Note:—(All temperatures given in this paper refer to actual copper temperatures and degrees Centigrade.)

1. "The standard ratings of Westinghouse alternating turbo-generators are based on two different methods of determining capacity:

First. A rating with gurantees covering performance at normal loads and definite overloads, momentary peak loads being within the guaranteed overload capacity.

Second. A rating corresponding to the maximum safe operating capacity of the particular machine in question, with no guaranteed overload capacity.

This method of maximum rating originated with the New York Edison Company and, though comparatively new, has much in its favor." (The Westinghouse Diary for 1912, page 23.)

Presented at the Annual Convention of the A. I. E. E. Niagara Falls, Ontario, June 26-30, 1922.

It is more important to present a comprehensive survey of the relations, as they now can be ascertained, which have existed in practise between the rated temperature limits and the actual temperatures sustained by the apparatus in service.

Before doing this, it is important to approximately define the relations which different stresses, due to voltage, temperature and time, vibration and mechanical stresses, bear to the life of the insulation.

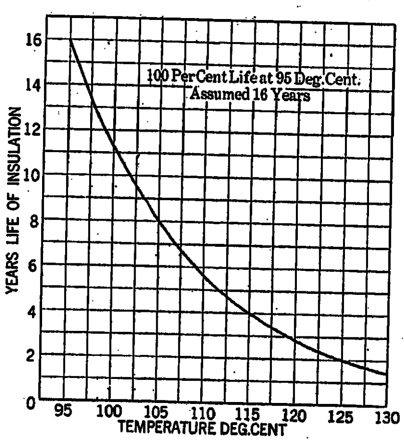

FIG. 1—LIFE CURVE OF FIBROUS INSULATION AS AFFECTED BY TEMPERATURE

EFFECT OF VOLTAGE

It is now a well recognized fact that all insulating materials, including mica, will be destroyed by ionization, if any air voids are present in the insulating covering of an electrical conductor and the potential gradient at these points exceeds the limit of about 75 volts per mill. Imperfections in the material like small iron impurities, will also cause distortions of potential gradients and accentuate the danger of ionization or reduce the effective thickness of insulation. It follows, therefore, that as a general rule the experience with life of insulating materials is only applicable within the limits of voltage of the apparatus investigated.

EFFECT OF TEMPERATURE AND TIME

Up to a few years ago, there was an impression in the minds of operating people that a machine rated for 110 or 115 deg. two- or three-hour overload—would operate safely if the overload was limited to two or three hours *in each day* but would be rapidly destroyed if the overload was carried for much longer periods in one day. The fact that these short overload periods usually covered the occasional peak requirements took away from the operators the inducement to study more closely what higher temperatures would have prevailed if the occasional overloads had been carried for more than two or three hours, and what would have been the effects on the insulation.

In recent years considerable progress has been made in coordinating the relations which exist between temperature, time of application and resultant deterioration and shortening of life. In a paper presented before the Institute in February, 1921, I gave abstracts of results of the classic tests of the British Engineering Standards Committee of 1905, and extended the discussion to experiments made on paper insulation and the observation of considerable investigation of conditions of paper insulation used in cables subjected to occasional high temperatures. At the same meeting D. W. Roper presented results of similar observations, while Fisher and Atkinson gave an experimental formula for determining the reduction of life strength of paper subjected to different temperatures. From these and other studies made on fibrous insulation, it is possible now to plot a characteristic curve of the effect of temperature upon the life of fibrous insulation if not otherwise affected by ionization or mechanical stresses. While the actual years of life at different temperatures are not established by experience, the relative proportionality of the length of life may safely be represented by the relation given by the curve in Fig. 1. This tentative curve would roughly indicate that, other things being equal, a machine operating at 105 deg. will have a life of 50 per cent of a similar machine operating at 95 deg. Similarly, if we operate a machine 90 per cent of the time at 95 deg. and the remaining 10 per cent of the time at 115 deg., the life of the machine will be 77 per cent of the virtual life at 95 deg. for 100 per cent of the time. From this law we can now more clearly see how the double rating may have practical advantages.

From similar studies on mica insulation, there appears to be no doubt that aside from the influence of ionization due to voltage and mechanical stresses, mica insulation can safely withstand almost indefinitely high temperatures probably as high as 200 deg.

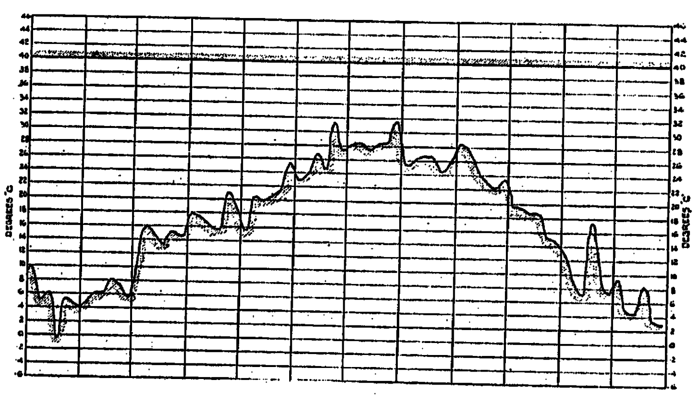

FIG. 2—FIVE-DAY AVERAGE OF MAXIMUM AIR TEMPERATURES IN NEW YORK CITY FOR THE YEAR 1921

EFFECT OF VIBRATION AND MECHANICAL STRESSES

Vibrations are obviously always present in rotating machinery due to movement and reactions of the rotating elements and the periodic pounding of the insulation due to the drag of the rotating field and the abnormal heavy blows under system short circuits, etc. With well wrapped and unimpaired insulation and well supported coils, these stresses will not affect

the elastic limits of the materials, but if the copper temperature is high, the varnishing materials in the insulation may distill and loosen the binder, allowing a play for the copper to pound and powder the insulation as a continuous drop of water will hollow out a stone. Stresses in the insulation are also imposed by different rate of expansion and contraction of the copper and the insulation under large changes of temperatures which may cause bulging and voids in the insulation between the insulating slots, with consequent ionization if the voltage stresses are sufficiently high.

The possible damages to insulation due to vibrations and mechanical stresses are, therefore, to be looked for mainly in machines of large power and relatively high voltages where ionization may ensue. From the coexistence, in large power machines, of high temperatures with high voltages, failure may be caused either by bulging of insulation due to uneven expansion and contraction, or powdering of insulation due to softening and disappearance of the varnishing materials.

Where only low pressures of around 110 volts are present, relatively high temperatures like 110 deg. for fibrous insulation do not appear to destroy the usefulness of the insulation. Where voltages are high, the mechanical stresses must be seriously considered for temperatures higher than 105 deg. for all types of insulation.

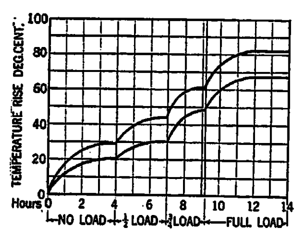

Fig. 3—Characteristic Temperature Rise of Two Generators from No-Load to Full Load

Operating Experience

In analyzing practical experience of life of insulation on electrical apparatus, it is very important that weighty consideration be given to the foregoing three characteristic factors of service. We would be in error to conclude that because satisfactory results were obtained with certain limiting temperatures in a certain class of machines, similar service could be obtained in other classes of machines.

One of the greatest difficulties in making comparisons of practical experience with apparatus in different installations is the uncertainty of the actual temperatures which have actually prevailed in the machine.

The most common error made by engineers discussing temperature limits is to assume that a machine rated for say 105 deg. if insulated with fibrous materials, or 150 deg. if insulated with mica, because it has operated successfully for a number of years, therefor 105 deg. or 150 deg. have proved satisfactory in practical service. Nothing can be further from the truth than such assumptions.

The machine may be cooled by air usually 10 to 20 deg. lower than the 40 deg. standard ambient. Fig. 2 gives the five-day averages of maximum daily air temperature for 1921 in New York City. These show, at a glance, the large margin between the actual maximum temperature throughout the year and the assumed 40 deg. base of reference.

The machine may never have carried the rated load, so that instead of the 65 and 110 deg. rises allowed for the full rated loads, the actual rises in operation at partial loads may have been 10 or 15 deg. less. Fig. 3 shows characteristic temperature rises for two machines from no-load to full load. As large turbo units are operated at the most economical point at 75 per cent to 80 per cent of full rating, the actual rise in operation at those loads may be at least from 10 to 15 deg. less than at full rating.

The result of these and other variable conditions of service is that the actual temperatures sustained by the machine may have been 25 or 35 deg. lower than the assumed limits. As the vast majority of the machines operate under such conditions, it becomes of vital importance that when we speak of temperature limits, we clearly state whether we mean the actual temperature or an arbitrary figure assumed for purposes of commercial ratings and arrived at by striking a reasonably safe limit, which, on account of the aforesaid service conditions, it is not expected to be reached in practise by the vast majority of the machines. If in applying the results of our experience we will eliminate from consideration all machines which, while nominally rated at say 105 deg. or 150 deg., in practise have only operated at 20 or 30 deg. below those limits, we will come to consider only relatively few cases where actual temperatures of 105 or 150 deg. have really obtained.

Only from the experience of such machines can we derive conclusions as to safe temperature limits.

The maximum copper temperatures of the machines in the following illustrations were obtained either by direct copper temperature measurements or by adding to the highest reading of the thermometer detectors between coils an allowance calculated on the basis of 2½ per cent of that rise over the inlet air for each thousand volts of the rated voltage of the machine. This correction seems to be as close as we can ascertain from elaborate tests which are under way under the auspices of manufacturers and large users.

In interpreting these records, it must be remembered that these maximum temperatures were present only during the period of peak load less than four hours a day, and generally of much shorter duration. For the balance of the time, the copper temperatures were lower than the indicated maximum, mainly on account of lower loads and sometimes on account of lower temperature of the inlet air.

Fig. 4 gives the log of maximum temperatures sustained by one turbo-generator, which has had several failures, and Fig. 5 the log of maximum temperatures representative of three turbo generators, two of which have had several failures. The characteristic features of these failures were either bulging insulation, pow-

under the same conditions of service without failures, though when the coils were removed they showed the same characteristic features of impaired insulation.

The records of failures of machines designed for high temperatures could be extended, but the writer was not able, within the very short limits of time allowed for the preparation of this paper, to secure the necessary details of operating temperatures and hours of service to make the presentation complete as in the case of the three machines A, B and C.

In Fig. 7 are given the maximum copper temperatures representative of five machines, one of which has

(3) Inlet air temperature
No coil failures have occurred on these machines.
One in service for eight years, two for two years, and two for five months.

These data cover varied experiences with large machines of different manufacturers.

DEDUCTIONS FROM EXPERIENCE

From this experience it appears that we would be justified in concluding that mica insulation would not safely withstand temperatures of 150 deg. in high-

voltage turbo-generators. This conclusion would seem to be in disagreement with the often repeated statement that mica insulation on the original Niagara generators safely withstood temperatures as high as 185 deg. for a long period of years. If, however, we apply to that experience the consideration of the three factors with which I prefaced this presentation, and recollect the special circumstances of the Niagara case, involving heavy copper bar windings in a generator armature of relatively smaller length than in large turbo-generators, relatively smaller kw. power per pole, relatively slower speed, and a very moderate pressure of 2200 volts, we would conclude that these conditions are so essentially different from the conditions existing in a modern large size, high-speed, high-voltage generator that such experience is of no real value in our problem.

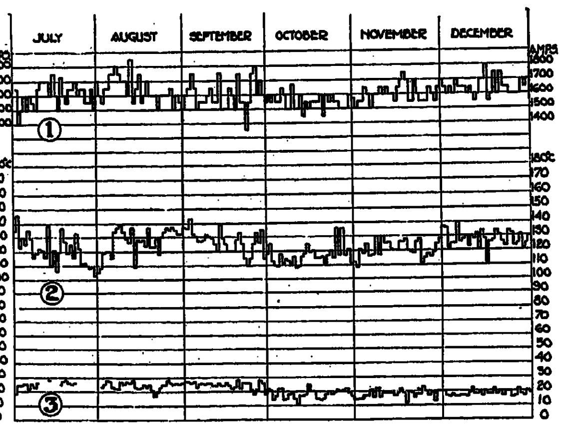

FIG. 8—CHARACTERISTIC OPERATING CONDITIONS
For two 35,000-kv-a., 1200-rev. per min., 12,000-volt generators
(1) Daily maximum amperes load
(2) Daily maximum copper temperature
(3) Inlet air temperature
No coil failures have occurred on these machines.
In service three and four years.

The experiences I have reviewed should lead us to the conclusion that maximum copper temperatures of not exceeding 105 deg. for mica insulation in high-voltage turbo-generators should give safe operation. Temperatures around 150 deg. are unsafe. It is probable that some higher maximum temperature than 105 deg. might prove satisfactory. To what extent the limit of 105 deg. might be safely raised is a question which cannot be definitely settled in the light of the experience available.

ENGINEERING AND ECONOMICAL CONSIDERATIONS

Having arrived at the conclusion that, with the present knowledge, about 105 deg. should be the limiting copper temperature in large machines, the question arises whether it is practical and economical to impose such a limit on the industry.

From an engineering standpoint, there appears to be no difficulty in building 105 deg. generators larger than required for the largest size steam turbines that have been produced for the two speeds of 1200 and 1500 revolutions. For the 1800- and 3600- rev. per min. speeds, the 105 deg. generators are today close to the limits of the steam turbines, *i. e.*, about 8000 kv-a. and 35,000 kv-a. at 85 per cent power factor for 6000-kw. and 30,000-kw. steam turbines. If improvements in the steam turbine will make it feasible to increase the capacity of the 3600- and 1800-revolution turbines, it seems reasonable to expect that corresponding improvements will also be made to permit the construction of correspondingly larger generators without increasing the temperature limit.

There is, therefore, no engineering obstacle to the adoption of about 105 deg. limiting temperature for the largest sizes of machinery now built. There remains only to be considered the question of economy. Does the 105 deg. limit make the cost of the machine unjustifiably high?

Unquestionably, a machine designed for a high temperature is cheaper than a machine designed for a cool temperature. A difference of say 25 deg. may make a sensible difference in cost. On the other hand, the machine designed for a cool temperature will be more efficient than the machine designed for a high temperature. It is difficult to evaluate in dollars per kilowatt to what extent these differences will affect the net results.

For an approximation, I would make a rough guess that the purchaser would be justified in paying $1 per kilowatt more for the cooler machine for the saving in higher efficiency.[2] This would leave the purchaser the net advantages of the greater factor of safety of the machine designed for cool operation.

As to the manufacturer, I cannot state how far the $1 would go to cover the increased cost of the cool operating machine especially if, in large size machines, he should be compelled to use more and higher quality iron and more copper and insulating materials. However, the fact that machines of large sizes designed for cool temperatures are commercially produced and

2. From tests for losses and efficiency of two generators under load conditions, using the air measurement method, are obtained the following comparative results:

Machine No. 1, having a temperature rise at maximum load of 120 deg., gave the following efficiencies of generator:

½ Load....................	91.9 per cent
¾ Load....................	93.8 per cent
Full Load..................	94.9 per cent

Machine No. 2, having a temperature rise at maximum load of 80 deg., gave the following efficiencies of generator:

½ Load....................	94.6 per cent
¾ Load....................	96.1 per cent
Full Load..................	96.8 per cent

The total losses of machine No. 1 exceed those of machine No. 2, as follows:

½ Load....................	331 kw.
¾ Load....................	389 kw.
Full Load..................	405 kw.

Even allowing for inaccuracies in the method of measurement, the results illustrate the point that, at least in this case, the cool machine had a materially higher efficiency than the hot machine. While with other machines the differences may not be as great, they will undoubtedly be of sufficient value to produce a sensible saving at the coal pile in the operation of the cool machine.

marketed would seem to indicate that the 105 deg. limit does not impose unjustifiably high costs of manufacture.

The result of these considerations is that while nominally the machine designed for cool temperature is somewhat more expensive to build than a machine designed for high temperature, its slightly increased cost is more than balanced by its greater efficiency and greater reliability.

Value of Greater Reliability

There is undoubtedly general agreement that, other things being equal, a machine designed for cool temperature is safer than a machine designed for high temperature. To find the value of this greater safety we must consider that with the rapid growth of the central station industry, two new factors are becoming of primary importance.

One is, that with increased size of generating units and fewer of them in a station, it becomes imperative to obtain a greater factor of safety. Also, with the expansion of the systems and superpower line interconnections over large areas, the load factors on the generating plants tend to increase, requiring longer service from each generating unit.

The other is that, with the development of new plants improvements always become available in the art, like utilization of higher steam pressures, higher superheat, higher boiler economy, less heat losses in gases, better economy of auxiliaries and better heat balance. To secure the economy of this better efficiency, new generating units in old as well as new stations must be operated to carry the base loads of the system while the older units are operated to carry the balance of the loads of shorter duration. Therefore, the burnout of an armature in a modern generator is vitally serious, not so much for the damage and cost of repairs, but mainly for the loss of business, if it cripples the system, at the time of peak loads, and the increased cost of operation of older and less economical units while the large new unit is out of service for repairs. With prevailing prices of coal, the failure of a large unit may cause a loss in production costs alone of $500 to $600 a day for each day the machine is out of service for repairs. If the failure also happens at a time when the service would have to be crippled, the losses would be incalculably serious.

Conclusions

Central station managers are keenly alive to the necessity of securing the most reliable apparatus to safeguard their interests and the interests of the public they serve. Designers must approach the problem of producing machines of highest reliability. Central station engineers should cooperate with the manufacturers in standardizing for all bidders the same limit of temperature so as to place the competitive business on equal terms. The present Institute rule which specifies 85 deg. copper rise for mica insulation but also allows 110 deg. cent. subject to special guarantees is not right. Only one standard should be adopted for the best interests of all concerned. The limiting copper rise of 85 deg., which corresponds to the present *conventional* limiting temperature of 125 deg. for the *conventional* 40 deg. standard ambient temperature, appears to be the maximum safe limit dictated both by reasons of economy and safety. With this conventional limit of 125 deg. it should be understood that in practise it would be expected that the temperature of the inlet air would be around 20 deg. instead of 40 deg. so that the actual operating temperature would be about 105 deg. In all special cases where the inlet air is near 40 deg., as with machines in Fig. 4 and Fig. 7, the rise should be limited to about 65 deg. instead of 85 deg.

The manufacturer, in taking a conservative stand on such an important question, must also consider the practical point that the calculation of the ventilation of a large machine is relatively uncertain so that the results may be several degrees higher than calculated. It becomes, then, of practical importance to aim at a lower limit to permit of some higher variations to which the user may adjust himself without requiring expensive changes, rather than to set the limit too near the danger point so that any higher deviation would necessitate derating the machine or subjecting it to early failures.

Discussion

QUESTIONS RELATING TO STANDARDS OF RATING (Newbury);
PROBABLE VALUES OF CONVENTIONAL ALLOWANCE FOR A-C. GENERATOR STATOR WINDINGS (Newbury)
TEMPERATURE LIMITS IN LARGE MACHINES (Torchio);

Niagara Falls, Ontario, June 28, 1922

W. J. Foster: I agree closely with Mr. Newbury's conclusions and with his recommendations regarding the method of rating machines by temperature rise and also the figure that he has mentioned as the ultimate temperature rise of Class *B* insulation in the armature windings.

This paper of Mr. Newbury's on the Conventional Allowance is a fine example of laboratory work, but I consider it like all laboratory investigations, something that should be used with caution in applying the results.

There are differences in the way in which the temperature is attained in the different parts of the Laboratory Model that vary very widely from what exists in rotating electric machines. For example the temperatures of the iron are obtained by heat entirely from within the coils embedded in the slots, while in the ordinary machine, only about one-half of the heat is generated in the coils.

Now, in the case of the heat originating inside of the insulated coils, it is necessary to have the temperature attain a very much higher value in order to bring the core up to the temperatures that are carried through the investigation as shown in the tables ranging from something like 10 deg. to 70 deg., and consequently the embedded detector which lies in the line of the heat dissipation has quite a different temperature; in other words, the difference between the inside temperature of the coil and the embedded detector is in my opinion, greater than in the average rotating electric machine. Similarly, the variations that are taken to represent the different types of machine—long core,

short core and the different potentials, I do not think should be taken as equivalent to test results on actual machines.

I speak of this, because I do not want it to be generally imagined or thought there will be a 15-deg. difference, between the measured temperature and what may exist inside.

In these investigations, concerning which I have a great deal of interest, having more or less charge of such investigations in our company, fully one-half of the machines referred to in Mr. Newbury's paper, the inside temperatures at the ratings of the machines, in many cases were no higher than those measured by the detector, indicating no drop whatever, which is not unreasonable. The fact is, we can conceive of a machine so designed that the temperatures in the inside of the insulated coils are no higher than at the spot where embedded detector is located outside the insulated coil.

Such machine would involve a broad slot, and thin insulation, and a very narrow temperature detector, and the machine very conservatively rated, with certain relations existing between the heat generated in the iron and that in the copper.

I was very much pleased with Mr. Torchio's paper, since it is a contribution along the lines that are very greatly needed. It is experience that should be taken as the basis of standardization. In my opinion, standardization should not anticipate too much the possible progress that may be made. We should know our ground well, before we standardize for the future. Standardization is largely a matter of present knowledge, based on past experience.

As I understand Mr. Torchio and Mr. Newbury, the 80 deg. allowable temperature rise is recommended, and I am in sympathy with basing the rating on temperature rise, rather than hot spot temperatures. As I understand it, this 80 deg. rise is to be considered good practise, but the upper limit of good practise.

R. F. Schuchardt: The great importance that attaches to this subject is due not only to the millions of dollars invested in these large units, but also to the fact that the reliability of the service, and also in large measure the safety of the system, are involved.

Mr. Torchio deserves the gratitude of the industry for the most heroic insistence and persistence with which he has fought for conservatism in this line, and I want to voice my accord with his position. As a result of his work this compromise of 80 deg. has been reached. From the very limited data that are available, this must of necessity be a compromise.

On the one hand, the maker naturally is optimistic over his own work, and perhaps he has more faith in the materials than the user would have, and feels that a higher temperature makes for greater progress. It is entirely natural he should feel that way. The engineer, who has these large systems to operate, on the other hand, believes that reliability is the first thing to be sought, and the very last thing to be given up. Because of their comparatively high economy, these large units must be as dependable as it is possible to make them. The economy is realized only when these units are in condition to be operated on the base load. The operating engineer, therefore, naturally does not take the same optimistic view of the situation as the manufacturer might. He must be conservative.

We have heard that some of our foreign colleagues feel that higher temperatures are advisable. Without data, that seems to us as accepting a shorter life, and particularly for the very large units with the long coils. It is not entirely a question of the temperature that the materials themselves will withstand, so much as the mechanical result of the expansion and contraction, due to these large ranges in temperatures.

I think the evidence of the failures in Mr. Torchio's machines indicate it is not the temperature itself that caused the breakdown, so much as the effect of expansion and contraction—the mechanical rubbing on the mica, and grinding it up.

In conclusion, the thing we should do first is to cooperate to get more data, but meanwhile the user, because of his responsibility for safety and for reliable service must be conservative.

W. F. Dawson: I think, with the gentleman who spoke before, that we are to be congratulated on this compromise, as we call it, because I know there are some members of the Institute who think the value is too low, and others who think it is too high. I personally think that they have decided on a splendid value for the rating of Class B insulation in stators.

There is one feature about the temperature of 100 deg. cent., which I do not think has been mentioned, although it may have been hinted at. Nothing has been said about the possibility of aging of armature steels at high temperatures. I have not had any personal experience with aging, but I do know from the experience of transformer designers that steels which are not alloyed, which are not the silicon steels, will not stand continuous operation at 150 deg. cent., without a large increase in the loss.

As I understand it, this happy compromise allows 80 deg. rise with the ambient temperature of not over 40 deg. That makes 120 deg., and when one adds the hot spot correction, of, say, 10 deg., gives total of 130 deg. That is high enough, but I believe it is not too high.

I think that Mr. Newbury recommends 100 deg. rise in field. That seems reasonable and I don't think we need go down to 80 deg. rise.

You can say that you want something reliable to be able to understand what the manufacturers are bidding on—yes, but you want something which is competitive too, to get the most in capacity, for the dollars you put into your investment. We do not want to fix any false standards we cannot live up to.

R. B. Williamson: I feel very much gratified to see that we are going back to the idea of specifying a straight temperature rise. Machines have been built for a great many years under a specification of 40 deg. cent. rise by thermometer for Class *A* insulation.

Now, in the case of Class *B* insulation on stators, we are considering 80 deg. rise, with the difference that instead of specifying it by thermometer we are specifying it by imbedded detector and omitting all temperature corrections. This simplifies the whole method of determining temperatures, and it is in effect simply going back to the former method except that the measurement is made in a different way.

Mr. Schuchardt has brought up an important point in connection with Mr. Torchio's paper. That is, it is not, whether 80 deg. or 90 deg. is safe for mica, because we know that mica in itself will stand higher temperatures than these, but it is a question as to the mechanical effects of the high temperature on insulation. It has been demonstrated by Mr. Torchio that high temperatures may affect the binder causing the insulation, in some cases to loosen to a certain extent; we then have the condition of loose conductors in a magnetic field, and these are bound to vibrate more or less and chafe the insulation, so that a breakdown finally results from the mechanical action rather than from the heat. In rotors, the insulation will stand these high temperatures without trouble, because the mica is held very firmly mechanically, and there is not the opportunity for vibration that exists in the stator. Also in the rotor the voltage is low whereas in the stator of large machines the voltage is usually high.

C. E. Skinner: Referring in Mr. Torchio's paper to Figs. 4, 5 and 8, the graphs showing the temperatures of these machines. Mr. Torchio states that the temperatures are either from copper measurements or are arrived at by a method giving the equivalent conventional allowance. Now, these particular machines 4 and 5, are older machines, and they have heavy, solid conductors, while the machine referred to in Fig. 8 has laminated conductors. It is very possible, therefore, that the differences in Figs. 4 and 5, as against Fig. 8 are greater than the figures given in Mr. Torchio's graph, for the reason that the eddy currents, particularly in the top conductor, are probably very much greater in the first two

machines than in the later machines, and consequently the earlier machines have a greater hot spot temperature than the graph would indicate.

I think that may possibly account for the greater difficulty of the earlier machines.

F. W. Peek, Jr.: I do not believe that it is good engineering to use insulations at extreme temperatures. It is my opinion that the Sub-Committee has come to a fortunate conclusion in adopting this principle.

H. L. Wallau: In connection with Mr. Torchio's paper,

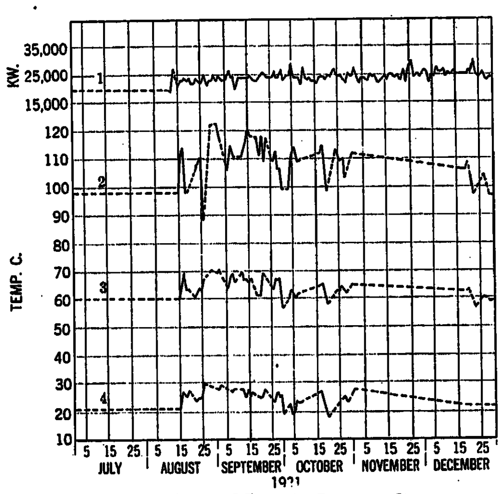

FIG. 1—OPERATING LOG NO. 8 TURBO-GENERATOR, LAKE SHORE STATION FOR 5 MONTHS OF 1921, 25,000 KW., 11,431 VOLTS, 1800 REV. PER MIN.

1. Daily Maximum Kw. Output
2. Daily Maximum Field Temperature
3. Daily Maximum Armature Coil Temperature

3A. Daily Maximum Calculated Temperature on 2¼ Per Cent Increase per 1000 Volts

4. Daily Temperature of Intake to Air Washer

Dotted lines indicate no recorded readings.

there have been a certain number of experiences in Cleveland which may be of interest. The question raised by Mr. Torchio as to what limiting temperature shall be standardized for large turbo-generators is of vital importance to the central station industry, and requires thorough and painstaking investigation.

Mr. Torchio's curve, Fig. 1, showing the life curve of fibrous insulation based on the data obtained by three independent sets of investigators is very interesting, but is limited to the effect of temperature alone and cannot of course, show the combined effects of temperature, mechanical stress and ionization.

It is possible that the shape of this curve holds true for Class *B* insulation although by definition the "binder is used for structural purposes only, and may be destroyed without impairing the insulation or mechanical qualities of the insulation."

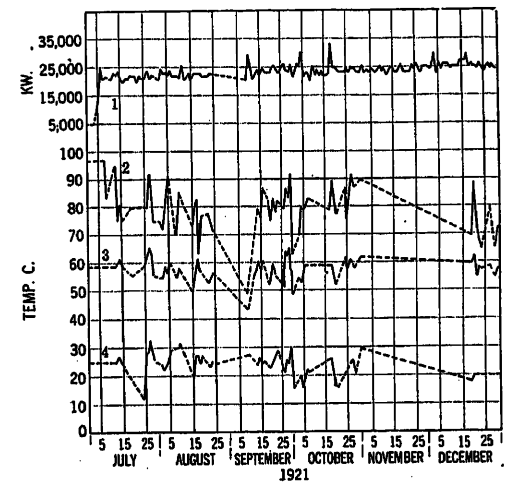

FIG. 3—OPERATING LOG NO. 10 TURBO-GENERATOR, LAKE SHORE STATION FOR 6 MONTHS OF 1921, 25,000 KW., 11,431 VOLTS, 1800 REV. PER MIN.

1. Maximum Daily Kw. Output
2. Maximum Daily Field Temperatures
3. Maximum Daily Copper Temperatures
4. Maximum Daily Temperature of Intake to Air Washer

Dotted lines indicate no recorded readings.

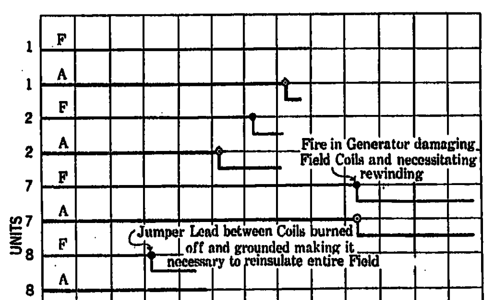

FIG. 4—RECORD OF GENERATOR COIL FAILURES

Hours out of service for rewinding armature and field are deducted from these given hours.

If this is strictly true the life curve for Class *B* insulation as affected by temperature alone, probably would be quite flat over a range of 150 deg. cent. in temperature.

Fig. 2 shows that the average air temperature in New York is much nearer 20 deg. than 40 deg. cent. with a maximum for the year of 32 deg. cent.

This is roughly typical of our lake cities, but is probably much

lower than temperatures prevailing in the Mississippi Valley during the summer months.

It would therefore seem that the standard ambient reference temperature of 40 deg. cent. should be retained.

Mr. Torchio's Figs. 4, 5 and 6 indicate conditions prevailing in his plant quite at variance with those obtaining in Cleveland. In general, no machines in Cleveland have been operated at armature temperatures of 145 deg. to 155 deg. cent. maximum.

The bulk of the Cleveland load is an alternating-current industrial supply, the power factor averaging about 80 per cent during the day.

This condition has resulted in making the field temperature the limiting factor and it is our practise to limit the field temperature to 125 deg. cent. The operating temperature is determined by resistance measurement.

Armature temperatures as determined by imbedded coils or thermo-couples have generally not exceeded 70 deg. cent. except in the case of one unit. This unit has reached 122 deg. cent. and making the correction suggested by Mr. Torchio of 2½ per cent increase per 1000 volts computed on the rise above air has reached the 149.2 deg. cent. (Manufacturer guarantees 150 deg. cent. safe operating temperature).

Charts Figs. 1, 2 and 3 for three units similar to Mr. Torchio's Fig. 4 are appended. A chart Fig. 4 similar to Fig. 6 is given showing the performance of our horizontal units. In each case the upper line refers to the field and the lower to the armature.

It will be noted that we experienced field trouble on units No. 2, 7 and 8 and armature trouble on units No. 1, 2, 7 and 9.

All of these units are in commission.

The maximum armature temperature (by thermometer) reached by any unit was 69 deg. cent., and the approximate average armature temperatures during the summer months have been 55, 58, 50 and 50 deg. cent. respectively since installation.

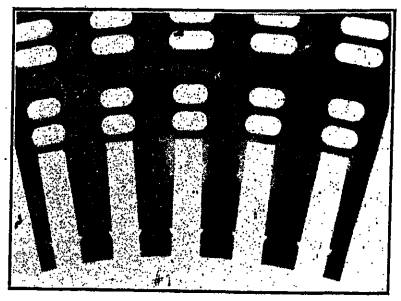

Fig. 6—Armature Lamination Showing Portions Subjected to High Temperatures which Destroyed Insulating Varnish No. 9 Generator

The maximum field temperatures (by resistance) reached were 93 deg. for the coolest field to 109 deg. cent. for the hottest field, that of No. 5 unit. For all that, this is the one unit on which no field trouble has occurred.

In practically all cases armature failures have been accom-

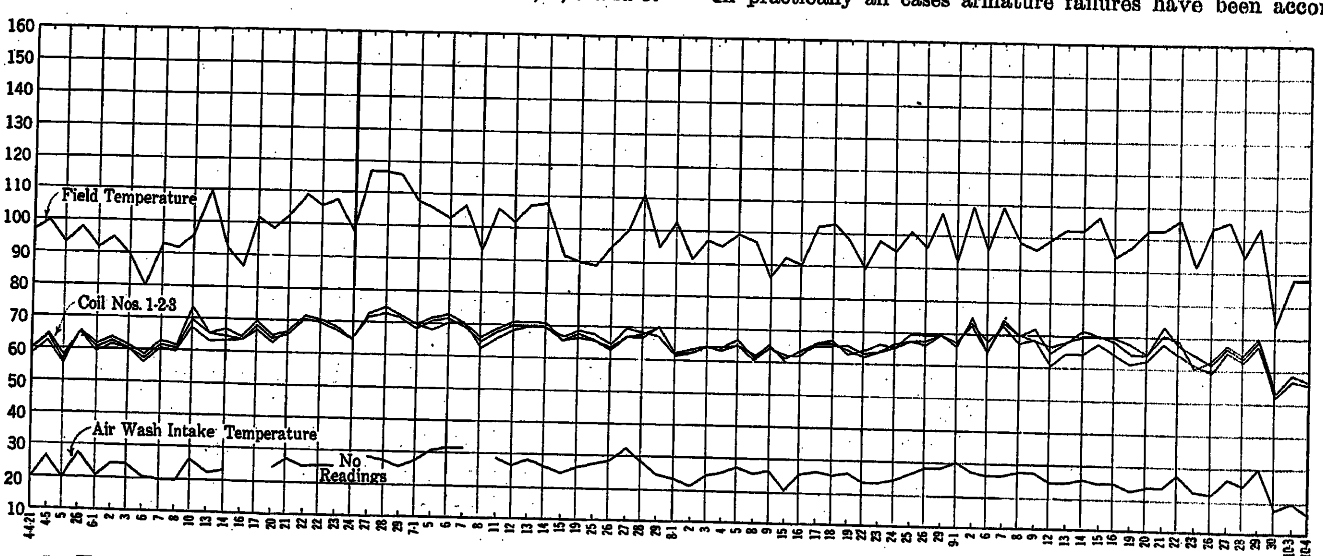

Fig. 5—Temperature Readings on No. 1 Turbo-Generator Lake Shore Station Starting April 4, 1921 to October 31, 1921

The life without failure in years was

Unit No.	Field	Armature
1	—	4.17
2	3.59	3.03
7	5.42	5.42
8	1.82	—
9	—	1.82
10	—	—

(Dashes indicate no failure to date.)

The record of our vertical 14,000 and 15,000 kv-a., 1 power factor, 11,430-volt units is as follows:

Unit	Installed	Repairs	Date	Elapsed time
No. 3	Sept. 1911	Field reinsulated	July 1920	8.8 yrs.
" 4	Aug. 1911	" "	May 1918	6.7 "
" 5	Dec. 1912	No repairs		9.5 "
" 6	Oct. 1913	Grounded field repaired	May 1918	4.6 "

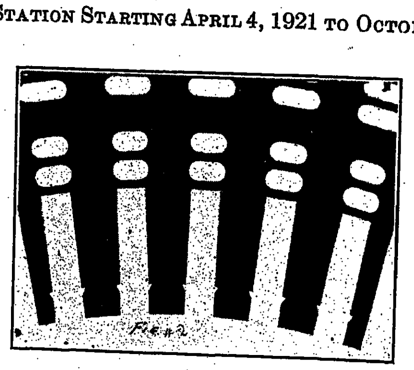

Fig. 7—Another Portion of Overheated Armature Core No. 9 Generator

panied by more or less pulverization of the mica, indicative of mechanical pounding, often by bulges in the insulation, resulting in air pockets and consequent ionization.

The armature failures of two of our horizontal units were plainly the result of grounding of the corona shields in certain slots. On rewinding these shields were omitted.

In the case of a third unit, this was suspected but could not be definitely established.

The fourth unit which failed ran hotter than the others from

FIG. 8—A PORTION OF A DAMAGED COIL THAT CROSSED TEN AIR DUCTS. COIL BULGED AND INSULATION CRACKED AT EDGE OF DUCTS. NO. 9 GENERATOR.

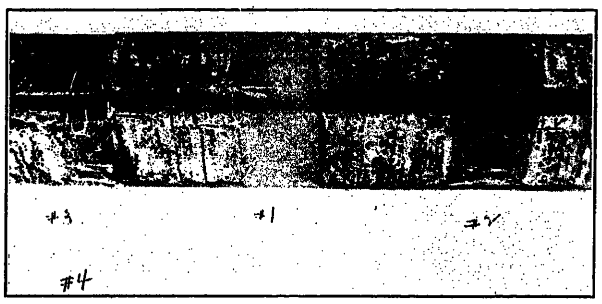

FIG. 9—CLOSE UP OF FIG. 3—SHOWING BULGES AND POWDERED MICA INSULATION AND EFFECT OF STATIC. NO. 9 GENERATOR.

FIG. 10—CLOSE UP OF OTHER SIDE OF BULGE NO. 3 SHOWN IN FIG. 4—NO. 9 GENERATOR

FIG. 11—CLOSE UP OF ANOTHER BULGE IN A DAMAGED COIL. NO. 9 GENERATOR

the beginning. In installing the armature coils it seems that the slots were filed to allow the windings to be inserted. It is our belief that the burrs resulting from this filing, caused severe local heating in the laminations. In the accompanying cuts, Figs. 6 to 12, the lightly shaded areas show the spots where the insulating varnish on the laminations had been completely destroyed.

It was necessary to install an entire set of new laminations as well as a complete armature winding.

Two other illustrations Figs. 13 and 14 show the condition of various coils of No. 1 generator, in one a burned wedge shows very plainly. The bulges and powdered mica (white pots on coils) are readily discernible.

After this machine unit No. 9 had been rewound and placed in service one of the detectors indicated a coil temperature of 195 deg. cent. The field was withdrawn and the armature examined.

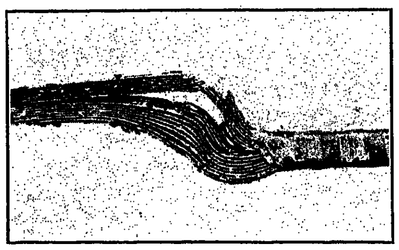

FIG. 12—THE SECTION OF COIL THAT BROKE DOWN. THE BEND IN THE COIL WAS DUE TO ITS REMOVAL FROM THE SLOT. NOTE THAT THE BREAK-DOWN WAS AT THE AIR DUCT. NO. 9 GENERATOR.

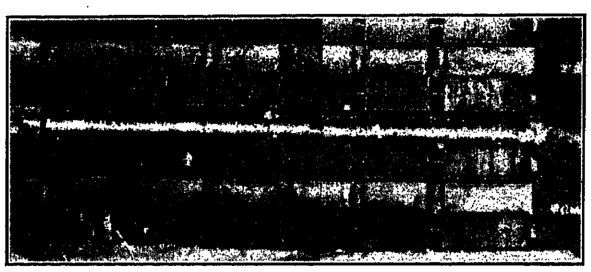

FIG. 13—DAMAGED COIL IN PLACE. NOTE BURNED WEDGE AT LEFT. OTHER WEDGES WERE EITHER PARTLY BURNED OR COMPLETELY DESTROYED. NO. 1 GENERATOR.

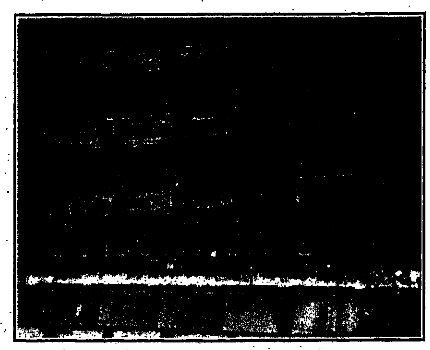

FIG. 14—ANOTHER DAMAGED COIL—WEDGES REMOVED. NO. 1 GENERATOR

A small hexagonal nut was discovered lying on top of one of the slots near the detector in question. When in operation the magnetic stresses had caused this nut to vibrate and peen the edges of the laminations considerably. This confirmed our belief that the original trouble was caused by the filing of the armature slots. (In the rewinding process the slots were lined up and after the coils had been inserted the bolt holes were filed where necessary for the proper insertion of the through bolts.)

After the nut was removed and the edges of the laminations ground and varnished, insofar as possible, the machine was again put in service.

Before carrying load, but operating at full speed and excitation, it was found that five of the detectors indicated an average temperature of about 78 deg. cent. while the sixth, still showed high, reaching 131 deg. after a 3½ hour run. Intake air 17 deg., exhaust air 29 deg., maximum rise 114 deg. cent.

Under load this difference in temperature between different detector coils irons itself out and the maximum difference noted is about one-third as great as that and often less.

In conclusion, our experience as a whole indicates that our troubles have not been caused so much by temperature as by mechanical pounding and ionization.

Since the higher temperatures would aggravate these effects, we are in accord with Mr. Torchio that a limiting temperature of 125 deg., for standardization purposes is as high a value as should be adopted.

H. R. Woodrow: The manufacturers are greatly indebted to Mr. Torchio for bringing before the Institute in such concrete form the requirements and methods from the operating field, giving a definite idea of what they consider reliable and satisfactory service. Mr. Torchio is also responsible to a large extent for making it possible for men with different ideas to get together on temperature ratings. For instance, on conventional allowances opinions vary from 5 to 30 deg. In the larger machines of today, we know from experimental data what these allowances should be.

Another point which the Institute should clear up is the classification of Class *B* insulation. As Mr. Newbury brought out, there is still considerable uncertainty as to Class *B* insulation, and how much Class *A* material should be permitted in its construction.

The question of field insulation temperature limits as Mr. Williamson brought out should be definitely classified. There has been some trouble due to field insulation failures, and as the papers do not cover that point, would it not be possible to have it covered in this discussion.

H. G. Reist: I too wish to congratulate the Committee on getting back to the old standard of giving the rise instead of the more complicated expression for determining the temperature, which we have used for the last several years. It has been pointed out that since the French standard has been changed, and the American standard of a lower temperature has been adopted, that they have had better results than formerly with their machines.

A friend of mine, an engineer, who has been in France within the year, told me that in one installation of large American built induction motors that was made during the war, the owners expressed extreme delight in the service which they had obtained. They said they never had an experience such as they had with the use of these motors, because they have not had any trouble from burnouts. That is due to the fact that they were running at lower temperatures than the French motors.

Several speakers have expressed the opinion that 80 deg. rise for Class *B* insulation, which we all know usually has some organic material in its makeup, should be the limit.

I would like to ask the question, since the French engineers have followed our lead with good results, and we would like, as far as possible to lead the rest of the world in this industry, is it good policy for us to standarize to the limit?

This idea I am going to speak of has already been expressed in a different way, but it seems to me the question may be resolved into a mathematical equation, the same as the amount of material you can afford to put in a machine, or how much you can spend for the roof on your house,—Is it not a question whether the first cost, the cost of the loss in the machine, the repairs, and the lack of service of one temperature balance against similar results if you use some other temperature. Would not the solving of that equation give you the answer? It has been pointed out that generally high temperatures means greater loss and less efficiency, and we all agree that however good we make an insulation, for 80 deg. or any other temperature rise, it will be a little bit longer lived if we run at lower temperatures and therefore repairs will be less frequent and the expense of repairs and the loss from lack of service will be less.

James Lyman: I believe that we all heartily agree with the standardization that has been presented to us. The manufacturers of large turbo-generators have so improved and advanced the design of the machines, that as regards temperature they are able to build machines corresponding to these lower temperatures.

There is no part in the development of the industry of greater importance than the reliability of these big turbo-generators. We have read, within a few months, the report of the Super-Power Committee. More rapidly than most of us realize there will be in use throughout the length and breadth of this country, a universal 60-cycle power supply. It will be on the order of the outlines of the Super-Power Committee. On the Pacific Coast, in the Middle States, in the East, we shall soon have in operation 220-kv. power lines, transmitting power of the order of 100,000-kilowatts per circuit supplying cheap power, not only in our industrial centers but wherever industry wishes to locate in the country, and nothing can be of more vital importance to the success of these undertakings than the reliability of the large turbo-generator units which are the source of supply for these systems.

L. T. Robinson: It seems to me we have made a great gain in our method of procedure, by giving weight to the things which we know about, as opposed to starting from the end that we were least certain of, to arrive at the result. On the old plan we started with 125 or 150 deg., or whatever it was, and which we at that time were not at all certain of, and which we have subsequently become even more doubtful of, and we assumed a certain conventional allowance, and took that off, then we assumed an ambient temperature of the surrounding cooling medium, and took that off, choosing such values so that after we had taken them off, we would have the circuit temperature rise left.

Now, we have decided to start from the other end, and take what we know, and forget the other things. Therefore, it is unnecessary to discuss this matter of 15 or 20 or 30 deg., conventional allowance, as opposed to the present five, and propositions that have been made for 5 and 10. The way it looks to me is that all the figures, taken together, do not point to any change with sufficient definiteness so that the change should be made.

I am, therefore, very pleased to know that we can in the future be satisfied to rate machinery on temperature rise alone, and I am also pleased to endorse Mr. Newbury's proposition that all other subject matter that relates to how the temperature rise was arrived at, be taken out of the rules, and perhaps be put into an introduction that would show the mental processes we went through in order to arrive at the values chosen.

With regard to Mr. Torchio's figure of 80 deg., I join the others in complimenting him on having so steadfastly stood for a certain figure throughout all the time that the rest of us have gone back and forth, sometimes have advocated one thing, and sometimes another, but we have returned to the original figure of ten years ago, and the rules as they now stand are exactly in accordance with the proposition which has been advanced and agreed to, if the foot-note No. 2 to §1005 of the 1921 Rules which refers to the 150 deg. is crossed out.

I would like to say one word about the distinction that I think should be observed between rating and application, and if we can have that distinctly and clearly in mind, I think even the difficulties of some of our foreign associates can be removed.

We now rate machines on temperature rise, and therefore the temperature rise determines the kw. or kv-a. that is marked on the nameplate, the question of "ambient temperature of reference" does not come into the matter, I think that what we want are rules for marking a machine of definite size, and therefore definite capacity, with a certain rating, *i. e.*, a certain kilowatt capacity, and then we should clearly know that it is well within the province of the user, if he pleases, to make some allowance for the fact that conditions of use may not be exactly the conditions that were established as the basis of the rating.

There may be some questions as to what extent anything of that kind should be done, but clearly, if the situation is such that the surrounding temperature is more than 40 deg., we should hesitate to put as much load on the machines as the rating calls for. On the other hand, I think in the interest of conservatism we should—when the ambient temperature is lower than the 40 deg. which has been established—hold in reserve that capacity which must, to some extent, be there, for a reasonable margin of safety.

P. Torchio: In answer to the question of Mr. Foster, I confirm his understanding that the 80 deg. rise is to be considered good practise, but the upper limit of good practise. Mr. Skinner's comments on the copper temperatures of the machines Nos. 4 and 5 are correct, but perhaps the figures I have given may still represent the actual maximum temperatures because since the paper was printed I found that the assumed constant of 2½ per cent increase per 1000 volts computed on the rise of the detector between coils is in fact excessive, a constant of about $1^2/_3$ per cent being closer to the average of result of several tests on machines especially equipped with exploring detectors in contact with the copper.

Mr. Wallau's valuable contribution fittingly supplements my paper. He, however, with some of the other speakers, emphasizes the importance of establishing a different standard for the temperature rise of the rotor windings. I am in full agreement with Mr. Dawson that a higher limit must be allowed for the rotor. From Mr. Wallau's presentation, a rise of 90 deg. would represent good and safe practise. I would endorse such a limit. It may be that the higher figure of 100 deg. suggested by Mr. Dawson may prove necessary for structural reasons. A little further study and cooperation should lead to an early agreement also on this point.

Referring to Mr. Wallau's and other speakers' comments on the life curve of fibrous insulation of Fig. 1, I do not know whether Class B insulation would have any similarity with the behavior of fibrous insulation. My reason for incorporating this Fig. 1 in the paper was not in an attempt to apply the results of fibrous insulation to Class B insulation. The only idea was that as in all windings we are always confronted with the presence of fibrous insulation either as binder of mica or in straight insulation of coils in the end turns, therefore, to cover fully the subject it was necessary to introduce the data given in Fig. 1. Incidentally, I call the attention of all engineers to the varied application that this fundamental information may have in all practical applications of the power industry.

F. D. Newbury: Mr. Foster questions the results obtained from the laboratory model described in my paper on Conventional Allowances, mainly because of the different manner in which heat is produced in the model, and in a generator. I do not see that this has any bearing on the conclusions reached. The problem was to establish the relations between certain temperatures inside and outside the insulation. To study the desired relations, a range of temperature values was produced. How this range of temperatures was produced was of no more consequence in this case than would have been the manner in which values of e. m. f. might be produced in a similar study of voltage drops in an electric circuit.

The particular values of temperature produced in this model were also of little significance so long as they covered a wide range. Thus, the fact, noted by Mr. Foster, that the difference between the copper temperature and core temperature in some of the experiments is greater than found in most generators is of no moment.

The model was used to establish certain temperature relations and a rational method of calculation for the conventional allowance. These relations and method were then checked by comparison with the results from generator tests. These generators were selected for test and tested under the supervision of Messrs. Foster, Williamson and the writer (each acting separately for generators manufactured by their respective companies.) Table IV, showing the comparison between calculated and tested values, is the criterion by which the work with the laboratory model should be judged. Considering the difficulties and errors inherent in machine temperature measurements, I believe Table IV shows a satisfactory degree of agreement.

Mr. Foster also points out that in fully one-half of the machines tested there was little difference between the inside temperature and the temperature measured between coils. This is true because these machines were of such dimensions (as to core length, insulation thickness, etc.) as to result in small temperature differences. Reference to Table IV will show that, in general, where the tested values are low, the calculated values are low also.

I do not believe that Mr. Foster has said anything that justifies any change in the conclusions reached as to probable values of conventional allowance, summarized in Fig. 10.

Mr. Torchio has used an empirical relation to calculate the conventional allowance that takes into account the single factor of rated voltage of the generator. The principal factors that determine the conventional allowance are the temperature difference between copper and outer coil surface, the temperature difference between top and bottom coil-sides (determined principally by eddy current factor) and the insulation thickness. In generators of less than 40-in. core length, the core length is also a factor. It is obvious that a relationship that neglects all but one of these factors can give reasonable results only if the other factors do not vary in generators of varying sizes, proportions and manufacturers.

This matter of conventional allowance has ceased to be of importance in specifying performance of machines, but is still of major importance in the work of standardizing committees in deducing allowable temperature rises from safe limiting temperatures of insulation. This, I hope, justifies this rather long discussion of what might be considered a purely academic question.

The agreement on 80 deg. as a satisfactory standard that has been expressed is very gratifying to all those interested in progress in this matter, and should make it possible for the Standards Committee to put this agreement in official form. The Standards Committee will, no doubt, also consider the question of rotor temperature limits. While this phase of the question has not received the same attention as has the armature winding temperature there has not been the same divergence of opinion and agreement should not be difficult.

Jean Canivet: In answer to Mr. H. G. Reist's remark concerning the satisfaction which was given in France by the American motors, I would like to emphasize the fact that the trouble we experienced with the French motors built according to our old rating was probably not due so much to the high temperature rise admitted than by the overload *without temperature limit* which was then allowed.

Higher Steam Pressures or Pulverized Coal?

BY FREDERICK A. SCHEFFLER
Fellow, A. I. E. E.
Fuller Engineering Company, New York

The author assumes a hypothetical power or public service steam plant of 100,000-kw. nominal capacity and compares the cost of operation of such a plant on a basis of 250 lb. pressure and 600 deg. fahr. total steam temperature, and 400 lb. pressure and 700 deg. fahr. total steam temperature, when fired by stokers and pulverized coal.

The results of the comparison indicate that, with much lower capital costs, even better thermal plant efficiency will pertain with the use of pulverized coal and the lower steam pressure than would be the case with the higher steam pressure plant, stoker fired.

TWO years ago, when the Edison Association of Illuminating Companies held its Annual Meeting at New London, Conn., the technical section developed a discussion as to what should be done with a view to lowering the cost of producing a kw-hour, which was at that time over 100 per cent greater than before the World War.

Various suggestions were made by engineers and others present, one statement being that the boiler pressure should be increased to 400 or 500 lb. Another official and engineer of a large public service corporation in the East quite emphatically made the statement that the only way to reduce these costs, in his opinion, would be to use pulverized coal and he predicted that in two years time this practise would begin to be generally used.

The writer, in discussing this subject, predicted that the excessive cost of the high-pressure idea would prevent a realization of lower costs, on account of the additional capital or fixed charges absorbing any gain which would be made from better thermal efficiency of the plant, and also said that rough figures would show that the desired results would be more likely to be obtained if only a portion of the additional expense involved was used in equipping the plant to use pulverized coal.

This question of higher pressures and temperatures is still a mooted one and is quite thoroughly discussed in a most excellent manner in a paper presented by Col. C. F. Hirshfeld, Chief Research Dept., of the Detroit Edison Co., before the Cleveland Section of the A. S. M. E. in March 1921. In this paper the author states that it is "his personal opinion that 700 deg. fahr. is about as high as we can safely go at present" and suggests a working pressure of steam at 400 lb.

As it is quite evident that there must be some point where the capital costs and fixed charges accompanying same will prohibit the reduction of the present kw-hr. cost from being benefited thereby, the author has made a study of the question from an investment and operating standpoint, comparing the present average practise as to pressures and temperatures with the above suggested 400 lb. pressure and 700 deg. final temperature. The basis on which the following estimates are made is as follows:

Capacity of plant, 100,000 kw.; consisting of four 25,000-kw. units and twelve 1600-h. p. boiler units (19,200 rated boiler h. p.) or approximately 5 kw. per boiler h. p.

As we are primarily interested more particularly in the *difference* in cost between the present average practise and the higher pressures, we have made a study of the various items entering into the costs of both suggestions, consulting with prominent manufacturers in order to obtain this information, which may be considered authentic and reasonable. For the lower pressures and temperatures we have adopted 250 lb. and 600 deg. fahr. temperature. For the higher, as above stated, 400 lb. and 700 deg. fahr. temperature. The items which are affected by the increase of pressure and the additional expense involved, due to the difference in pressure and temperature, are as follows:

(a)	Difference	in cost of boilers and superheaters 19,200 h. p. at \$13 per h. p., or \$2.49 per kw., including freight and erecting charges	\$249,600
(b)	"	in economizers \$4 per h. p. or \$0.768 per kw.	76,800
(c)	"	in steam turbines 100,000 kw. @ \$2 per kw.	200,000
(d)	"	in steam piping, forged valves and pipe covering at \$2 per kw.	200,000
(e)	"	in feed pumps and auxiliary apparatus 50 cents per kw.	50,000
	Estimated total difference in cost		\$776,400

The average water rate of the turbines at 250 lb. pressure is assumed to be 10¾ lb. per kw-hr. and at 400 lb. pressure, 10 lb. per kw-hr., and an allowance of 5 per cent for additional power or steam for auxiliaries.

In the operation of the plant we have adopted an annual load factor of 40 per cent and a fair average bituminous coal has been assumed in both cases of 13,000 B. t. u., and 8 per cent of ash and the combined boiler furnace and economizer efficiency with stokers at 78 per cent, and with pulverized coal an equivalent efficiency of 85 per cent. The following costs have been used:

Cost of coal delivered \$5 per long ton.
Cost of power ¾ cent per kw-hr.
Cost of common labor 40 cents an hour.

In the operating costs we have omitted taking into consideration the firing room labor, as these items would be practically identical in either case.

With the above items fixed, the steam requirements

Presented at the Annual Convention of the A. I. E. E., Niagara Falls, Ont., June 26-30, 1922.

per hour for the 250-lb. pressure plant will be 451,500 lb., which translated into steam per hour from and at 212 deg. is equivalent to 569,793 lb. For the 400-lb. pressure plant these figures are 420,000 lb. and 547,260 lb. respectively.

Additional data may be determined from the foregoing as follows:

of operation as compared with pulverized coal on the low-pressure plant will be over $144,000 more per year and the thermal efficiency of the plant will be better with pulverized coal (17030 − 16250) by 780 B. t. u. per kw-hr., or reduced to percentage of B. t. u. in the coal utilized, the difference is nearly 1 per cent (21.20—20.26).

Item	250 Lb. Press. Plant Col. 1 Stoker fired	250 Lb. Press. Plant Col. 2 Pulv. coal fired		Lb. Press. Plant Col. 3 Stoker fired	Lb. Press. Plant Col. 4 Pulv. coal fired
(1) lb. coal per kw-hr.	1.36	1.25		1.31	1.214
(2) B. t. u. per kw-hr.	17680	16250		17030	15782
(3) Thermal eff. of plant-per cent	19.31	21.20		20.22	21.75
(4) Evap. per lb. coal from and at 212 deg. fahr.	10.43	11.27		10.43	11.27
(5) Fuel, tons per hr.	24.40	22.36		23.42	21.23
(6) Fuel cost per hr.	$122.00	$111.80		$117.10	$106.15
(7) Fuel cost per day	$2928.00	$2683.00		$2810.40	$2547.60
(8) Repairs ($1.50 per rated h. p. per year) per day	78.80		Pulv., dyring, repairs, labor, power, conveying and air supply 34c. ton*	78.80	198.22
(9) Power for operating stokers, air supply, coal handling 4 per cent	117.00	204.00		117.00	
(10) Fixed charges 12 per cent per yr. on $422,400 incl. coal bunkers and conveying and ash handling, stokers and air supply	138.00	141.00	Fixed chgs. pulv. coal plant, conveying system, bunkers, coal burning equip. air supply ash handling. Cost $476,000 inc. $60,000 for bldg.	138.00	141.00
(11) Ash removal 48 tons @ 25 cents	12.00	4.00	4 tons day av.	12.00	4.00
(12) Total cost per day, Items 7, 8, 9, 10 and 11	A-$3273.80	B-$3032.20		C-$3156.20	D-$2890.82
			Additional fixed chgs. @ 12 per cent. (See below)—per day	250.60	250.60
			Additional maintainence charges (See below) per day	21.25	21.25
			Actual total daily costs Col. 3 and 4	C′ 3428.05	D′ 3162.67

*These costs are based on pulverizing thousands of tons of bituminous coal and are, consequently, accurate. The items are as follows: Per net ton

Repairs—complete system	8	cents per ton
Power for all operation @ ¾ cents Kw-hr. (17 Kw-hr.)	12¾	" " "
Drying	6¼	" " "
Labor	7	" " "
Total	34	" " "

The cost of operation per diem in Col. 3, letter *C*, $3156.20, is not entirely complete as to this cost should be added the additional fixed charges due to the cost of the 400-lb. pressure plant as compared with the 250-lb. pressure plant, which, as previously shown will be $776,400. The per diem interest charges on this amount at 12 per cent equals $250.60.

Furthermore, there will be additional maintenance costs, due to the higher pressures and superheat, which may be taken as 1 per cent. The per diem cost of this item will be $21.25. These two daily costs added to the above item *C* is $3156.20 + 250.60 + 21.25 equal *C′* $3428.05. This is consequently, the total daily operating and fixed charges cost of the plant, so far as it refers to the furnace equipment, for the 400-lb. pressure plant.

Comparing this with the daily operating costs of the 250-lb. pressure plant fired with pulverized coal, Col. 2, Item 12, *B*—$3032.20, it will be noted there is a difference of $395.85 which constitutes the saving which would be effected by the use of pulverized coal and this is equal to $144,485 per year.

These figures demonstrate therefore, that under the same operating conditions the high-pressure cost

The estimate shows that the pulverized coal plant and necessary storage and burning equipment, auxiliaries and distributing system, etc. can be built in a substantial manner for approximately $476,000 (at present prices, Dec. 1921), of which $60,000 is allowed for a separate building (42 ft. by 144 ft.) for the milling and drying plant, having a capacity of 750 to 800 net tons of pulverized coal per day. This cost is only slightly more than the complete stoker equipment with distributing system, auxiliaries etc. installed. The costs of these equipments would be the same for both the 250 lb. and 400 lb. pressure plants.

The question might be raised as to the basis on which these estimates have been made in regard to thermal, boiler and furnace efficiencies. The author believes he is quite safe in stating that at the present time there is no plant in this country at any rate, operating on a B. t. u. basis of 17,680, stoker fired, as shown in Column 1 of above tables, although plans have been laid down for one or two power houses not yet in operation to give these results, so that this figure would indicate the best possible practise that can be obtained under the assumed load factor and other conditions of a plant of this size and pressure.

On the other hand, actual performance of boilers fired with pulverized coal in power plant service indicates that there is no difficulty in operating under these load conditions at the 85 per cent efficiency we have used for the basis of our calculations, which, as shown in Column 2, is equivalent to 16,250 B. t. u. per kw-hr. or 1¼ lb. of coal, containing 13,000 B. t. u.

In the appendix there is a record of some pulverized-coal-fired boiler tests which show a higher combined efficiency than we have assumed.

The final conclusions are:

(a) It will cost a great deal less money to equip and use pulverized coal in power plants in order to obtain the highest efficiency and the lowest operating costs than it would to use high pressure of 400 lb. and high superheat of 700 deg. final.

(b) That lower B. t. u. per kw-hr. and higher over-all thermal efficiency will be obtained by substituting pulverized coal firing in lieu of any other known method using the moderate high pressure and superheat in common practise today, compared with higher pressures and temperatures.

(c) That the benefits accruing from the net difference in station water rate between the present practise as to pressure and temperatures and the higher pressures and temperatures are comparatively small and do not warrant the excessive additional first cost and yearly fixed charges for the higher pressures and superheat.

(d) That the cost per short ton of coal handled and burned by stokers in the 250-lb. pressure plant (exclusive of the cost of the coal) will be 52 cents and with pulverized coal 58 cents. For the 400-lb. pressure plant this cost would be increased to 95 cents per ton with stokers, which increase is due principally to the additional fixed charges over the 250-lb pressure plant.

Appendix

Tests of Pulverized Coal Fired Boilers Made in Accordance with the Standard A. S. M. E. Boiler Code

The equipment consists of a 1306-h. p. four-pass horizontal water tube Edgemoor boiler with 4-in. Fuller feeders and 4-in. flared type Fuller burners, located in a horizontal position, all as shown in the accompanying illustration.

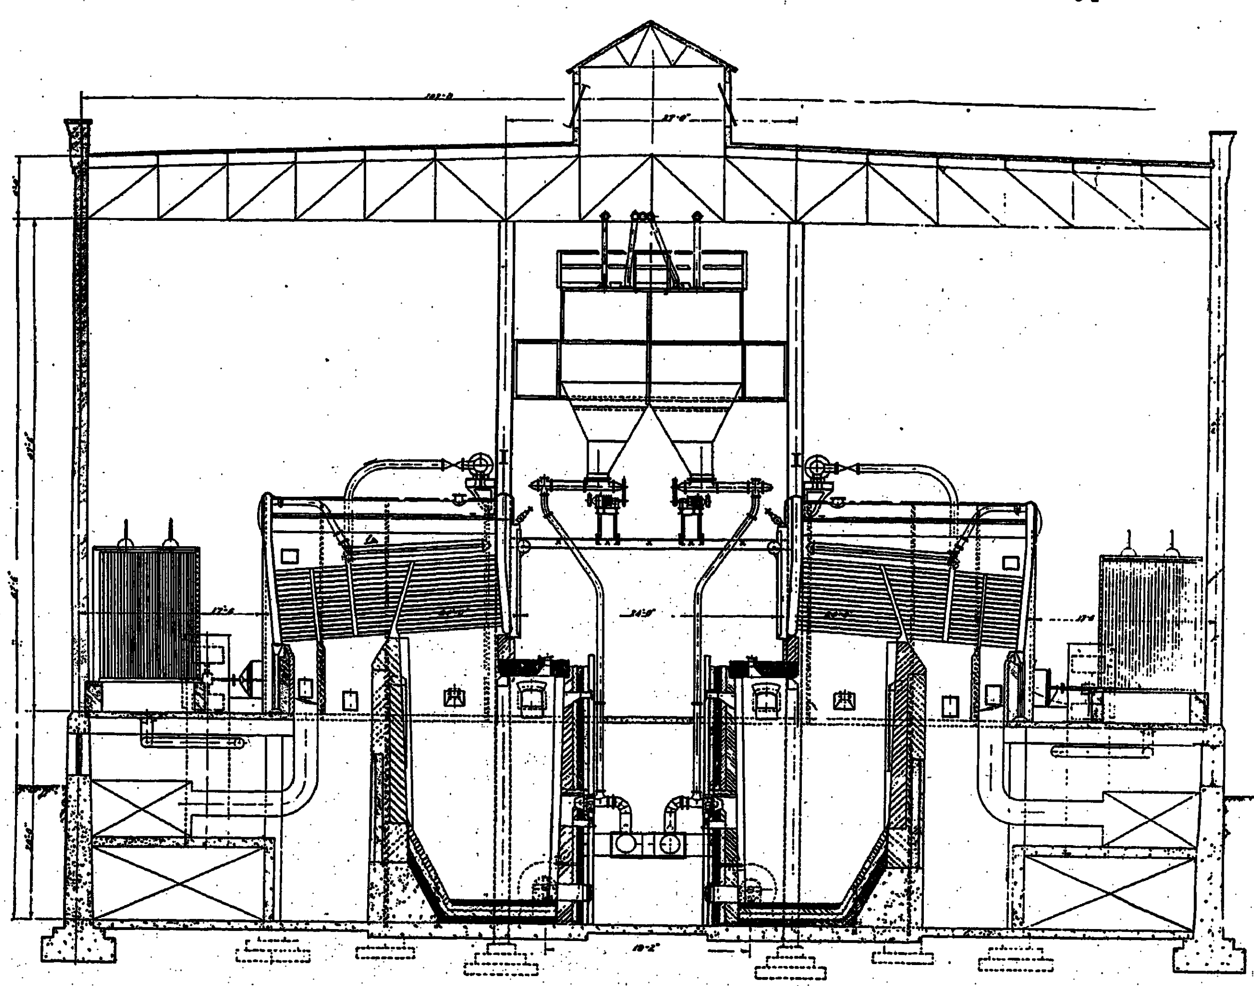

Fig. 1—Cross-Sectional View of Two 1308-H.P. Edgemoor Boilers
Arranged for burning pulverized Illinois coal.

The furnace conditions were most excellent and did not result in the formation of any slag. The furnace was not cleaned out during the time these two tests were run. There were but a few hours time between the finishing of No. 3 test of 48 hours and No. 4 test

of 48 hours. The boiler was kept on the main steam header and no special efforts were made to obtain high efficiency. The boiler tubes had not been turbined for sometime before the tests were conducted, neither had the outside of the tubes been washed out except as they were blown every day with soot blowers.

DATA AND RESULTS OF EVAPORATIVE TESTS NOS. 3 AND 4

1. Test of Edgemoor Boiler No. 1.
   To determine efficiency of boiler furnace and superheater.
   Test conducted by Fred. Darnbrook and A. Hoffman
   Ralph Galt and R. A. Kleppinger.
2. Edgemoor watertube boiler No. 1.
3. Powdered coal furnace.
4. Combustion space 9057 cubic feet.
5. 13057 sq. ft. water heating surface.
6. superheating surface.
7. total heating surface.
8. Date—Boiler Test No. 3 First half—June 30th & July 1st, 1921.
   Second half—July 1st and 2nd.
   Boiler Test No. 4 First half—July 5th and 6th.
   Second half—July 6th and 7th.
9. Duration—Boiler Test No. 3.
   First Half —24 hr. 53 min.
   Second Half—23 hr. 25 min.
   Average —48 hr. 8 min.
   Boiler Test No. 4.
   First Half —24 hr. 5 min.
   Second Half—23 hr. 45 min.
   Average —47 hr. 50 min.
10. Illinois coal powdered.

Discussion

Philip Torchio: I would like to ask Mr. Scheffler why contrast higher steam pressures against pulverized coal. Why not both? What is inconsistent between the two? The pulverized coal situation as affecting large cities is mostly a question of improving means to handle the ashes that come from the stacks. Until that problem has been definitely solved, it would be practically inadvisable to attempt, in a densely populated district, to install on a very large scale a system of coal burning that would scatter a considerable amount of ashes in the territory surrounding the station.

The question of using higher steam pressures is of vital importance. I do not know that the figures of cost of present standard pressure boilers and piping would be much exceeded if we had a fully developed system of high pressure machinery, and the boiler makers would standardize production on higher pressures that they have been doing. In that event, the increased cost of the equipment might not be as great as shown by the figures of Mr. Scheffler.

It seems to me that the difference in saving of less than five per cent between low pressure and high pressure is probably somewhat low, and that a larger saving would be realized in practise.

Abroad, there is now a station operating at 450 lb. pressure and 750 deg. steam temperature. We should look to the performance of that station with a great deal of interest.

Wm. McClellan: I have been in contact with pulverized fuel a great deal, and the burning of it at the mine. I could not quite see the point involved in the title of the paper "Higher Steam Pressures or Pulverized Coal." If there is any economy in high steam pressures, the economy is there, and if there is any economy in pulverized fuel, it is there.

My idea, without looking into the question of ashes, is that it can be cared for, and with some profit. So far as blowing out the ashes is concerned, that is not a vital feature of the problem. If you choose coal at $5.00 a ton, you may come out all right. There are lots of plants in this country which will be built to order, using cheap fuel.

Of course, if you have not sufficient load factor to work out all the advantages of economy, and if you do not use the more efficient methods long enough, you do not derive the greatest benefit, but in any event, it is no more expensive, and if it is no more expensive, this particular point vanishes. I do not quite see the distinction, first of all, between the antithesis which has been set up in the title of the paper, nor do I see that any one particular problem with a fixed coal price, and with a high one, without much discussion of the load factor, answers the question very definitely.

F. A. Scheffler: The President answered Mr. Torchio's question so far as the ash disposal from the stacks is concerned, but this is not an important part of the proposition. If the location of the plant is such that the fine ash coming out of the stacks is disturbing to the surrounding country, prevention can be taken care of more readily and with less expense than would be the case with cinders coming from stokers from the stacks.

The title of this paper probably should have been "Higher Steam Pressures and Pulverized Coal" as it is a little misleading as it now stands. The writer in dealing with this question had more particularly in mind the possibility of equipping low-pressure plants in such a way that they would compare favorably with the more expensive and higher pressure plants, even showing better efficiency with lower operating expenses. This is clearly shown in Column 4, page 347 as that column deals with a plant which was fired with pulverized coal, using higher steam pressures.

In order to really appreciate and understand fully the principal features developed in this paper, it is necessary to read it in toto carefully and I judge, from the remarks made by the President, as well as the other speakers in the discussion, that they have not done this, otherwise they would have noted that the answers to the questions they brought up were practically taken care of in the paper.

Rating of Cables in Relation to Voltage

SUMMARIZED HISTORY OF PUBLISHED KNOWLEDGE BEARING UPON THE PERFORMANCE OF INSULATION UNDER ELECTRIC STRESS

Prepared by the Subcommittee on Wires and Cables of the Standards Committee

INTRODUCTION

UNDER the auspices of the Wires and Cables Subcommittee of the Standards Committee of the Institute, a symposium on the rating of cables with reference to heating due to conductor losses only, was held during the 1921 Midwinter Convention of the Institute with the object of checking the Institute's standards in regard to permissible operating temperatures for cable insulation. That is, the discussion was limited to the matter of the safe maximum operating temperature of low-voltage cables with negligible dielectric losses.

The six papers presented and the discussion thereon did not show any general agreement on the point at issue. In fact, the divergence of views was still just about as great as had been previously suspected, judging from views expressed informally in committees and elsewhere. The great importance of the subject was, however, emphasized and the need for sufficient comprehensive research work to establish the fundamental physical facts involved was made evident. The result has been the inauguration of a comprehensive research on this and other fundamental cable problems by the Research Department of the Massachusetts Institute of Technology under the auspices of the Paper-Insulated-Cable Research Committee, which is a sub-committee of the A. I. E. E. Transmission and Distribution Committee, the N. E. L.A. Underground Systems Committee and the A. E. I. C. Committee on Electricity Distribution and Use.

It is believed that a similar situation exists with reference to the rating of cables with respect to voltage and the Subcommittee on Wires and Cables of the Standards Committee has therefore arranged this symposium on the rating of cables with respect to voltage only, which will be a corollary of the symposium held last year on cables with respect to heating only (*i. e.*, current only). It is further believed that a discussion of the matter at this time is particularly timely, both because of a demand for the standardization of insulation thickness for impregnated paper cables and because of the many proposals under consideration for cables to operate at much higher voltages than any now in extensive use. It is hoped that the papers presented and the discussion thereon will enable cable engineers to more efficiently design and operate cables and thereby utilize more effectively the investment which the cables represent.

Presented at the Annual Convention of the A. I. E. E., Niagara Falls, Ontario, June 26-30, 1922.

CONTENTS

I. Geometric Relations which Affect Dielectric Stress.

JONA, E. (*Trans. Int. Elect. Cong.* 1904, vol. 2, p. 550) showed that the electric stress in a dielectric between two concentric conducting cylinders, which is the simplest geometric representation of a single-conductor cable, follows the law.

$$H = \frac{E}{x \log \epsilon \dfrac{R}{r}}$$

where

H = stress in kv. per cm. at any point x cm. from the axis
E = difference of potentials between cylinders, in kv.
R = radius of outer cylinder, cm.
r = radius of inner cylinder, cm.

LEVI, CIVITA, (*Rendiconti Circolo Matematico di Palermo*, vol. XX, 1905, part 1, p. 173) gives formula for maximum stress including the effect of stranding.

THORNTON, W. M. AND WILLIAMS, O. J. (*Electrician* 1909, vol. 63, p. 833) gave experimentally-determined diagrams of electrostatic force both for round and sector triplex cables.

DEUTSCH, W. (*E. T. Z.* 1911, vol. 32, p. 1175) derives approximate formula for the maximum stress including the effect of stranding.

GORGAS, BENISCHKE, PETERSEN ETC. (*E. T. Z.* 1913, vol. 34, pp. 637, 783, 984, 1186, 1354) correspondence and discussion of stress at conductor surface, especially on approximate formula for stresses between parallel cylinders.

MIDDLETON, W. I. AND DAWES, C. L. (TRANS. A. I. E. E. 1914, vol. 33, p. 1185) discussed the logarithmic formula, and showed that the stress at the surface of a conductor was a minimum when $d = D/2.72$, where d is the diameter over the conductor, D is the diameter over the insulation, and 2.72 is the Naperian logarithmic base e. There is also a discussion of overstressing of cables.

RUSSELL, A., (*Proc. Phys. Soc.* London, 1919, vol. 33, p. 111) derives formula for stress between parallel cylinders.

ATKINSON, R. W., (TRANS. A. I. E. E. 1919, vol. 38-2, p. 971) developed a method of estimating the stresses in a triplex cable.

DEL MAR, W. A. (TRANS. A. I. E. E. 1919, vol. 38-2, p. 1018) gave diagrams of equipotential and stress lines in round and sector triplex cables.

DAVIS AND SIMONS (JOURN. A. I. E. E. Jan, 1921, p. 12) published tables of maximum stresses based on Atkinson's method.

EMANUELI, LUIGI (*L'Eletrotecnica* 1921, vol. 8, p. 573) gives experimental determinations of stresses in three conductor cables.

II. Dielectric Failure of Air.

STEINMETZ, C. P. (TRANS. A. I. E. E. 1893, vol. 15, p. 281) suggested that the diameter of a corona in air is such that the corona reduces the electric intensity (or potential gradient) at its boundary, to the constant value of the electric strength of air.

RYAN, H. J. (TRANS. A. I. E. E. 1904, vol. 21, p. 275) found

that the apparent dielectric strength of air around a wire varies with the diameter of the wire.

JONA, E. (*Trans. Int. Elect. Cong.* 1904, vol. 2, p. 550) said that the diameter of the air corona, for a given arrangement of conductors, is independent of the size of wire and depends only on the voltage.

TOWNSEND, J. S. (*Trans. Int. Elect. Cong.* St. Louis 1904, vol. 1, p. 106) said that free ions exist in air which are accelerated in their motion when subjected to electric stress. When they attain a certain speed, they knock electrons from their atomic orbits thus liberating the electrons and converting the atoms into ions.

WHITEHEAD, J. B. (TRANS. A. I. E. E. 1910, vol. 29-2, p. 1183) said that as the logarithmic law for concentric cylinders indicates different stresses at a given distance from the axis, with different conductor diameters and as corona observations indicate the same stress, the logarithmic law must fail when corona is present and therefore the air carrying a corona must have a relatively high conductivity.

HAYDEN, J. R. AND STEINMETZ, C. P. (TRANS. A. I. E. E. 1910, vol. 29-2, p. 1125) showed that the disruptive discharge through a dielectric requires not merely a sufficiently high voltage, but also a definite minimum amount of energy.

WHITEHEAD, J. B. (TRANS. A. I. E. E. 1910, vol. 29-2, p. 1159) said that an electron requires an intensity of 170 kv. per cm. to give it sufficient velocity to break up a molecule by collision, and concluded from this that the ionizing agents, in the ionization by collision which creates corona, must be of atomic or molecular dimensions. Such ions require only 30 to 40 kv. per cm. He showed that there is no dielectric loss in air until the corona point is reached, that the electric strength of air is independent of the material of the electrode, that the corona voltage is lowered by surface impurities, that the corona has high conductivity, and that most of the dielectric loss takes place beyond it.

RYAN, H. J. (TRANS. A. I. E. E. 1911, vol. 30-1, p.1) applied th electron theory to the explanation of corona loss.

WHITEHEAD, J. B. (TRANS. A. I. E. E. 1911, vol. 30-3, pp. 1883-1885) gave evidence that corona is due to the liberation of ions from neutral molecules when the latter suffer collision with free ions moving under the impulse of an electric field.

PEEK, F. W. (TRANS. A. I. E. E. 1911, vol. 30-3, p. 1889) showed that the corona loss around a wire varies as the square of the excess voltage above the voltage at which corona starts. He also showed that the electric strength of air is about 30 kv. per cm. and that corona starts when this intensity is attained at a distance of 0.301 $\sqrt{r}$ cm. from the surface of the conductor. This distance is called the energy distance. A finite thickness of air must be under a stress of 30 kv. per cm. or more before breakdown occurs.

PEEK, F. W. (TRANS. A. I. E. E. 1912, vol. 31-1, p. 1051) showed that the energy distance for corona around cylindrical wires varies with the relative air density s and is.

$$0.301 \sqrt{\frac{r}{s}} \text{ cm.}$$

PEEK, F. W. (TRANS. A. I. E. E. 1913, vol. 32-2, p. 1767) showed that the energy distance for spheres is

$$0.54 \sqrt{\frac{r}{s}}$$

and that where the electrodes are placed closer together than the energy distance, the apparent dielectric strength increases.

PEEK, F. W. (TRANS. A. I. E. E. 1915, vol. 34-2, p. 1857) showed that the time lag of breakdown is conveniently measured in micro-seconds, and that the lag varies with the electrode and is a maximum for the needle gap and a minimum for a uniform field or for a sphere gap.

WHITEHEAD, J. B. AND BROWN, W. S. (TRANS. A. I. E. E. 1917, vol. 36, p. 169) showed that corona appears at a lower value when the wire is positive than when negative, the maximum excess of negative over positive (which occurred for small diameters) being 6.3 per cent. The values for alternating current coincide with those for negative continuous voltage. Evidences in favor of Townsend's theory of ionization by collision are given.

PEEK, F. W. (Dielectric Phenomena, p. 84) says that air between concentric cylindrical electrodes has its maximum electric strength when the diameter ratio is 3 instead of 2.72, the value to be expected if the logarithmic formula were strictly applicable. This he deduces from the energy-distance and checks experimentally.

PEEK, F. W. (Dielectric Phenomena, p. 85) says that the corona in air seems in effect to be either a series resistance or it grades or distributes the flux density when the conductor configuration is such that corona occurs before spark-over. He said that under this condition spark-over between concentric cylinders, does not occur when $\frac{R}{r_1}$ = critical ratio, where r_1 = radius of corona, and R = radius of outer cylinder.

III. Ionization of Gas in Solid Insulation

FESSENDEN, R. F. in 1898 made experiments which showed the danger of air bubbles in solid insulation.

PERRINE, F. A. C. (TRANS. A. I. E. E. 1902, vol. 19, p. 1067) said that the failure of cable insulation is sometimes due to the presence of spaces filled with rarefied gases.

PETERSEN, W. (*Archiv. fur Elektrotechnik*, 1912, vol. 1, p. 28) called attention to the fact that air films in a dielectric of specific capacity K, are subjected to a stress of K times that in the surrounding medium, and that ionization may therefore occur therein at comparatively low voltages. He also said that ions are shot from these films into the surrounding medium.

DUBSKY, F. (TRANS. A. I. E. E. 1919, vol. 38-1, p. 537) measured the dielectric strength of thin air films between glass plates. He then applied these data theoretically to assumed gas spaces in solid dielectrics and showed the possible conditions under which ionization was likely to occur.

SHANKLIN, G. B. AND MATSON, J. J. (TRANS. A. I. E. E. 1919, vol. 38-1, p. 489) measured the ionization voltage in actual insulation designs by the dielectric loss method. In the case of coil insulation, such as varnished cambric and mica-paper, they give evidence showing that ionization not only occurs in the entrapped gas spaces but that it can cause serious damage. In the case of paper-cables, evidence is given showing that a true ionization occurs. However, the exact nature of this ionization, its position, and the possibilities of serious damage are not clearly shown.

IV. Dielectric Failure of Transformer Oil

TOBEY, H. W. (TRANS. A. I. E. E. 1910, vol. 29, p. 1189) after discussing generally the testing of oils for dielectric strength, gives particulars of the influence of moisture on this property.

HENDRICKS, A. B. (TRANS. A. I. E. E. 1911, vol. 30-1, p. 167) showed that moisture has an important effect in reducing the dielectric strength of insulating materials. In the case of transformer oil, if E be the kilovolts producing breakdown between 0.5 in. discs, 0.2 in. apart, and x = parts of water in 10,000, by volume, then

$$E = \frac{19.2}{x^{0.284}}$$

HENDRICKS, A. B. (TRANS. A. I. E. E. 1911, vol. 30-3, p. 1975) stated that transformer oil between concentric cylindrical electrodes has its maximum electric strength when the diameter ratio is about 7 instead of 2.72, the value to be expected if the logarithmic formula were applicable. He also said that the dielectric strength of transformer oil is increased by mechanical pressure, an increase from 0 to 200 lb. per sq. in. increasing the dielectric strength 50 per cent. This, by the electron theory, is due to the decreased mobility of the ions under pressure.

PEEK, F. W. (*General Electric Review*, Aug. 1915, vol. 18, p. 821) states that a phenomenon similar to corona in gases also takes place in liquid insulations, such as oil, due to tearing apart of the molecules of the oil or occluded gases. It seems that occluded gases often take an important part in supplying initial ionization. The effect of moisture is also pointed out.

PEEK, F. W. (TRANS. A. I. E. E. 1915, vol. 34-2, p. 1857) found that the time lag is much greater for oil than for air.

HIROBE, T. OGAWA, W., AND KUBO, S. (*Report*, Electrochemical Laboratory Tokio, Japan, 1916, report No. 25-3) showed that dust and fibrous matter in oil impair its insulating power, and that moisture has but little effect without absorbing media.

PEEK, F. W. (Dielectric Phenomena, 1920) showed that the dielectric strength of transformer oil can be increased by the use of baffles which confine the motion of the ions, impurities, etc.

PEEK, F. W. (Dielectric Phenomena, 1920) showed that transformer oil under electric stress exhibits properties similar to air. He showed that the energy distance is about $1.2\sqrt{r}$ cm. *i.e.*, about four times that of air, and that with such an energy distance, corona and spark-over voltages wil be equal for ratios of $\frac{R}{r}$ up to at least 300.

HAYDEN, J. L. R. AND EDDY, W. N. (JOUR. A. I. E. E., Feb. 1922) show how the failure of transformer oil depends upon the presence of impurities. They compare the number of failures at each voltage with the number to be expected according to the curve of probability, and find that they do not agree.

V. Electric Properties of Petrolatum.

MALCLES, L. (*Comptes Rendus* 1910, vol. 151, p. 63) furnished the idea that the behavior of petrolatum in an electric field is the result of free ions which are mobile when the petrolatum is fluid and immobile when it is jelly.

VI. Residual Charge, Power Factor and Associated Effects.

FARADAY, M. (Experimental Researches in Electricity, 1839) was probably the first to notice the phenomenon of residual charge.

HOPKINSON, J. (*Phil. Trans.* 1877, vol. 167, p. 599) showed that the residual charge is proportional to the exciting charge and gives results on experiments performed on several kinds of glasses, showing the effects of temperature. He noted that the residual charge in a Leyden jar can be promoted by tapping the dielectric, an indication that such charges are due to some internal polarization which is affected by shock.

AYRTON, W. E. AND PERRY, J. (*Proc. Royal Society* 1878, vol. 27, p. 238) said that dielectrics exhibit an increase of strain under a prolonged constant dielectric stress and said that this was due to the "viscosity of the dielectric". They explained viscosity on the basis of the presence of comparatively conducting particles in "dielectrics of heterogeneous composition" and suggested that dielectrics and metals might owe their different properties to the presence of rotary molecular motion in the one and motion of translation in the other.

MURAOKA, H. (*Wied. Ann.* 1890, vol. 40, p. 329) found that while paraffin and xylol showed practically no residual charge when separate, a layer of xylol on a layer of paraffin showed residual charge.

MAXWELL, J. C. (A Treatise on Elec. and Mag. 2nd ed. 1881, vol. 1, chap 10, p. 412) proved theoretically that a compound dielectric built up of layers of different non-absorptive dielectrics would exhibit both absorption and residual charge effect provided that the product $\rho\, k$ is different for each lamina. (ρ = resistivity and k = specific capacity.

STEINMETZ, C. P. (*Elec. Eng.* 1892, vol. 13, p. 272) showed that the energy consumed by a dielectric medium under alternating electrostatic strain is directly proportional to the square of the intensity of the electrostatic strain or $H = k\,E^2$. Hence, whereas magnetic hysteresis follows the law of the 1.6th power, dielectric hysteresis follows the law of the square, that is, it acts just the same as a mere dead resistance connected into the circuit.

BEDELL, F. AND KINGSLEY, C. (*Phys. Rev.* 1894, vol. 2, p. 170) showed by the use of curves, the effects of a previous negative charge upon successive residual discharges, he effect of absorption upon the discharge curves, the effects of temperature on the resistance of oils and solid dielectrics.

STEINMETZ, C. P. (*Elec. World* 1901, vol. 37, p. 1065) cited experiments on a paraffined paper condenser, showing that the dielectric loss is proportional to the square of the voltage and practically independent of the frequency. He suggested that the loss was largely due to mechanical motion of occluded air molecules under the influence of the alternating stress.

DRYSDALE, C. V. (*Electrician* 1901, vol. 46, p. 890) gave data on dielectric loss in cables and condensers, and called attention to its importance due to the energy loss being a continuing one regardless of the load. He also gave tables of losses in dielectrics, power factors, etc., for different types of mica condensers with varying pressures.

TORCHIO, PHILIP (*Trans. A. I. E. Cos.* 1902, pp 217-219, quoted in TRANS. A. I. E. E. 1917, vol. 36 pp. 499-501) gave results of measurements of dielectric losses on long feeder cables installed, and stated that "the dielectric losses are approximately proportional to the frequency, to the square of the voltage and to a certain function of the temperature not yet determined. The temperature however, increases considerably the dielectric losses."

SKINNER, C. E. (TRANS. A. I. E. E. 1902, vol. 19, p. 1047) showed that dielectric loss varies with frequency, but not always in direct proportion. The variation from proportionality was especially marked at higher temperatures. He also showed that not only is the loss greater at high temperatures, but so is the rate of increase of loss.

PERRINE, F. A. C. (TRANS. A. I. E. E. 1902, vol. 19, p. 1067) said that work with cables has shown that a slight amount of moisture in the insulation will materially increase the heating and that heating of this character almost invariably results in final breakdown.

MONASCH, B. (*Annalen d. Physik* 1907, vol. 22, p. 905) says that the loss varies strictly as the square of the impressed voltage up to the point of formation of corona and that in cables at ordinary frequencies, the loss is approximately proportional to the frequency.

FISHER, H. W. (TRANS. A. I. E. E. 1907, vol. 26-2, p. 997) gave data on the dielectric loss in rubber compounds and showed that compounds containing a large amount of extractive matter may have lower losses than those containing small amounts.

TRAUTON, F. T. AND RUSS, S. (*Proc. Royal Soc.* 1907, vol. 20, p. 551) showed experimentally that the recovered (residual) charge does not follow an exponential law as derived by Maxwell, but a logarithmic law.

SHUDDEMAGEN, C. L. B. (*Prov. Am. Acad. of Arts & Sci.*, 1909, vol. 44, p. 467) showed that the current which forms residual charge, or in other words, the absorption current, is far from negligible when the charging interval is very small.

HOCHSTAEDTER, M. (*Elek. Zeit.* 1910, vol. 31, p. 467) reported that tests on impregnated paper cables showed the dielectric loss to be exactly proportional to the frequency. He found that the maximum voltage in each cycle occurs simultaneously with the zero value of the current, but the maximum current does not coincide with zero voltage. He made a "dielectric hysteresis loop" from oscillograms and deduced therefrom the capacity, residual charge and dielectric loss.

DECOMBRE, L. (*Comptes Rendus*, 1911, vol. 152, pp. 315 and 1755) discusses dielectric loss in relation to polarization and makes some developments of Maxwell's theory. His reasoning, which is typical of that of several other physicists, is as follows:

The charge in a condenser is made up of two parts, one $k\,E$,

due to an ether displacement and the other m, to a polarization of the dielectric, or $q = m + k E$. According to the theory of Lorentz,

$$a \frac{d^2 m}{d t^2} + C \frac{d m}{d t} + b m = E$$

where a, b, and c are positive coefficients. If the voltage E is alternating the term $\frac{d^2 m}{d t^2}$ which is proportional to f^2, where f is the frequency is negligible, unless the frequency is of the order of that of light. Hence

$$c \frac{d m}{d t} + b m = E$$

But the energy absorbed is $E\, d q$, i. e., $E\,(d m + k\, d E)$. For a complete period the energy lost, if assumed to be dependent on the polarization of the dielectric, therefore equals

$$\int_0^T E\; d m \text{ or } \int_0^T c \left(\frac{d m}{d t}\right)^2 d t$$

Hence, the alternate charge or discharge of a condenser causes a dissipation of energy proportional to the square of the polarization current, $\frac{d m}{d t}$.

Rayner, E. H. (*Jour. I. E. E.* 1912, vol. 49, p. 3) reported the results of an extended investigation to determine the relative effects of a short application of high test voltage or longer application of lower test voltage. He also gave considerable information about the effect of humidity and temperature on the dielectric strength of insulating materials. The paper has a bibliography on the subject of dielectrics, containing 300 references, dated from 1864 to 1912.

Walker, Miles (*Jour. I. E. E.* 1912, vol. 49, p. 71) showed that if curves be made with temperature for abscissas and watts for ordinates, one curve giving the power lost in the cable and the other the power dissipated, an increase of temperature will be cumulative if the dissipation curve is above the loss curve, and non-cumulative if the reverse is true.

Fleming, J. A. and Dyke, G. B. (*Jour. I. E. E.* 1912, vol. 49, p. 323) showed that two non-absorptive condensers of different capacities, each in series with a non-inductive resistance and the two connected in parallel, will act as a single condenser having absorption, if the products $c_1 r_1$ and $c_2 r_2$ are unequal. This paper and the discussion thereon, give a clear theoretical treatment of the subject and considerable experimental data to support the theory.

Addenbrooke, G. L. (*Electrician*, 1912, vol. 68, p. 829) showed by measurements at different frequencies that dielectrics may be considered to consist neither of capacities and resistances in series nor of capacities and resistances in parallel. He also showed that the loss in liquid dielectrics is independent of the frequency above a certain point whereas in solids it increases with the frequency, but not always according to a linear law.

Pungs, L. (*Archiv. f. Elektrotechnik* 1912, vol. 1, p. 329) showed that the dielectric losses in transformer oil are practically independent of the frequency. He concluded from this that the losses are due to ionic conduction rather than hysteresis. Resin oil showed similar properties the loss increasing but slightly with the frequency.

Addenbrooke, G. L. (*Electrician* 1913, vol. LXX, p. 673) gives data on dielectric loss in gutta-percha. He found the power factor to vary as follows with frequency.

Cycles	Power Factor Per Cent
46	4.0
12	5.5
6	6.3
3	7.2
1.5	7.5

Wagner, K. W. (*Ann. der Phys.* 1913, vol. 40, p. 817, and *Elek. Zeit.* 1913, vol 34, p. 1279, developed Maxwell's theory of residual charges arriving like Maxwell, and unlike Trauton and Russ, at an exponential equation for residual charge current. He showed that his theory is consistent with observed facts regarding the relation between power factor and frequency. He also showed that his theory leads to the possibility of more than one maximum of dielectric loss at various temperatures, this also being in accordance with observed facts.

Evershed, S. (*Jour. of I. E. E.* 1914, vol. 52, p. 51) says that in absorbent insulators the conduction is not normally through continuous filaments of moisture but by endosmose. He explains endosmose as a motion of films of water along the walls of an insulator due to the water being electropositive to practically all solid insulating materials and being therefore drawn through the pores of the solid toward its electronegative end, where a potential gradient is impressed on the solid. He explains the well-known time fall of insulation resistivity as being due to the spreading of moisture globules over internal surfaces of the solid insulation under the influence of endosmose, *i. e.*, normally the moisture exists in globules separated by dry internal labyrinth surfaces of solid, but when a potential gradient is applied, these globules spread over the surfaces of the labyrinth and reduce the resistance. When the potential gradient is removed, the films coalesce into globules causing the resistivity to rise. Under the influence of an alternating potential gradient, the globules do not have time to spread over the surfaces, but vibrate, causing a loss of energy. Evershed made a model insulator consisting of an inverted *V*-tube containing alternate drops of water and air, the ends of the tube being each set in a beaker. When a potential gradient was established between beakers, the drops of water spread along the walls of the glass tube, and the resistance characteristics were found to be similar to those of an absorbent insulator. When the potential gradient was raised, failure began in the form of sparking along the films from one drop to another.

Wagner, K. W. (*Elek. Zeit.* 1915, vol. 36, p. 111) developing Maxwell's theory of composite dielectrics shows by simple calculations that in a dielectric composed of two elements, one of which has resistivity r and specific capacity k and the other resistivity R and specific capacity K, the residual charge will be zero if $r k = R K$. He also suggested that the dielectric loss would be zero under these conditions.

Skinner, C. E. (*Jour. Franklin Inst.* 1917, vol. 183, p. 667) showed that the dielectric loss in transformer insulation follows the equation $W = k E^n$ where the constants have the following values:

Temperature Deg. Cent.	k	n
30	0.025	2.34
40	0.032	2.27
50	0.044	2.22
60	0.068	2.21
70	0.107	2.18
80	0.155	2.15

W = Watts lost and E = effective kilovolts.

Bang, A. F. and Louis, H. C. (Trans. A. I. E. E. 1917, vol. 36, p. 431) following the method suggested by Walker, developed a method of determining the influence of dielectric losses on the rating of cables. They determined dielectric losses by the heating effects and gave data on the emissivity of conduit lines.

Clark, W. S. and Shanklin, G. B. (Trans. A. I. E. E. 1917, vol. 36, p. 447) give formulas for calculating dielectric loss in three-phase cables, data on dielectric losses, resistivities and specific capacities. They showed that when an impregnated paper cable is bent, voids are created which become filled with gases from the volatilization of the oils, pp. 458-460. These

reduce the resistivity at high voltages due to the ionization of the gases. A comparison of losses in old and new cables is given.

ATKINSON, R. W. (TRANS. A. I. E. E. 1917, vol. 36, p. 521) says that tests on impregnated paper cables at 25 and 60 cycles showed that the loss at 25 cycles is always somewhat less than at 60 cycles, and in some cases, is in almost direct ratio with the frequency. In other cases, there is little difference. Tests on a dried but unimpregnated paper lead cable showed the dielectric loss to be extremely low at all temperatures.

SWYNGEDAUW, R. (*Revue Gen. d'Elec.* 1919, vol. 5, p. 283) said that tests on triplex cables indicate that the dielectric loss obeys the following law:

$$W = (a + b\,E)\,f\,C\,E^2$$

where a and b are constants, C is the capacity, f the frequency and E the voltage.

VII. Grading of Insulation

JONA, E. (1898) made graded cables and exhibited them at Milan.

O'GORMAN, M. (*Journal I. E. E.* 1901, vol. 30, p. 608) showed that to get uniform stress in a dielectric, the product $K\,x$ must be constant where K is specific capacity and x = radial distance from the axis of the cable.

MORRIS, J. P. (*Jour. I. E. E.* 1907, vol. 40, p. 50) claims to have first suggested the use of intersheaths in the cable installation, in order to anchor the potential of the various layers of insulation in any manner desired by means of connections outside of the cable.

RUSSELL, A. (*Jour. I. E. E.* 1907, vol. 40, p. 7, and *Electrician* 1907, vol. 60, p. 160) said that when a dielectric under stress breaks down, a disruptive discharge ensues only when the effect of this partial breakdown is to increase the electric stress on the remaining portion. He also pointed out that in a composite dielectric subjected to alternating pressures, the voltages across the layers are usually out of phase with one another, and therefore that across each layer may be greater than indicated only by the thickness of the layer.

OSBORNE, H. (TRANS. A. I. E. E. 1910, vol. 29-2, p. 1553) gave revised form ulas for the design of graded cables. He also advanced the theory that solid heterogeneous dielectrics fail due to corona in the elements of lower specific capacity. This corona is assumed to be in the form of needle points.

BEAVER, C. J. (*Jour. I. E. E.* 1914, vol. 53, p. 57) mentions disadvantages of graded insulations and claims that desired results could be better obtained by means of intersheaths, because (1) no chemical interactions, (2) easier to joint, (3) no electrical discontinuity, (4) could be tested layer by layer as manufactured, (5) much wider latitude in choice of potentials.

CLARK, W. S. AND SHANKLIN G. B. (TRANS. A. I. E. E. 1919, vol. 38-1, p. 923) say that practically no advantage is gained by an attempt to grade with rubber, varnished cambric and impregnated paper because the maximum allowable working stresses in these materials are inversely as their specific capacities. They claim that it is better to have the insulation a homogeneous compact mass of impregnated paper.

VIII. Miscellaneous Data

RHEINS, G. (*Comptes Rendus*, 1900, vol. 131, p. 505) says that the metal of cables penetrates the insulation and destroys its insulating properties. He said that after 20 years, gutta-percha insulation will show copper in its outer layers, whereas with impregnated paper only a few layers were penetrated in four years. (No other experimenters report this phenomenon).

O'GORMAN, M. (*Jour. I. E. E.* 1901, vol. 30, p. 608) called attention to the effect of putting in series two elements of insulation having different specific capacities. He showed that the potential gradient is altered, the material of lower specific capacity carrying the greater part of the total potential drop across the two elements. (This fact seems to have been known to others at an earlier date.)

NEWBURY, F. J. (Cited by Perrine, TRANS. A. I. E. E. 1902, vol. 19, p. 1067) said that in his experiments with fiber cables he could increase the dielectric strength of the cable up to a certain point, by increasing the thickness of insulation; beyond that point the cable seems to breakdown at almost the same potential, irrespective of increase in thickness.

LANGSDORF, A. S. (*Elec. World* 1908, vol. 52, p. 942) reported tests on various insulating materials at frequencies from 30 to 110, that seemed to indicate that if the applied e. m. f. is above a certain critical value, breakdown occurs after a definite number of repetitions of the electrostatic stress.

THORNTON, W. M. (*Phil. Mag.* 1910, vol. 19, p. 390) showed that the electrical movement in a dielectric, when isolated in the field, is entirely confined to the molecule and is therefore neither metallic nor electrolytic in type, but is a continued displacement of the atomic charges to a greater degree of separation.

PETERSEN, W. (*Archiv. fur Elektrotechnik* 1912, vol. 1, p. 28) showed that the refraction of lines of forces at the junction of two particles of different specific capacity in a dielectric may lead to an increase of dielectric stress.

HOLTTUM, W. (Abstracted from a report to I. E. E. in *Electrician* 1913, vol. 71, p. 640) made tests on the relative dielectric strengths of ebonite for instantaneous and prolonged 50-cycle voltages and found that for stresses lasting a tenth of a second, the strength is only 25 per cent greater than for long continued stresses.

LICHTENSTEIN, L. (*E. T. Z.* 1917, vol. 33, p. 1179) says that the progress in the use of thin walls of insulation for high voltages is not due to a lower standard of safety in working, but to improved chemical, physical and mechanical processes of manufacture. He says that probably at very high test pressures an excess of 25 or 50 per cent over the working pressure ought to suffice.

BUTMAN, C. A. (*Elec. World* 1918, vol. 71, p. 812) showed that the specific capacity of a heterogeneous combination, such as of fullerboards soaked in oil, separated by three layers of paraffin, may be greater than that of either component alone. Thus, combination = 4.25, fullerboard = 3.32, paraffin = 3.69.

FERNIE, F. (*Electrician* Oct. 10, 1919, p. 416) pointed out the superior dielectric strength of oil around small as compared with large conductors.

ZELENY, J. (*Phys. Review* 1920, vol. 16, p. 102) explained the added dielectric strength of an ionizable dielectric in contact with a small electrode as being due to the high potential gradient at the surface of the electrode as compared with that a short distance away, the velocity of the ions consequently dropping below the value necessary for ionization by collision, when they have travelled a short distance from the electrode.

FERNIE, F. (*Beama*, Sept. 1921, p. 244) suggested that the stress which determines the failure of a cable is the minimum stress not the maximum.

FLIGHT, W. S. (*Journal I. E. E.* 1922, vol. 60, p. 218) gives data on the effect of heat on the electric strength of paper, micarta, varnished cloth and other materials. He showed that the electric strength of varnished cloth is about 42 per cent less at 100 deg. cent. than at 30 deg. cent., that of oil saturated paper, about 27 per cent less.

Acknowledgment is made of the assistance given by the following Institute members who were so kind as to assist the subcommittee in the preparation of this summarized history: Messrs. R. W. Atkinson, F. W. Peek, C. E. Skinner, D. M. Simons and F. A. Westbrook. The Subcommittee on Wires and Cables appreciates the incompleteness of the summary, and has made but little effort to settle questions of priority in discovery. It is hoped that the discussion will correct whatever deficiencies may exist.

Discussion

For discussion on this paper see page 611.

Dielectric Losses and Stresses in Relation to Cable Failures

BY D. W. ROPER
Fellow, A. I. E. E.
Commonwealth Edison Company, Chicago

Review of the Subject.—*When transmission cables were first operated at potentials exceeding about 7500 volts, it was noted that cable failures occurred in service with loads materially below those which had theretofore been found to be permissible with low-voltage cables, and this reduction in carrying capacity increased with increase of the normal working potential. For example the author has previously reported that No. 0 A. W. G. four conductor cables operating on a four-wire three-phase system with a maximum normal potential of about 4000 volts between phases carry 200 amperes on each of three conductors without damage due to the overheating, whereas a 250,000-cir. mil cable operated at 20,000 volts was found to have excessive burn-outs if the load exceeded 175 amperes per conductor.*

For a number of years it has been recognized that this reduction in carrying capacity of high-voltage cables was due to the dielectric losses and a number of papers have been presented to the Institute on this subject. A temperature survey of the 20-kv. cable above mentioned showed that nearly all of the burn-outs occurred in a portion of the conduit near the substation, which conduit contained a large number of heavily loaded cables, and in which the temperature was 10 deg. to 15 deg. cent. higher than the rest of the conduit. This portion of the 20-kv. line was replaced over two years ago with cable having a low dielectric loss, since which time no further cable failures have occurred.

The method of analysis first suggested by Bang and Louis and later extended by Clark and Shanklin was applied to this particular case, and the carrying capacity for the cable as determined in this manner was found to agree closely with the results of experience. The method was therefore extended so as to determine the law connecting the size of conductor, the dielectric loss and the carrying capacity. Curves and charts are presented showing the carrying capacity of all sizes of three-conductor cables above 100,000 cir. mils and of the entire commerical range of dielectric losses. These results were then compared with the operating records of a transmission system having cables ranging in size from No. 00 A. W. G. to 500,000 cir. mils and with operating voltages of 9, 12, 20 and 22 kv. The results of this comparison appear to indicate that practically all failures on these transmission lines, which were not due to external damage to the lead sheath, were due to the cables being loaded beyond their safe carrying capacity, and that the dielectric losses had not been given proper consideration in determining the carrying capacity of these cables.

During the year 1921 the number of cable failures on the 20,000-volt lines was about one per hundred miles. This was about the same as the record on the 9000-volt cables, and this result leads to the conclusion that when the transmission cables are operated at safe loads, in the determination of which dielectric losses have been given proper consideration, the resulting failures are of the order of one per hundred miles per year. This result indicates that very few of the cable failures which have occurred in the past are due to dielectric stresses and that most of the failures occur due to the reduction in dielectric strength caused by the heating of the cables above their critical temperature.

Foreign cable manufacturers and operating engineers have apparently appreciated the reduction in carrying capacity due to dielectric losses as they ordinarily limit their maximum conductor temperature to a point well below the critical temperature as determined by these investigations. Their publications also appear to indicate that they fully appreciate that the quality of the insulation is of prime importance and that increased security cannot be obtained by increasing the thickness of insulation without improving the quality. The tests on cables made at the factory indicate that with the thicknesses of insulation that are commonly used in this country, and with the insulation of the first quality, the cable will pass the test required by the Standards of the A. I. E. E. with a wide margin of safety.

Dielectric strength tests made on foreign cables and reported in the technical press indicate that the dielectric strength is generally materially above the corresponding figures obtained from tests on cables made in this country by a number of leading manufacturers. Apparently some material reductions in the thicknesses of insulation now used in this country for the transmission voltages can be made if the insulation is of first quality and has a low dielectric loss.

CONTENTS

INTRODUCTORY

DURING the past few years a number of papers concerning dielectric losses of impregnated paper insulation has been presented to the Institute and has contributed interesting and valuable information to our knowledge of this subject. As this knowledge increased, it has been apparent to some engineers that many of our transmission cable burn-outs were due to the dielectric losses and the resultant heating and not primarily to the dielectric stresses. In the past, engineers in charge of the operation of transmission cables have repeatedly stated that transmission cables did not burn out from overload, and apparently based this statement on their experience with the carrying capacity of low-voltage cables. It now appears that these statements were in error, and that in making these statements, the engineers did not appreciate the extent to which the carrying capacity was limited by the dielectric losses. If the present symposium, of which this paper is a part, will do something toward clarifying our ideas on the relation of dielectric losses, dielectric stresses and temperature of the insulation to cable failures, it will have served a very useful purpose.

Presented at the A. I. E. E. Annual Convention, Niagara Falls, Ontario, June 26-30, 1922.

Data on Cable Failures

In order to secure some data which might assist in reaching proper conclusions on this subject, the records of the transmission line of the Commonwealth Edison Company for the past eighteen years have been compiled and are shown in Figs. 1, 2 and 3. In preparing these records, all failures caused by external injury to the lead sheath or by lightning, or failures on test, and all joint troubles have been eliminated so as to leave only failures of the cables which occurred in service. The amount of transmission line in service throughout this period is shown in Fig. 4.

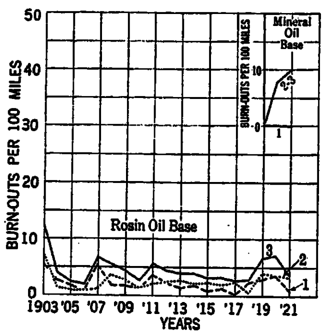

Fig. 1—Record of 9000-Volt Transmission Cable Failures

On system of Commonwealth Edison Company.
Curve 1—Internal troubles.
Curve 2—External damage.
Curve 3—Total.
Troubles due to lightning; failures on tests and joint troubles excluded.

Previous to 1919 all of the cables on this system had the paper insulation impregnated with a rosin oil compound. Beginning with that year, the cables have been purchased under specifications which included a dielectric loss guarantee, and in each succeeding year there has been some reduction in these guarantees. As a result, this record includes transmission cables ranging in size from No. 00 A. W. G. to 500,000 cir. mils and having dielectric losses ranging from about

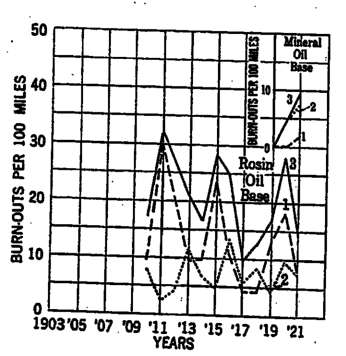

Fig. 2—Record of 12,000-Volt Transmission Cable Failures

Curves 1, 2 and 3, same designations as Fig. 1.

0.5 to 15 watts per foot or more when measured at 85 deg. cent. at their normal operating voltages of 9, 12, 20 and 22 kv. It would be confusing to show the dielectric loss curves in watts per foot for this large range of sizes, as the losses vary with the size of the conductor. It will be more illuminating to show the range of power factors of the dielectric loss for the various kinds of cable, and an assortment of such curves is shown in Figs. 5 and 6.

In order to analyze the operating results for the purpose of determining which, if any, of the cable failures have been due to dielectric losses, it is necessary to

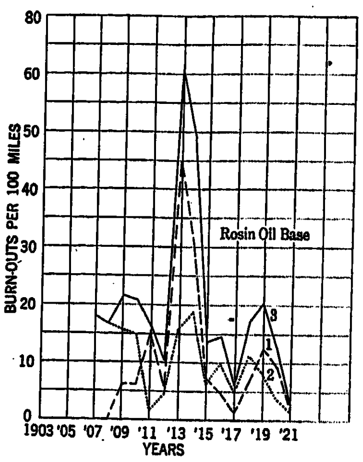

Fig. 3—Record of 20,000-Volt Transmission Cable Failures

Curves 1, 2 and 3, same designations as Fig. 1.

devise some method of rating the cables, that is, a method of determining their carrying capacity which will take into consideration the dielectric losses as well as the copper losses. Such a method was suggested by Bang and Louis in their Institute paper on Dielectric Losses, presented in June, 1917, and further developed by Clark and Shanklin in their paper on Single-Conductor High-Tension Cable, presented to the Institute in June, 1919. The application of the method may be best understood by its application to a specific example.

In March, 1917 there was placed in service a 250,000-cir. mil three-conductor 22,000-volt transmission line,

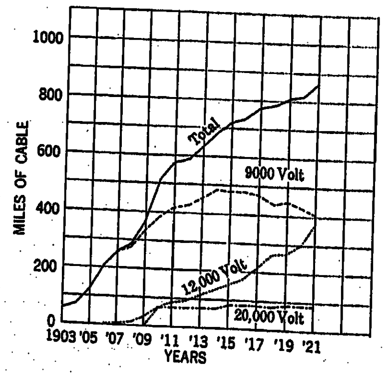

Fig. 4—Amount of Underground Transmission Cable in Service, Commonwealth Edison Company

No. 3801, from a suburban generating station into one of the outlying substations. The 4000 feet of this cable next adjacent to the substation was in a heavily loaded conduit, and repeated burn-outs occurred in this section. A temperature profile of this conduit taken by a recording thermometer in one of the vacant

is shown in Fig. 7. A sample of this cable was for dielectric loss, and the results are shown in In the hope of reducing the number of failures cable, the 4000 feet in the heavily loaded con-

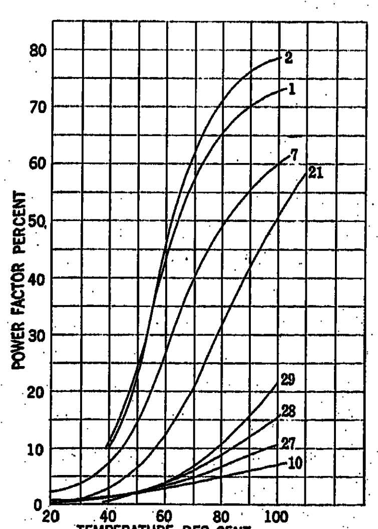
ghest power factors are from cables impregnated with rosin oil ds. The lowest losses are from cables impregnated with a mineral ound. The intermediate curves are from cables with various of the two compounds.

as replaced with cable having a low dielectric shown in Fig. 8. In the same figure is also the Clark and Shanklin line for average duct on which was obtained as the average of a large r of observations, and shows for each tempera-



DATA SIMILAR TO FIG. 5 FOR 20,000-VOLT CABLES

e number of watts that can be radiated from le in one duct. In order that the temperature cable may be constant, the losses in the cable equal the amount of heat radiated. With a curve showing the variation of dielectric loss with temperature to start with, we can for any temperature subtract the dielectric losses from the total radiation and secure the copper losses. From the latter figure, the current in the cable can be readily calculated. The results of such calculations for the old and the new cable are shown by curves in Fig. 8.

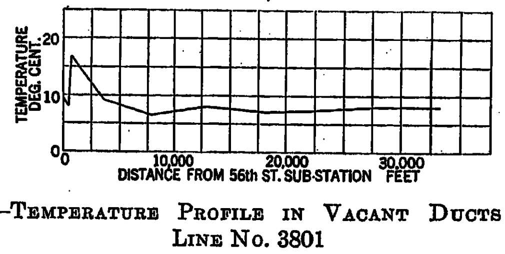


FIG. 7—TEMPERATURE PROFILE IN VACANT DUCTS ALONG LINE NO. 3801

Taken about April 1, 1922.

The temperature near the substation was lower at this time than at the time of the line failure described in the text due to several loaded cables having been removed from the conduit line, thus reducing the total losses in conduit about 15 or 20 per cent.

A chart from the recording ammeter on this line is shown in Fig. 9. This chart shows a normal load of about 150 amperes on the line up to about 5:20 p. m. at which time, owing to some trouble in other portions of the system, the load was increased to about 225 amperes for about an hour and three-quarters. As it was known that this line would not carry this load continuously, the load was reduced about 7:15 p. m. to what was considered a normal load for the line, and this load was carried until about 11 p. m., when a

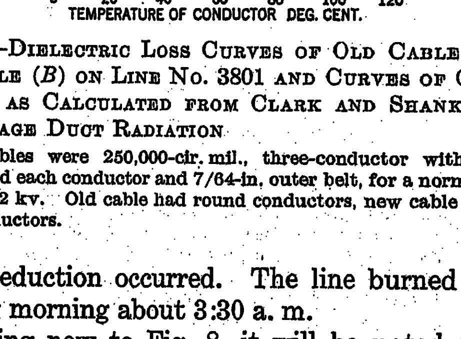

FIG. 8—DIELECTRIC LOSS CURVES OF OLD CABLE (*A*) AND NEW CABLE (*B*) ON LINE NO. 3801 AND CURVES OF CARRYING CAPACITY AS CALCULATED FROM CLARK AND SHANKLIN LINE FOR AVERAGE DUCT RADIATION

These cables were 250,000-cir. mil., three-conductor with 19/64-in. paper around each conductor and 7/64-in. outer belt, for a normal working voltage of 22 kv. Old cable had round conductors, new cable has sector-shaped conductors.

further reduction occurred. The line burned out the following morning about 3:30 a. m.

Referring now to Fig. 8, it will be noted that the current of 225 amperes was materially above the critical current for this line. This means that the losses in the cable were greater than the radiation, so that the temperature rapidly increased. A peak load of 175 amperes had previously been found possible

with this line if it did not continue very long and was sharply reduced thereafter. In this case, however the load of 175 amperes, which is about the critical load for this line, followed a peak load somewhat greater so that the temperature of the line having been materially increased by this heavy load, the total

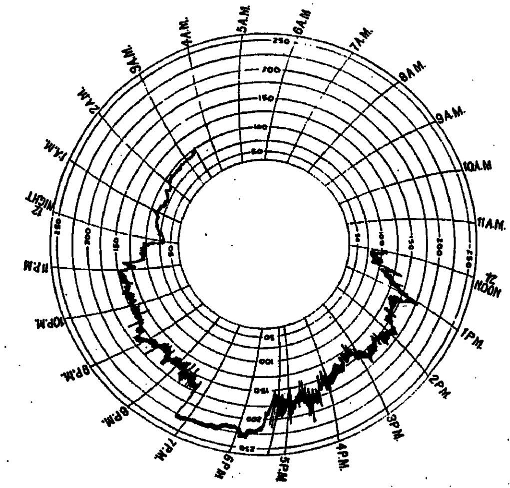

FIG. 9—RECORDING AMMETER CHART ON LINE No. 3801
Showing a load in excess of the critical current in the evening, followed by failure about 3:30 the following morning, October 28, 1919.

losses with 175 amperes were still above the radiation line, and the temperature continued to increase so that when the load was still further reduced to 100 amperes about midnight, the temperatures continued to increase until the line failed. These statements do not mean that the temperature of the cable throughout its entire length increased as above described, and

B. 225 amperes, 0 volts. Temperatures taken by thermometers.

in fact it is very probable that the temperature did not increase above normal except for a very small portion of the cable where the dielectric losses were higher than in the adjacent portions. This is demonstrated by Fig. 10 which shows the results of a laboratory test made on a piece of 250,000-cir. mil, three-conductor cable and is from the N. E. L. A. Underground Systems Committee report for 1913. This cable was operated with 225 amperes on each conductor, and with 12,000 volts between conductors. It will be noted that the heating in the cable was far from uniform throughout its length and that at one point the temperature was about 18 deg. cent. above another point eight feet distant. The figure indicates that had the thermometer at this high point been a little further to the right, a still higher temperature would have been recorded.

Following the experience in this case, the practise was adopted of shifting the load within a few hours after a heavy peak load had been carried so that the line could be opened at both ends thus stopping the dielectric losses. The line then cooled rapidly so that it was at normal temperature before being placed in service for the day load the following morning. This method of operation was followed until the cable in

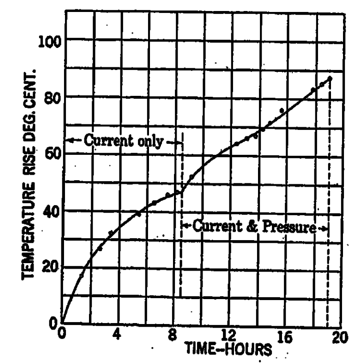

FIG. 11—HEAT RUN ON No. 00 THREE-CONDUCTOR CABLE
With 9/32-in. insulation around each conductor and 6/32-in. outer belt paper insulation, impregnated with rosin oil compound.

the 4000 feet of hot conduit had been replaced by the cable with low dielectric loss, and as a result, no further burn-outs have occurred on this line.

It is quite possible however, that cable failures due to dielectric losses may not occur until several days after the line has carried a load in excess of the critical current. This may be illustrated by Fig. 11 which shows the increase in temperature in a cable which carried current only for about 9 hours and then current and potential for 10 additional hours. The upper part of this temperature curve indicates that had the test been continued a few hours longer, the curve would have become concave upward in which case the cable would have failed within a short time.

If a cable carries a maximum load that is less than the critical current each day on an ordinary load cycle with a daily load factor of about 50 per cent, then the cable will cool to about the same minimum temperature each night. If the cable carried for an hour or two a peak load, that exceeds the critical current, the minimum temperature at the time of minimum load

will be a little higher than the minimum which occurs in the ordinary cycle. Suppose, now, that the peak load exceeded the critical current for a sufficient time so that the minimum temperature following was, say,

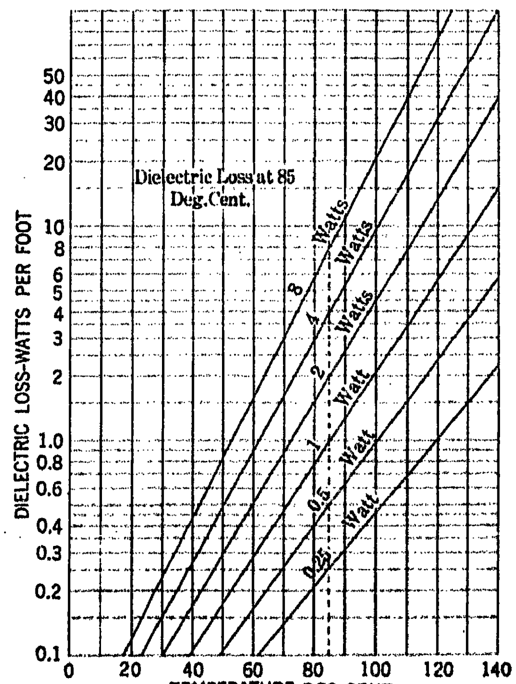

FIG. 12—DIELECTRIC LOSS DATA ASSUMED FOR PURPOSES OF CALCULATIONS

Based on a number of laboratory tests made for Commonwealth Edison Company.
In referring to these curves later, the lines will for convenience be designated by their loss at 85 deg. cent.

15 deg. higher than normal. This would mean that the cable would start on its ordinary load cycle 15 deg. warmer than usual, and its maximum temperature with its ordinary load cycle would probably exceed the

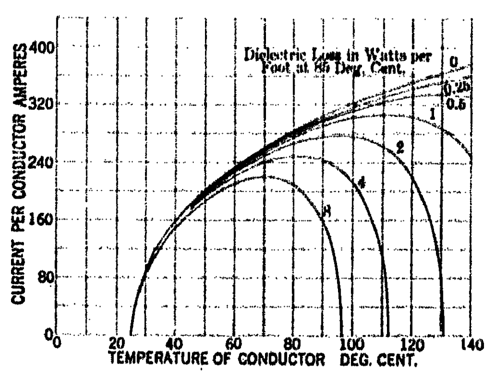

FIG. 13—CARRYING CAPACITY OF 250,000-CIR. MIL. THREE-CONDUCTOR CABLES

With dielectric losses as shown in Fig. 12 calculated from the Clark and Shanklin line for average duct radiation.

critical temperature on the following day. Under such circumstances, the maximum temperature would increase somewhat day after day, with the ordinary load cycle, and in a few days the increase would be sufficient so that the cable would not fall below the critical temperature even at the time of minimum load. Then a burn-out would follow in a comparatively few hours, as illustrated above on Line 3801. Many of the failures of cable due to dielectric losses have occurred in this manner several days after the unusual load or other abnormal temperature conditions which were the primary cause of the failure.

It is not necessary that the exact cycle above described be followed in order to produce a cable failure from dielectric loss, and a failure may result whenever the temperature of the cable is raised in any manner to a point above the critical temperature. The trouble may be due primarily not to the load on the cable which fails, but to heavy loads being carried on other cables in the same conduit so as to raise the ambient temperature.

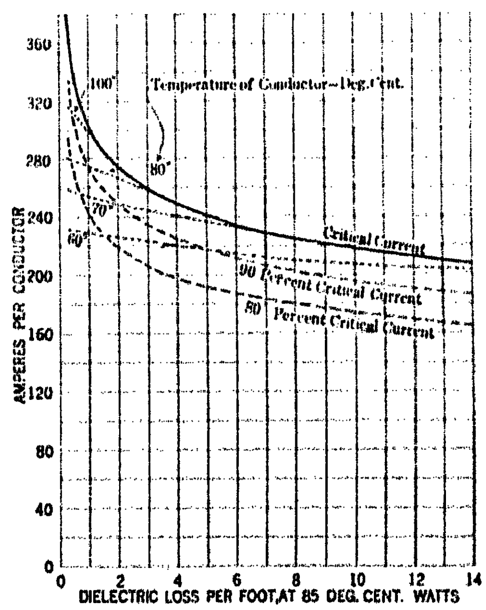

FIG. 14—CURVE SHOWING THE EFFECT OF DIELECTRIC LOSS ON THE CRITICAL CURRENT OF 250,000-CIR. MIL. THREE-CONDUCTOR CABLE

Plotted from curves in Fig. 13.

External sources of heat will also produce the same result, such as steam being turned into a sewer which is adjacent to the conduit line. Most companies operating high-voltage transmission lines have had experience with cable failures due to such causes. One company reports that it had to move transmission lines out of conduits which were laid close to the curb wall because of a bake oven located under the sidewalk and next to the curb wall. Other companies have reported difficulties due to the radiation losses from underground steam mains 15 to 20 feet distant.

EXTENDING THIS METHOD TO COVER ALL GRADES OF CABLE

By securing dielectric loss curves from cables covering a wide range of losses per foot, we can make similar calculations for a number of sizes and thus discover

the manner in which dielectric losses affect the carrying capacity.

Figs. 5 and 6 give the dielectric loss results from a large number of cables, and with these and other similar data we can assume a number of dielectric loss curves

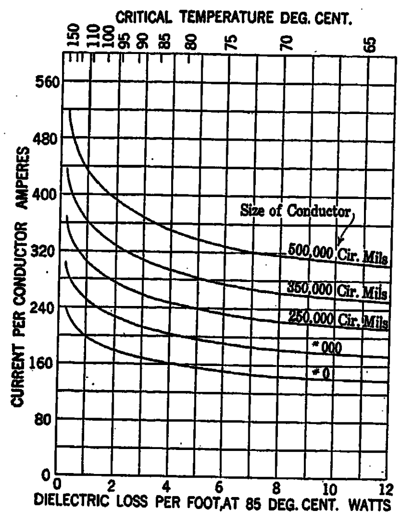

Fig. 15—Curves Showing for Several Sizes of Cable, the Variation of Critical Current and Critical Temperature with Dielectric Loss

over the entire commercial range of dielectric losses. It is not possible to make these assumptions with minute accuracy because the dielectric loss curves of cable furnished by different manufacturers are of different shape. After trying a number of ways of plotting the curves, it was found that when they were plotted on semi-log paper, part of the curves

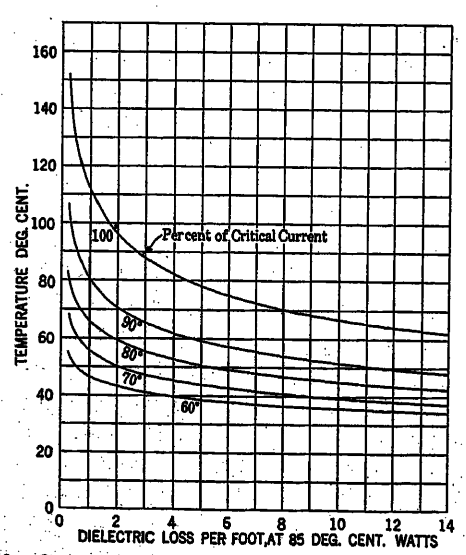

Fig. 16—Curves Showing Variation of Critical Temperatures with Dielectric Loss

would be convex upward, part straight lines, and part convex downward. Accordingly the assumptions were made as shown in Fig. 12 and these assumptions fairly represent the average of the dielectric loss curves from cables over a wide range of quality as obtained from six different cable manufacturers.

For each of these assumed dielectric loss lines, calculations for 250,000-cir. mil, three-conductor cable were made as shown in Fig. 13. It will be noted in this figure that each of the curves of cable having the higher dielectric losses has a maximum point, called the critical current, which occurs at the critical temperature. It is, therefore, possible to plot this critical current against the dielectric loss as shown in Fig. 14. By adding the isothermal lines and the curves corresponding to 80 per cent and 90 per cent of the critical current, the data plotted in this way become a very convenient form for studying the performance of any particular size of cable.

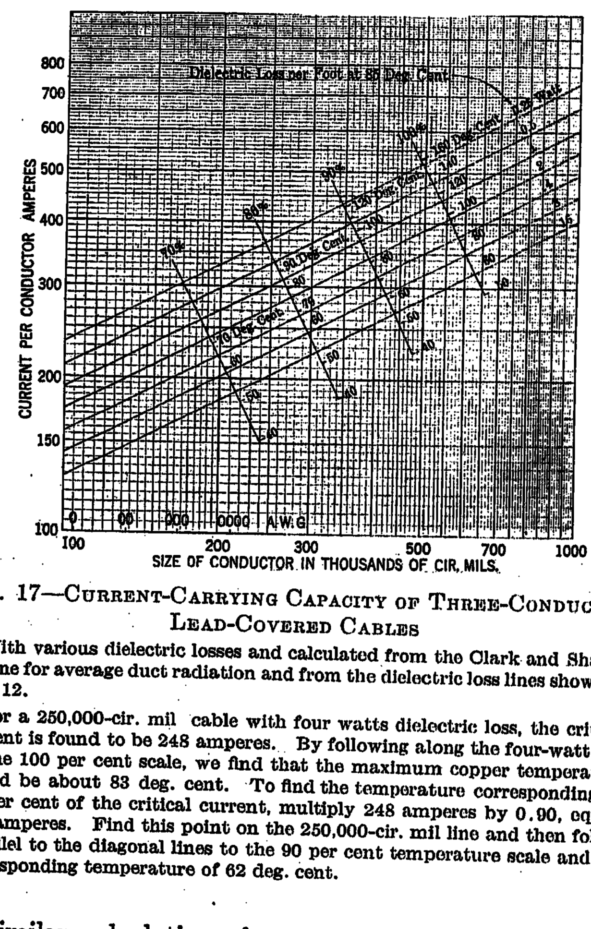

Fig. 17—Current-Carrying Capacity of Three-Conductor Lead-Covered Cables

With various dielectric losses and calculated from the Clark and Shanklin line for average duct radiation and from the dielectric loss lines shown in Fig. 12.

For a 250,000-cir. mil cable with four watts dielectric loss, the critical current is found to be 248 amperes. By following along the four-watt line to the 100 per cent scale, we find that the maximum copper temperature would be about 83 deg. cent. To find the temperature corresponding to 90 per cent of the critical current, multiply 248 amperes by 0.90, equals 223 amperes. Find this point on the 250,000-cir. mil line and then follow parallel to the diagonal lines to the 90 per cent temperature scale and get corresponding temperature of 62 deg. cent.

Similar calculations for a number of sizes of cable have been made, and their critical currents plotted against dielectric loss are shown in Fig. 15. In plotting these curves, it was noted that all sizes of cables having the same dielectric loss in watts per foot reach their critical current at the same temperature. It is therefore possible to add a temperature scale as shown in Fig. 15. From Fig. 13 and Fig. 15 it will be noted that a cable without dielectric loss has no critical current, and also that a cable with a low dielectric loss reaches its critical current at a temperature above the maximum permissible temperature for impregnated paper insulation.

In Fig. 16 is shown the curve of variation of the critical temperature with the dielectric loss. It would obviously be quite impossible to operate cables at their critical temperatures as determined by a dielectric loss test on a sample of cable, as such a test gives the average loss per foot for the entire sample and does not show the maximum dielectric loss at any point on the cable. Accordingly additional curves are included in Fig. 16 which show the temperatures that would be reached with several percentages of the critical current. From these curves it will be noted that a material reduction in the maximum temperature of the insulation can be made by a moderate reduction in the current below the critical current.

If the curves shown in Fig. 15 are transferred to logarithmic coordinate paper as shown in Fig. 17, it is found that the curves become straight lines and this permits using the calculations for all sizes of cable.

Fig. 17 shows the rating of all sizes of cables and in a full commercial range of dielectric losses as calculated by this method. By comparing this rating with the operating records of the system under discussion, and using as the ambient temperature the temperature obtained by a recording thermometer in an idle duct and about twenty feet from the manhole, we find that first, the transmission cables have in the past been frequently operated at or above their critical currents, and second, if the loads on the transmission cables are limited to about 90 per cent of the critical currents during the cooler months of the year and to about 80 per cent in the summertime, transmission line failures due to the dielectric losses will be practically eliminated.

Analysis of the Cable Failure Records

Referring now to the cable failure records of the 9000-volt cables, as shown in Fig. 1, this curve shows occasional peaks, and although the dielectric losses at 9000 volts are comparatively low, we know that some of these failures followed serious overloads. Some of these cases of trouble have occurred on one of three lines to a substation when one line was out of service on account of construction work in the substation, and some accident placed a second line out of service, thus putting the whole load on one line. In Fig. 3 showing the cable failure records of the 20,000-volt cables, there are several very pronounced peaks. It is now quite thoroughly understood that these peaks were due to the overloading of the cables beyond their critical current. The very pronounced peak in 1913 and 1914 followed the addition of a 24-hour load to the load previously carried on one group of lines which was reduced by the installation of an additional line in 1915. The pronounced peak in 1919 was due largely to the troubles on Line 3801 above mentioned. In 1921 however, after the low-loss cable had been substituted for the high-dielectric-loss cable in the hot conduit, and after a portion of the load on certain other lines had been transferred to the 12,000-volt, 60-cycle system, thus bringing the load on all 20,000-volt cables below their critical current, it is to be noted that the cable troubles dropped to about one per hundred miles per year or about the same as for the 9000-volt cables. This result indicates that practically all of our previous cable troubles on the 20,000-volt lines were dielectric loss failures and that when the load on these cables are kept within the limits at which the dielectric loss failures occur, then the remaining failures, that is, the failures due to dielectric stresses are quite insignificant.

The causes for the peaks in the 12,000-volt cable failures are more complicated. When the 12,000-volt system of tranmission to substations for alternating-current distribution was first installed to replace the motor-generators previously used for changing the frequency from 25 to 60 cycles, some of the old 9000-volt cables were transferred to 12,000-volt service. In addition, other cables were installed having the same insulation as the 9000-volt lines. Quite a few of these cable troubles were due to paper insulation being torn by sharp bends in manholes, and a larger number perhaps was due to the attempt to carry on these lines the same loads as had been previously carried on the 9000-volt lines, that is, due to the failure to make a proper allowance for the reduction in carrying capacity caused by the increase in dielectric losses at the higher voltage.

The two latter peaks were due in large part to the failures of cable forming tie line between large generating stations. On account of the necessity of cleaning and overhauling the turbo-generators in these stations, it is necessary to shut each generator down for a period of several weeks during the light-load period, and as a result of the load on these tie-lines is frequently at a maximum during this generator cleaning period in the summer-time. A number of these 12,000-volt cable failures also occurred in a conduit near the Northwest Station, where for a distance of about one block, two heavily loaded conduits were only a few feet apart, thus affording insufficient opportunity for the radiation of the heat. This trouble was stopped temporarily by cooling the conduit line with a stream of water applied intermittently. Later the 12,000-volt rosin-oil-impregnated cables were replaced with other cables having low dielectric losses.

Particular attention has to be paid to this question of conduit temperature, due to heavily loaded cables in the vicinity of stations and substations. Fig. 18 shows the temperature profiles of two conduit lines between the Fisk Street Station and the Calumet Station, in which there are several pronounced peaks along the route in the vicinity of substations. There is also a pronounced peak near the Fisk Street Station due to temporary storage of coal on the ground above the conduit line.

Another feature of interest in Fig. 2 is the record of cable failures due to external causes. These cables,

as above mentioned, have the same insulation thickness as the 9000-volt cables. On a large system it would, at first thought, be reasonable to suppose that the percentage of failures due to external causes would be the same for all voltages of cable. Quite a few instances have occurred, however, where 9000-volt cables had their lead sheath damaged and no failure occurred,

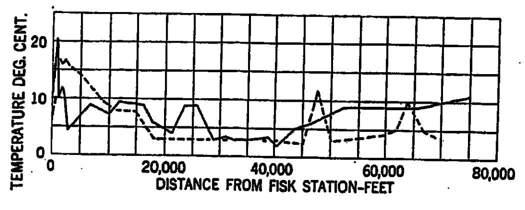

Fig. 18—Temperature Profiles Along Two Conduit Routes Between the Fisk Street Station and the Calumet Station

whereas under the same circumstances failures have occurred in the 12,000-volt cables. Several of these 12,000-volt failures assigned to external damage have occurred in cables which, upon being withdrawn for repairs after failure occurred, showed marks on the lead sheaths, indicating damage at the time of installation. A number of cases of damage to the lead sheath of 9000-volt cables have been found when the cables were being withdrawn for reinstallation at another location, and experience appears to indicate that had these cables been operated at 12,000 instead of 9000 volts, cable failures would have resulted. In one case, a 9000-volt cable, upon being withdrawn, was found to have the lead sheath burned off for a maximum length of two feet and a maximum width of about two inches, and the burn extended entirely through the outer belt insulation. This cable was installed in single-duct vitrified tile conduit and the damage had been caused by the failure of another cable in an adjacent duct about one year previously. The cable which was withdrawn had been in service throughout this period in the damaged condition and without developing any trouble at this location, although the cable was only six inches above the permanent ground water level.

These several experiences appear to indicate that the 9000-volt cables have such an excess of insulation for the working voltage, that the increased dielectric stress due to these injuries to the lead sheath is not sufficient to cause a cable failure, although failures of 12,000-volt cable would generally occur under the same conditions.

Another contributing cause for the increased number of external damage failures of the 12,000-volt cables is that these lines have been installed more recently than the 9000-volt lines, and are therefore installed in ducts above the 9000-volt cables. Damages due to digging in the street would, therefore, be more likely to affect the 12,000-volt cables.

Results of Tests on Cables at the Factories

During the past three years the cables for addition to this transmission system have been purchased under specifications practically identical with those included in the report of the Underground Systems Committee of the N. E. L. A. for the year 1920, and the cables have been carefully tested at the factory in order to insure that they complied with the specifications in all respects. In addition, laboratory tests were made on impregnated paper from the cables to determine its quality.

Fig. 19 shows the results of a series of such tests that is quite representative and typical. In the folding endurance test the number of double folds of different samples varied from 45 to 13,000, while the other tests showed a much smaller variation.

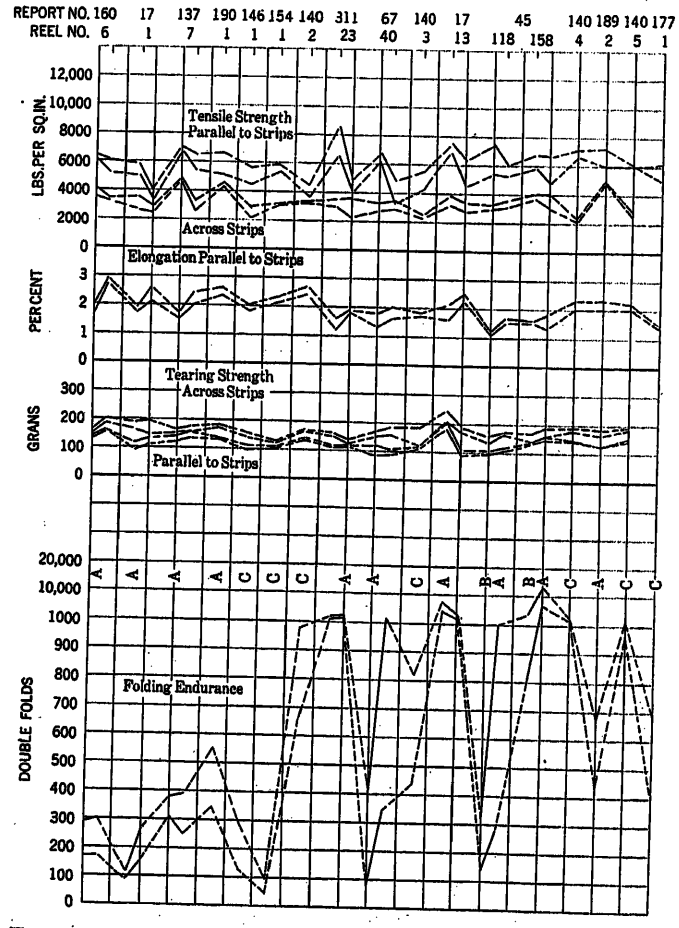

Fig. 19—Typical Tests on Physical Properties on Impregnated Paper Insulation Showing Variation in Quality of Paper

The two lines given for each series of tests represent the average and minimum values of results of tests on several samples of paper from each piece of cable. *A* denotes no tearing of paper in bending test in accordance with N. E. L. A. cable specifications; *B* denotes slight tearing, and *C* very bad tearing.

The tests made on these cables at the factory also showed a very large variation in the dielectric strength of the samples. In general, however, the cables passed the tests required by the Standards of the A. I. E. E. with a rather wide margin. As a result, the thickness

of insulation during this period has been gradually reduced. For low-voltage cables the reduction in thickness of insulation has been about 50 per cent and for the high-voltage cables about 25 per cent to 35 per cent. Before making the last reduction, sample reels of cables with thin insulation were secured from several manufacturers and submitted to all the regular and special tests called for by the Standards of the A. I. E. E. and the N. E. L. A. cable specifications. The thicknesses as finally adopted are practically the same as the recommendations by the British Engineering Standards Association for voltages below 6000 and above this are practically the same as the thicknesses being used by some of the larger English companies. However, one of the latter companies has recently, on the basis of its own experience and on the advice of its consulting engineers, made a further reduction of 25 per cent in the thickness of insulation of cable for 20,000 volts normal operating pressure, the insulation being 300 mils between conductors and 210 mils to ground. The usual British practise calls for a maximum copper temperature of about 50 deg. cent. for transmission cables. Correspondence with English consulting engineers and cable manufacturers shows that their high-voltage cables have about the same dielectric losses as those furnished by the leading manufacturers in this country, that is, if measured at 85 deg. cent. the dielectric losses on their 20-kv. cables would be of the order of one watt per foot. By referring to Fig. 14, it will be noted that for a dielectric loss of one watt per foot and a copper temperature of 50 deg. there is a rather wide margin between the operating current and the critical current which might result in cable failures due to dielectric losses. Apparently therefore our British friends are of the opinion that as long as they continue to operate their cables under conditions which eliminate burn-outs caused by dielectric loss heating, then they can secure satisfactory operation with an insulation thickness less than two-thirds of what is considered necessary in this country.

Relation Between Insulation Thickness and Dielectric Stresses

As a result of a thorough and persistent search, the author has reached the conclusion that there is in use in this country no scientific basis for determining the thickness of impregnated paper insulation on high-voltage cables. In the earlier days, when impregnated paper cables were first made, the manufacturers appear to have adopted the thicknesses of insulation previously used on cables with rubber insulation. No bending tests were made on these earlier cables, and the cables were installed with the same sharp bends that had previously been found permissible with rubber-insulated lead-covered cables. Our later knowledge indicates that many of these early failures must have been due to the tearing of the paper insulation caused by the bending during installation. Many of the older foremen and splicers who were raised on rubber insulated cables were quite firmly of the idea that it did not matter how sharp a bend or kink was made in the cable during its installation so long as these sharp bends and kinks were removed before leaving the cable in its final position.

As troubles from these earlier paper insulated cables occurred, the manufacturers and users, instead of making a determined effort to locate and remove the cause of trouble, adopted the simpler course of increasing the thickness of insulation, and until the last few years it does not seem to have occurred to anyone that they might have more insulation on their cables than necessary.

Several manufacturers in this country are making impregnated paper tubing consisting of paper impregnated with some insulating compound and then heat-

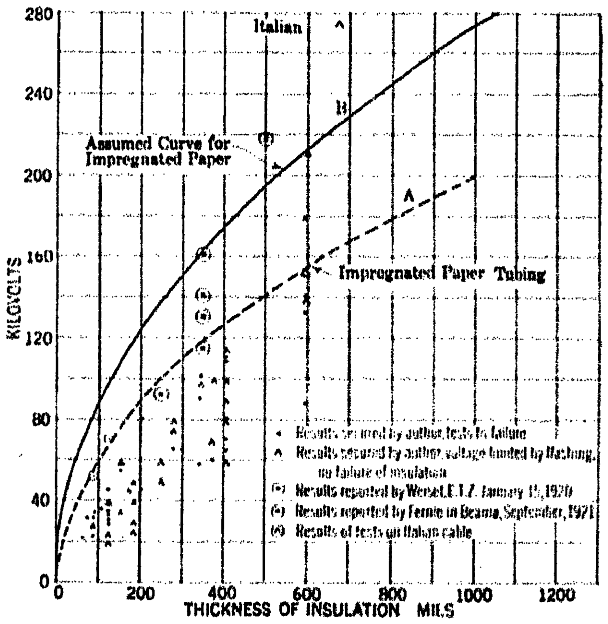

Fig. 20—Dielectric Strength Tests on Impregnated Paper Insulation

A. Curve of dielectric strength guaranteed by one maker of impregnated paper tubing, in which the dielectric strength is proportional to the square root of the thickness.

B. Curve similar to *A* assumed by author from results of one test on 33-kv. cable.

treated so that the resulting material is very similar in its make-up to impregnated paper insulation used in lead-covered cables. One of these manufacturers in its circulars states that a quarter inch thickness of this material will stand a 100-kv. dielectric strength test, and further, that the dielectric strength varies with the square root of the thickness. From these data, curve *A* in Fig. 20 has been drawn.

The author in criticising the manufacturer of some cable with 600 mils insulation between conductors because the manufacturer had been satisfied with a dielectric strength test that was limited by cable bell trouble, attempted to make a dielectric strength test on a 15-foot sample, carrying the pressure to 212 kv.

between conductors. In this case also the pressure was limited by cable bell trouble and there was no failure of the cable within the lead sheath. Assuming that the dielectric strength of impregnated paper insulation also varies with the square root of the thickness, and using this particular point as our starting point, then we get the curve shown by B in Fig. 20. On the same sheet are also shown two points given by Weiset in the *E. T. Z.* for January 15, 1920, also six points given by Fernie in *Beama* for September, 1921, and also one figure giving results from an Italian cable, the latter data being obtained from private sources. On the same sheet are also shown the results of a large number of dielectric strength tests on various thicknesses of insulation made for the author on cables purchased in the last three years. For those thicknesses of insulation where a large number of tests are available, these results show a ratio of maximum to minimum greater than 2 to 1.

In testing the cables purchased under specifications, it was noted that at first the paper was not applied smoothly, that is, without wrinkles, and that difficulty was encountered by some manufacturers in applying the insulation so that it would pass the bending test. As these difficulties were brought to the attention of the manufacturers, it was found that it was not a serious matter to eliminate the difficulties by having the paper tape of the proper thickness and width and applied with a suitable tension and the right amount of lap. As these difficulties were eliminated, the dielectric strength test of the cables increased, so that finally for such thicknesses of insulation as are common in this country for 25 kv. it was found that the voltage required to cause failure of the cable under the dielectric strength test was quite beyond the testing facilities available in practically all of the cable factories. It would thus appear that by suitable care and perhaps some additional inspection in the factories, the American cable manufacturers should be able to make their cable of more uniform quality so that it would give results more nearly corresponding to the available data on foreign cables.

The American Engineering Standards Committee in gathering foreign specifications and standards for the use of its recently appointed Sectional Committee on Insulated Wires and Cables received an interesting communication from a Dutch Standards Committee which includes the following statement:

> The Association of Managers of Electric Central Stations have made an extensive study on high-tension cables, the results of which have been published. * * * * The most interesting result disclosed by this study is that, contrary to most opinions of today, it is not the thickness of insulation which gives the best guarantee for the reliability of the cable, but that the influence of the quality of the insulation material is very much greater.

How long will it be before American manufacturers will adopt the Dutch plan of increasing the reliability of their cables, not by increasing the thickness of insulation but by improving the quality?

The author recently had an interesting discussion with one of the technical executives of one of the larger manufacturing companies. This engineer had made some suggestions that certain changes should be made in the details of the manufacture of a certain line of electrical apparatus so as to improve the quality of the product. These changes were at first violently opposed by the superintendent of this factory, but after a thorough investigation the changes were put into effect. Then it was discovered that, in spite of the increased inspection and greater care in manufacture which resulted in a marked improvement in the quality, the improved manufacturing methods had brought about a reduction of about 5 per cent in the cost of the finished product. Is it not possible that a similar result might be secured in the manufacture of impregnated paper-insulated lead-covered cables?

Conclusions

1. After excluding the cable failures caused by lightning, external damage to the lead sheath and joint troubles, the remaining transmission cable failures on the system have been largely dielectric loss failures; that is, the cables have been loaded beyond their critical current as determined by their dielectric losses and cumulative heating, which followed, caused the cable failures.

2. The only cable failures that can be definitely ascribed to the dielectric stresses are a few that have been caused primarily by the tearing of the insulation due to sharp bends during installation.

3. Temperature readings in conduits are just as important as ammeter readings in the stations in determining the safe loads for transmission lines.

4. Some scheme of testing should be devised so that by means of some simple measurements it may be possible to determine the radiation constants of different portions of conduit lines in service and establish current ratings of transmission cables so as to eliminate the burn-outs due to overloads.

5. The thicknesses of insulation considered necessary in this country for transmission cables have been determined largely by experience with the cables in which the insulation was impregnated with a rosin oil compound and had high dielectric loss. If the Rules in the Standards of the A. I. E. E. are a sufficient criterion of the quality of the cable, then the thicknesses of insulation ordinarily used for transmission cables in this country can be very materially reduced, as cables with the present thicknesses of insulation with material and workmanship of the first quality, will pass the tests prescribed by the Standards of the A. I. E. E. with a wide margin frequently exceeding 100 per cent.

6. High-voltage cables having a low dielectric loss can be safely operated at temperatures materially higher than are possible with high-loss cables, due to the increase of the critical temperature with the reduction in dielectric losses.

7. The permissible operating temperature of high-dielectric-loss cables is limited by the critical temperature above which cumulative heating occurs. In low-loss cables the temperature is limited, as in low-voltage cables, by the temperature which the paper insulation will withstand without deterioration.

8. Until the proper method of calculating the limiting stresses of high-voltage cables and the limiting values for these stresses is determined, it will not be possible to design cables with the thickness of insulation properly proportioned to the working voltage.

9. If the dielectric losses of transmission cables are properly taken into consideration in fixing their carrying capacity, then for the thicknesses of insulation that are commonly used in this country, the percentage of burn-outs of the high-voltage cables should be no larger than for the lower transmission voltages and should not exceed one or two per hundred miles per year.

10. When the carrying capacity of a transmission cable with high dielectric loss is limited by the temperature of a short portion of the conduit in which it is installed, it may be found profitable to replace this portion of the cable with low-loss cable, and thus secure an increased carrying capacity for the entire line.

Discussion

For discussion on this paper see page 611.

On the Minimum Stress Theory of Cable Breakdowns

BY DONALD M. SIMONS
Associate A. I. E. E.
Standard Underground Cable Company, Pittsburgh, Pa.

Review of the Subject.—*For the rational and economical design of electric cables, it is important to know the relation between the dimensions of the cable and its breakdown strength. Many different theories have been proposed in the past, such as the maximum stress theory, the average stress theory, Russell's theory, and Osborne's theory, all of them conflicting. Recently a new theory has been proposed by Fernie that the minimum stress, namely that at the sheath of a cable is the limit. It is the purpose of this paper to discuss Fernie's theory and data, inasmuch as it is so diametrically opposed to some of the earlier theories. It seems quite plausible that insulating materials have a specific breakdown stress. Fernie having discovered, as he states, that the minimum stresses were constant in his tests, feels forced to abandon this idea and attempts to explain his results in terms of a limiting value of stress at the sheath, namely the minimum value. An analysis of his test results, however, does not seem to justify him inasmuch as, although his minimum stresses were much more constant than the maximum stresses, they were by no means constant, and in fact, it could be claimed with almost equal justice that his test results vindicated the average stress theory.*

Since, however, Fernie's experimental minimum stresses present a certain degree of constancy, this phenomenon (which remains to be proved) is investigated further. It is shown that if it be assumed (1) that the inner layers of insulation may be overstressed without complete rupture of the cable due to the stable equilibrium of the remainder of the insulation, and (2) that insulating materials have a critical breakdown gradient, a direct result of these two hypotheses is that the minimum stress at breakdown is a constant, though it is not in itself the criterion.

It may be concluded therefore, that Fernie's experimental data are not sufficient to justify his claim that the minimum stress is a constant, and that if later tests should prove the constancy of minimum stress, this phenomenon could be explained otherwise than by assuming that the minimum stress itself is the limit.

CONTENTS

A KNOWLEDGE of the relation between the breakdown strength of cables and the size of conductor and insulation thickness is very important, if cables are to be rationally and economically designed. For instance, in a series of single-conductor cables all of the same insulation thickness, varying from small conductors to large conductors, will all these cables break down at the same voltage, or will those with small conductors break down at the highest voltage, or the lowest voltage? This fundamental question has not been adequately and convincingly answered even for the simplest case of all, the case of single-conductor cables. It is probable that it will never be possible to determine exactly the breakdown strength of a particular cable, due to the inherent lack of uniformity of insulating materials, but if a general law could be discovered, obtained by averaging the results of a great many samples, it would at least be possible to design cables with the same factor of safety. Any such law would also of course have to take into consideration the effect of time. A great many theories have been proposed, some of them quite conflicting, but there is a surprising lack of published experimental data on the subject. It has been claimed that the maximum stress in the insulation is the limit, that the average stress is the limit, as well as other intermediate theories. There has recently been proposed a radically different explanation. This theory is one offered by Fernie, who claims that the *minimum* stress or the stress at the sheath is the limit in the breakdown strength of single conductor cables[1]. Inasmuch as his theory is based on a greater amount of data than hitherto published and in view of the considerable

Presented at the A. I. E. E. Annual Convention, Niagara Falls, Ontario, June 26-30, 1922.

1. Fernie, "Insulating Materials," *Beama*, page 244, 1920.

interest evinced in this country in his conclusion, a discussion of his data and theory finds a proper place in this symposium. It is the purpose of the present article to discuss Fernie's data and to suggest a different explanation of his experimental results, and show that it is quite possible that the minimum stress may be constant and yet not in itself be the limit in the breakdown strength of cables.

For our purpose it will be assumed that insulating materials have a specific breakdown strength, which could be determined by puncture tests between parallel plate electrodes, inasmuch as in this case the stresses would be uniform throughout the insulation. Due to limits of space, no further discussion will be made of the many qualifications which should be made of this statement.

If an insulating material is contained between concentric cylindrical electrodes, such as the case of single-conductor cables, the stress, or gradient (or voltage per unit thickness) is by no means constant, but is a maximum at the conductor surface and a minimum at the sheath, and these two may be calculated by the following formulas:

$$G_{max} = \frac{E}{r \log_e R/r} \qquad (1)$$

$$G_{min} = \frac{E}{R \log_e R/r} \qquad (2)$$

where E is the voltage between the conductor and the sheath, R is the radius over the insulation, and r is the radius of the conductor.

One of the first theories of the breakdown strength of cables was that since every insulating material has a critical breakdown strength, which we may call G_0, as determined by the breakdown of layers of insulation between parallel plate electrodes, a single-conductor cable will break down as soon as this critical stress is exceeded in the insulation, which means that breakdown should occur when the maximum stress at the surface of the conductor is equal to the critical stress G_0. According to this maximum stress theory, if a series of cables of different dimensions and the same insulating material should be broken down, the calculated maximum stresses of all the cables at the breakdown voltage should be a constant and equal to the critical stress G_0. This would mean that for cables of a given insulation thickness, the larger the conductor, the higher would be the breakdown voltage.

The maximum stress theory of the breakdown strength of cable ignores one fundamental and well-known characteristic of the stresses in single-conductor cables, which may be briefly stated as follows. *For cables of a given outside diameter and given impressed voltage, the minimum value of the maximum stress at the surface of the conductor will exist when R/r equals ϵ, the base of the natural system of logarithms, or 2.72.* This characteristic may have an important bearing on the theory of the breakdown strength of cables. If a cable is of such proportions that R/r is greater than 2.72 and a high voltage is applied such that the inner layers of insulation tend to break down, this would result in virtually increasing the size of conductor, which would *diminish* the maximum stress in the insulation. The stresses in the remainder of the insulation would all be increased, but the maximum stress would be less than the maximum existing before the inner layers punctured, ane would therefore be less than the critical value. On the other hand, if R/r is equal to or less than 2.72, any puncturing of the inner layers of insulation will tend to *increase* the maximum stress. Cables may therefore be divided into two classes, which we shall call Class 1 in which R/r is greater than 2.72, and Class 2 in which R/r is equal to or less than 2.72. Russell[2] and Osborne[3] have developed different theories on the breakdown strength of cables, which take this feature into consideration, and which are well worth further study. Osborne takes issue with Russell's theory, but neither one publishes very much experimental data to prove his point. According to neither of these theories would the maximum stress or the minimum stress be constant at breakdown as calculated from the cable dimensions and the breakdown voltage.

Fernie's Theory

Fernie, as stated before, has advanced a new theory. He performed a series of breakdown tests on cables of different sizes of conductor and insulation thicknesses, and has published his results, these results being probably the most complete experimental data on this subject on record. He states that it seems a very plausible theory that an insulating material should have a critical breakdown strength, and that therefore the cable should break down as soon as this value is exceeded in the cable insulation. If the maximum stress theory is true, the calulated maximum stresses at breakdown for the cables of a given insulating material should be constant. His results show that the maximum stresses are far from constant, varying in fact by over 200 per cent in one series, but he makes the remarkable statement that his minimum stresses were very closely constant. Based on his experimental data, he proposes that the minimum stress is itself the limit, and advances an interesting explanation of why this should be so, which explanation does not take the specific breakdown gradient into consideration.

Fernie's Data

The comment has been made that Fernie's data are quite extensive, and it may be added that they are considerably more consistent than most of the data which have been published on this subject. It is by no means, however, intended to imply that they are

2. "Dielectric Strength of Insulating Materials and the Grading of Cables," A. Russell, *Journal I. E. E.*, Vol. 40, page 6, 1907.
3. "Potential Stresses in Dielectrics," H. S. Osborne, Transaction, A. I. E. E., 1910, page 1553.

sufficiently consistent to form in itself the basis of a new theory or to disprove some of the older theories. It is desired to discuss this phase of the matter briefly, and Fernie's experimental data are therefore shown in the following two tables. Table I refers to the data of his Table II, and Table II corresponds to the data of his Table III. R is the radius of the insulation, r is the conductor radius, and t is the insulation thickness.

TABLE I.

Certain types of experiment lead to quite definite results which can be repeated at will. Tests on the breakdown strength of insulating materials are of a very different kind, and very great discrepancies usually occur between tests on supposedly similar samples, or even on different samples of the same piece of insulation. It is therefore necessary in breakdown tests to perform an enormous number of tests in order to average out the irregularities. Fernie's experimental data are based on the average of a great many tests, but even this does not mean that the number was sufficient to establish a law. Probably the main cause of the difficulty in breakdown tests is the inherent lack of uniformity of insulating materials. Due to the essential difficulty of the problem, any set of experimental data must be examined very critically and consideration must be given not only to whether or not the data would tend to disprove one theory and prove another, but also to see if there are not other theories which might also apply with about the same amount of deviation from the observed results. It will be seen in Tables I and II that though Fernie's calculated minimum stresses present a certain constancy, they are by no means rigidly constant. Fernie makes no mention of either Russell's or Osborne's theories, nor of the average stress theory, and apparently had in mind only the maximum stress theory. The departures from constancy of his calculated maximum stresses are so much greater than those of his minimum stresses that he apparently felt justified in calling the latter constant. If those were the only alternatives, his results would probably be sufficient to establish his claim. In fact, it may be stated that his results give fairly strong evidence to disprove the maximum stress theory. The question, however, still remains as to whether or not his results are definite enough to establish a constant minimum stress theory as opposed to some of the other theories. In Tables I and II, are shown the calculated maximum, minimum (with some minor errors in his calculations corrected), and average stresses at the moment of breakdown, and also the maximum plus and minus, and average deviations from the average. It can be seen immediately that the deviations from constancy of his minimum stresses are only slightly less than those of the average stresses, and that in Table II, even the maximum stresses are not much less constant than the minimum stresses. It is believed therefore that Fernie's claim for constancy of minimum stress at breakdown is not justified by his own data, and, to epitomize, it could be claimed with almost equal justice that Fernie's data prove the constant average stress theory and also Osborne's theory. If considerable emphasis is placed upon the points obtained from the cables with small sizes of conductor given in Table I, Fernie's data give fairly strong evidence against the maximum stress theory, and would indicate that Russell's theory is not adequate, though the evidence is less pronounced in the latter case.

Even though Fernie's test results do not seem to be consistent enough to definitely claim that the minimum stress is constant and that the other theories are wrong, still it must be admitted that the deviations of minimum stress are somewhat smaller than the other deviations, and it is therefore worth while to consider his results further and see what conclusions could be drawn if a series of tests should definitely prove the minimum stress to be constant. The cables which would show the greatest difference in breakdown strength according to the different theories are those for the larger and smaller values of the ratio R/r, Fernie's entire range for this ratio is only from about 2.1 to 4.7. It seems unfortunate, therefore, that he did not use greater extremes in the dimensions of his cables in his tests, in spite of certain difficulties, since cables with large values of the ratio would so clearly differentiate between certain of the theories, and cables with small values of the ratio are more in accord with everyday practise.

Overstressed Insulation

The maximum stress theory assumes that the cable will puncture as soon as the critical stress is exceeded in any part of the insulation. Russell's theory assumes that no part of the insulation can sustain more than the critical stress, and that as soon as this value is exceeded, the insulation will break down and become

equivalent to a conductor; whether or not the entire cable will breakdown depends on the dimensions of the cable. The other theories of the breakdown strength of cables assume the possibility in some form or other of overstressed insulation. The constant average stress theory does so implicitly. Osborne's theory is based upon the conception that the critical stress may be surpassed in the insulation, but that this will lead to breakdown in certain weak points resulting in minute needle-like punctures extending outward from the conductor, which thereby relieves the stress in the remainder of this region of the insulation throughout which the stress will be constant and equal to the critical value.

The possibility of the existence of overstressed insulation is not a new thought. For instance we might quote Whitehead[4] as follows:

> There is no difficulty in the idea of a strain of dielectric material beyond the electrical elastic limit with no resulting structural breakdown and resulting conductivity. In a single-conductor cable, we may think of a string of molecules stretched radially along a line of electric force. When the interior portion of the insulation is overstressed, but the insulation as a whole unbroken, we may think of the component charges of a molecule in the stressed region as drawn apart, and a tendency on the part of opposite charges of two adjacent molecules to combine. If this tendency could take place along the whole line of force there would be combination throughout and resulting discharge. The phenomenon would then be similar to conduction in a metal. In the case as supposed, however, the outer portions of the insulation are not overstressed, consequently proceeding outward from the conductor along the line of force there comes a region where there is a molecule which is not overstressed, which therefore successfully resists the tendency of one of its charges to pass to the adjacent overstressed molecule. This restraining influence is therefore propagated backward toward the center and serves to keep the overstressed portion from breaking down entirely. In this way the region of safe stress may be said to aid that in which this stress is exceeded.

According to Whitehead's conception a certain critical value of stress is required to draw apart the component charges of a molcule. It seems reasonable to assume therefore, that this critical value of stress will be all that would be required in the inner layers in order to hold the charges in this physical condition. This would mean that the stress in the overstressed region of the insulation would be a constant and equal to the critical stress, and that the overstressed region of insulation would not maintain its proportional share of the voltage, but would consume only a sufficient amount of the total voltage to hold the entire overstressed region at the critical value of stress. This would lead to a theory of the breakdown strength of cables mathematically equivalent to Osborne's theory though physically different. It is interesting to note that there is no critical point, or critical radius such as occurs in Russell's theory. That is, if a certain amount of the inner layers of insulation which would tend to be overstressed are held at constant value of stress equal to the critical value, any tendency to puncture the layer of insulation immediately adjacent to the outer layer of overstressed insulation would result in diminishing the stress in the succeeding layers to a value below the critical value. In other words, the equilibrium is stable, and there is no tendency for complete breakdown of the cable according to this theory until the voltage is raised to such a point that *all* the insulation is subjected to the constant stress equal to the critical value. According to this theory, then, if a series of cables is broken down, the *average stress* in the insulation as calculated from the cable dimensions would be a constant equal to the critical breakdown strength of the insulation. This discussion, therefore, is merely an interpretation of the average stress theory, and it might be repeated that Fernie's data could with almost equal justice be claimed to prove either the constant minimum stress theory or the constant average stress theory. This conception of the conditions in the insulation does not however lead to a constant minimum stress at breakdown, which must therefore be sought on other hypotheses.

4. Whitehead, J. B., Discussion, TRANSACTIONS A. I. E. E., 1910, page 1582.

PROPOSED EXPLANATION OF THE MINIMUM STRESS THEORY

A given set of experimental data may often be explained by entirely different physical theories. It is hard to believe that the critical breakdown strength of a cable as determined by parallel plates is not in some way the limiting feature, and Fernie's explanation does not seem to be very convincing. It is desired to show here, that, if it is a fact that the minimum stress at breakdown is a constant, this may be explained rationally in terms of the critical breakdown strength of the insulation combined with the conception of overstressed insulation, as well as by Fernie's theory, based on the "skin resistance" hypothesis, though the latter may of course have to be considered also.

To do this, it it will be assumed first that overstressed insulation may exist if the *remainder* of the insulation is in stable equilibrium, and secondly, that the overstressed insulation can support its proportional share of the voltage; in other words, that the distribution of potential throughout the cable will not be affected by the fact that certain inner layers are stressed above the critical value. The case of a cable of Class 1 (R/r greater than 2.72) will be considered. Let us imagine that the voltage on the cable is raised until the critical gradient is reached across the layer of insulation next to the conductor surface. If this layer should break down, the result would be a virtual increase in the size of conductor diameter, which would mean that the stress on the next layer of insulation, though increased above its previous value, would still be less than the critical value. The equilibrium of the cable as a whole may therefore be considered stable, and according to this theory, it is assumed that the breakdown does *not* take place in the inner layer due

to the stable equilibrium of the whole cable. This is the distinction between this theory and Russell's theory. Russell assumes that actual breakdown and carbonization of overstressed layers take place. Here it is assumed that no action takes place but that the layers are overstressed due to the equilibrium of the whole system. Let us assume that the voltage is raised still higher. The inner layers of insulation will be stressed above the critical value, the maximum of course being at the conductor surface, and the critical stress will exist at a certain distance, x, from the center of the conductor. Having assumed the possibility of overstressed insulation, our attention must be directed upon the equilibrium of the remainder of the insulation, in other words between the region of radius x, where the critical stress G_0 exists, and the lead sheath. If R/x is greater than 2.72, any tendency for the critical gradient to puncture the layer at x would result in a stress upon the next layer which would be less than the critical gradient, and, as before, the equilibrium will be stable. On the other hand, if R/x is equal to or greater than 2.72, puncturing of the layer at which the critical gradient G_0 exists, would result in a stress upon the next layer higher than the critical value and we may consider the equilibrium as unstable. There is therefore apparently a critical point in the insulation, whose radius we shall call r' such that r' is equal to $R/2.72$. According to this theory, therefore, for cables of Class 1, as the voltage is raised continuously, the critical stress will first appear at the conductor surface and will then travel outward toward the sheath, all layers within this region being overstressed, the equilibrium of the cable as a whole being stable until the critical gradient reaches the raduis r', at which point it is assumed that breakdown will take place.

For cables of Class 2, in which R/r is equal to or less than 2.72, r' has no significance, and the cable would be in unstable equilibrium as soon as the critical gradient reaches the conductor surface. It would be expected, therefore, that breakdown would take place as soon as the critical gradient reaches the conductor surface, or in other words, the maximum stress theory would be applied to cables of Class 2, exactly as Russell did for cables of this class.

The results of this theory may now be examined mathematically. Let E' be the voltage between r' and R at the moment of breakdown. By formula (1) we may immediately express E' as follows:

$$E' = G_0\, r' \log_e R/r' \qquad (3)$$

and remembering that the natural logarithm of 2.72 is equal to unity and that r' equals $R/2.72$, we may state

$$E' = 0.368\, G_0\, R \qquad (4)$$

We may now solve for E, namely the actual breakdown voltage of the cable, inasmuch as the ratio of E to E' will be in inverse proportion to the relative capacities of the two sections. Therefore

$$E = \frac{\log R/r}{\log R/r'} \times E' = 0.368\, G_0\, R \log R/r \qquad (5)$$

The above equation gives the expression for the breakdown voltage of a cable in terms of critical stress and the dimensions of the cable according to the present suggested explanation.

The maximum stress at the moment of breakdown may now be obtained by substituting this value of E in equation (1) and we find that at the moment of breakdown

$$G_{max} = 0.368\, G_0 \times R/r \qquad (6)$$

The minimum stress at the moment of breakdown may also be obtained by substituting the value of E in equation (2) and we find that

$$G_{min} = 0.368\, G_0, \textit{ a constant} \qquad (7)$$

It will therefore be seen that a direct result of this theory is that for cables in which R/r is greater than 2.72, the minimum stress at breakdown will be a constant, as calculated from the actual cable dimensions and the breakdown voltage, and that this theory, based on the rational conception of a critical stress, will adequately explain Fernie's claim that the minimum stress is constant at breakdown.

It is desired to point out that for the case of cables of Class 1 there is a distinct difference between this suggested theory and Fernie's theory, in spite of the fact that according to both, the minimum stress will be constant. According to this theory, the cable punctures when the critical stress reaches the region whose radius is r', and a direct incidental result of this is that the minimum stress is constant. The critical stress G_0 at r' is in itself the limit, and not the minimum stress at the sheath. While these two theories are the same for cables of uniform dielectrics, they would lead to entirely different results in cables where different layers of insulation have different permittivities, such as in the case of graded cables. Only experimentation can determine which of these theories, if either, is correct. One test performed by Fernie throws some light on this point, inasmuch as he broke down two samples of cable, one uniform and one graded, and the results would tend to confirm his theory rather than the present one, and this test must therefore be taken into consideration. On the other hand, there is no indication that he broke down more than one sample of each type, which in itself would greatly discount the results of this one test.

While the theory outlined above explains the constancy of minimum stress for cables of Class 1 in terms of the critical gradient, it appears to be a rather difficult conception in one point at least, namely in the stability of the equilibrium of cables of Class 1 for values of the voltage intermediate between that given by equation (5) and the breakdown voltage according to Russell's theory. The present conception assumes the possibility of overstressed insulation and in determining the stability of the system places attention upon the

understressed outer portions of the insulation, ignoring the inner, overstressed section. If investigation should be made as to what would happen to the cable as a whole, if the overstressed layers should give way, which seems a perfectly reasonable method of approach, it will be found that if the impressed voltage is higher than the breakdown voltage according to Russell's theory, and the overstressed layers should puncture, the stress at r' will be greater than the critical value, and the whole system would be in unstable equilibrium. If the applied voltage is less than Russell's breakdown voltage, the equilibrium will still be stable, and in fact, this method of approach would lead directly to Russell's theory, and would not lead to a constant minimum stress at breakdown as calculated from the cable dimensions. This would mean that there would be no distinction between Class 1 and Class 2 cables for a voltage higher than Russell's breakdown voltage, which leads to a difficulty, inasmuch as Fernie's data for the small sizes of conductor as shown in Table I give fairly strong evidence that the breakdown of these cables is higher than would be obtained according to Russell's theory. To explain this, it might be assumed that overstressed insulation (bearing its full share of the voltage) is possible and that breakdown will not take place until the critical stress reaches the sheath. This conception would lead to a constant minimum stress at breakdown for all classes of cable, the minimum stress being equal to the critical value. The difficulty is that conditions in Class 2 cables seem so essentially unstable as soon as the critical stress exists in the insulation that it is a little difficult to conceive of breakdown not taking place until the critical stress reaches the sheath. Also, this theory, as stated above, would mean that the minimum stress is equal to the critical stress, and Fernie's values of minimum stress seem too low for the critical stress of impregnated paper insulation. It does not seem necessary to adopt either of these theories, Fernie's theory, or possibly an entirely different theory, until definite experimental proof is obtained that the minimum stress at breakdown is constant.

Effect of Time

Up to the present, no mention has been made of the effect of time on breakdown voltage. This is a matter of the greatest importance, and it is believed that whatever law may be determined for the instantaneous breakdown strength of cables, the law would be quite different for cables in which the voltage is raised very slowly, for cables under long time test, or for cables in service. For instance, the present theory which involves the conception of overstressed insulation could not possibly hold in a cable of high dielectric loss under long time test, inasmuch as the heating of the overstressed layers would greatly change conditions, and would undoubtedly lead to breakdown in some cases from other causes. Quite aside, however, from the matter of the general heating of the cables due to dielectric losses, it is conceivable, and indeed probable, that there is a gradual deterioration of insulation which is overstressed, so that the limitation of working voltage of a single-conductor cable may well be the stress at or near the conductor surface, whereas the limitation of the voltage which may be sustained for short-time tests may be dependent upon some other function, such as the average stress, or even the minimum stress as suggested by Fernie.

Conclusions

It may be concluded that Fernie's data are not sufficient in themselves to justify his claim that the minimum stress is a constant at breakdown. The deviations of the minimum stresses from constancy are practically no greater than the deviations of average stress. There is, however, an indication that for the conditions of the tests and primarily their duration, the maximum stress theory is incorrect, though the data are inadequate to form the basis of a definite conclusion.

It may also be concluded that if a set of experiments should definitely indicate the constancy of minimum stress, even this would not mean that the minimum stress, or the stress at the sheath, is in itself the limit. The constancy of minimum stress may be explained in terms of the critical breakdown gradient of the insulation, together with the conception of overstressed insulation, and undoubtedly there are other methods of explanation.

The great present need in this problem seems to be experimental data. No attempt is made herein to go beyond experimental data which have already been published. The theory outlined herein is intended merely to show that Fernie's claim that the minimum stress is a constant is susceptible of another explanation, and no claim is of course made that the present theory is correct, because an essential of the theory is the constancy of the minimum stress for cables of Class 1, and this is not proved by the data published.

Discussion

For discussion on this paper see page 611.

Effects of the Composite Structure of Impregnated Paper Insulation on its Electric Properties

BY WM. A. DEL MAR and C. F. HANSON
Fellow, A. I. E. E. Member, A. I. E. E.
Chief Engineer Director of Research
Habirshaw Electric Cable Company, Yonkers, N. Y.

The effect of composite structure upon the electric properties of dielectrics has been observed and theorized upon by various people, as mentioned in the Introduction. The present paper attempts to show a quantitative expression of power-factor and dielectric loss in terms of the resistivities and specific capacities of the elements of the insulation. It also shows the electrical function of the paper in impregnated paper insulation, and cites experiments which indicate that the electric failure of such insulation is due to ionic motion in the oil; the obvious deduction being that the voltage rating of cables should depend upon the degree to which ionic motion in the oil can be restrained.

CABLE dielectrics are composed of mixtures of various substances in which organic substances play the most important role.

Impregnated paper insulation consists principally of fibers of cellulose, surrounded by and filled with mineral oil. Rubber insulation consists of vulcanized rubber, hydrocarbons and various mineral substances. Varnished cambric insulation consists of cellulose fibers, air, oxidized oils and hydrocarbons. All of these components differ from one another in resistivity, specific capacity, and thermal characteristics and their juxtaposition leads to effects which influence the voltage at which they lose their insulating qualities.

Dielectric Loss

It is noted in the Committee's introduction that various physicists have explained residual charge and

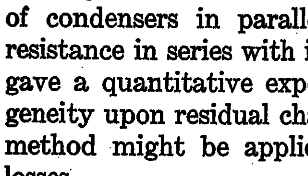

Fig. 1

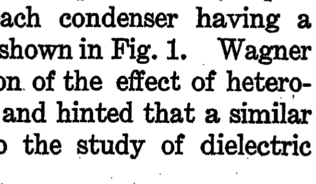

Fig. 2

associated effects on the basis of heterogeneity of the dielectric and that Fleming and Dyke suggested that a heterogeneous dielectric might be represented by a pair of condensers in parallel, each condenser having a resistance in series with it as shown in Fig. 1. Wagner gave a quantitative exposition of the effect of heterogeneity upon residual charge and hinted that a similar method might be applied to the study of dielectric losses.

Addenbrooke showed that Fleming's combination of parallel condensers leads to unsatisfactory conclusions. Following the logical development of Fleming's and Wagner's conceptions, the authors have tried the combination of condensers and resistances shown in Fig. 2.

If a leaky condenser, represented diagrammatically by C_1 and R_1 in Fig. 2 be placed in series with a resistance R_2 and an alternating potential impressed across the combination, the reactive as well as the active component of the current will, of course, be carried through the resistance R_2 and will cause a loss of energy therein. If the resistance R_2 be shunted by a condenser of capacity C_2 some of the current will be carried by that capacity (without energy loss) thereby reducing the energy loss in the resistance R_2. If the capacity C_2 be increased, a condition will be attained where the entire reactive component will be carried by the two condensers in series, and the active component by the resistances in series, no current then circulating across the connection. When the capacities and resistances are so proportioned, the energy loss in the combination will be a minimum for a given total resistance.

Some years ago, the authors noted a correspondence between residual charges and dielectric loss, those insulations having high residual charge invariably showing high dielectric loss. This afforded a confirmation of Wagner's suggestion and a theoretical analysis was made of the energy losses in a circuit consisting of two leaky condensers in series, for which see Appendix I.

The net result of this analysis was the following equation for the power factor of impregnated paper insulation. (See Appendix II)

$$\cos\theta = \frac{\dfrac{\rho_1}{a_1+1} + \dfrac{\rho_2}{a_2+1}}{\sqrt{\dfrac{\rho_1^2}{a_1+1} + \dfrac{\rho_2^2}{a_2+1} + \dfrac{2\,\rho_1\,\rho_2\,[1+\sqrt{a_1\,a_2}]}{(a_1+1)\,(a_2+1)}}}$$

Where ρ_1 = resistivity of impregnating compound ohm - cm.
ρ_2 = resistivity of cellulose fibres, ohm - cm.
K_1 = specific capacity of impregnating compound
K_2 = specific capacity of cellulose fibers
f = frequency of alternating e. m. f.

$$a_1 = \left(\frac{\rho_1\,K_1\,f}{18\times 10^{11}}\right)^2$$

$$a_2 = \left(\frac{\rho_2\,K_2\,f}{18\times 10^{11}}\right)^2$$

The specific capacity of petrolatum, the type of mineral oil generally used for this purpose, is about

Presented at the A. I. E. E. Annual Convention, Niagara Falls, Ontario, June 26-30, 1922.

two and that of cellulose fibers about four, values which do not vary greatly with the grade or temperature. The resistivities of both substances vary enormously with the temperature, and in the case of petrolatum, to a considerable extent with the chemical composition. It is therefore of interest to see how the power factor varies with the resistivity of the petrolatum at a given temperature, say 85 deg. cent. assuming the other quantities to remain constant.

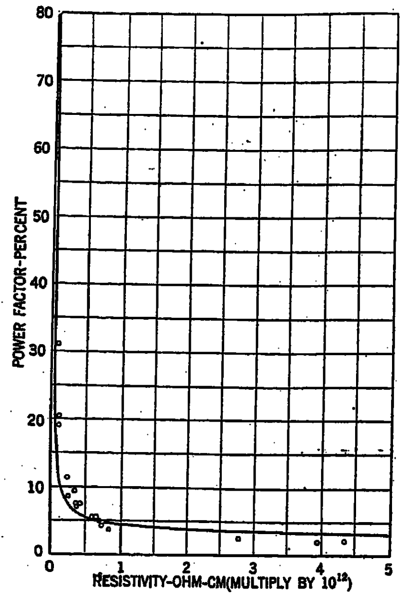

Fig. 3

Experimental data, represented by small circles, compared with theoretical curve.

Unfortunately a practical difficulty stood in the way —the determination of the resistivity of cellulose. The resistivity desired is not that of paper, nor even of paper fibers, but of the walls of the fibers. The fibers are about 7 mm. long and 0.02 mm. in diameter and they have a variable wall thickness of the order of 0.005 mm. It seemed almost impossible to make resistivity measurements upon such small specimens. Another difficulty was that the resistivity derived from measurement depends upon the time of electrification. As the research was primarily industrial, rather than purely scientific, it was decided to assume the equation to be correct, deduce the resistivity of the cellulose therefrom by tests based upon known values of specific capacity and oil resistivity. This was done for a one-minute electrification and at a temperature of 85 deg. cent. The resistivity of the cellulose at that temperature was found to be 0.07×10^{12} ohm-cm., a value consistent with tests by A. Campbell on other forms of cellulose.

Assuming this value, the power factor of the insulation was calculated for other oil resistivities. A graph of this relation is shown in Fig. 3.

Experiments were made both upon flat samples and upon cables and the results are shown by the circle-enclosed dots in Fig. 3. It will be observed that the experiments confirm the theory fairly well over a range of power factors from 2 per cent to 80 per cent.

This theory is not offered as a complete explanation of dielectric loss, but merely as an approximate working theory to guide designers. The phenomenon is undoubtedly far too complicated to be covered by any simple formula and a great deal of research work will be required before a complete explanation can be offered.

According to the above theory, the power factor should be inversely as the frequency when ρ_1 and ρ_2 are so great as to make the leakage current negligible. It should be independent of the frequency when ρ_1 and ρ_2 are so small as to virtually short circuit the capacities. For intermediate values, the power factor should decrease with increasing frequency according to the equation. The authors have not yet had an opportunity to make experimental checks of the effect of frequency.

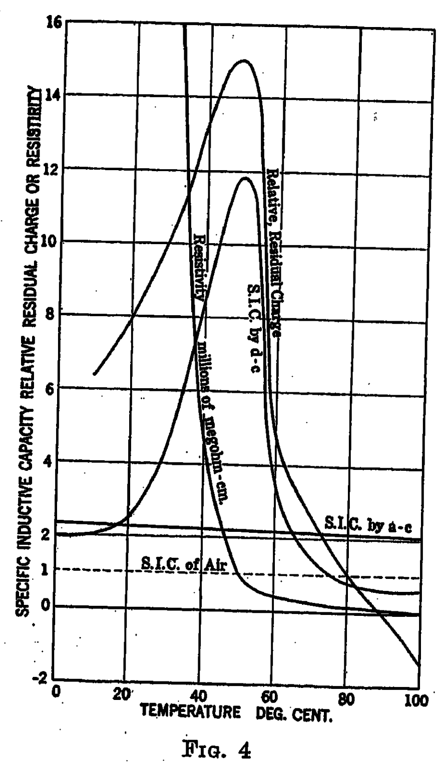

Fig. 4

The same general reasoning might be applied, although with greater difficulties, to the evaluation of dielectric loss in rubber compounds and varnished cambric insulation. It must be remembered, however, in applying the theory, it is assumed that no moisture is present, as a very small proportion will have a greater effect than even a fairly large reduction in the resistivity of one of the essential constituents. It is greatly to the credit of those concerned with manufacture that it is possible to obtain cables in which the moisture content is entirely negligible.

As dielectric loss in a well dried, well impregnated paper cable depends principally upon the conductivity of the oil, the loss must occur principally in the oil.

The work of Pungs, cited in the introduction to this symposium tends to show that conduction in oil is due to ionic travel rather than to mere ionic displacement. According to this theory, which is confirmed by tests cited below, a high-loss cable, *i. e.* one in which the "a-c. conductivity" is high, is liable to have the ions in its oil set into unduly rapid motion, a condition favorable to electric failure.

Evidences of Free Ions

The test of any theory lies in its ability to explain phenomena. The test is especially satisfactory if a simple theory is found to explain a complicated series of phenomena. Regarded in this light, the theory that petrolatum normally contains free ions of both polarities is very satisfactory. The theory was effectively used by L. Malclès to explain the phenomena which occur when a petrolatum condenser is charged and discharged, using an electrometer to measure the charges. He showed that the behavior of such a condenser depends upon the viscosity of the petrolatum which, in turn, depends upon its temperature, and he explained this on the basis that the mobility of the ions is an inverse function of the viscosity.

Tests of capacity were made both by the d-c. and the a-c. methods, readings being taken over a range of temperature from 0 deg. to 100 deg. cent. and on a great number of specimens. The d-c. tests were made with a ballistic galvanometer, the petrolatum being in a cell, details of which are given in Appendix III. An example of the results is shown in Fig. 4 which gives the characteristics of a rather poor grade of petrolatum chosen for purposes of illustration because of the exaggerated degree to which it shows the phenomena under consideration.

Consider first the curve of apparent specific capacity, as measured by direct current.

When the condenser is charged, the negative ions are drawn toward the positive electrode and the positive ions, toward the negative electrode. When the condenser is discharged the ions diffuse from the electrodes, and redistribute themselves at random throughout the petrolatum at a rate depending on its fluidity. The current resulting from this ionic diffusion may or may not add itself to the true discharge current for the following reason: An appreciable interval of time elapses, in testing, between the end of the charge and the beginning of the discharge through the galvanometer circuit and the diffusion of the ions may occur in this interval. In this case the diffusion current would not be observable and the apparent capacity would equal the true capacity. This was found to occur at about 75 deg. cent.

With lower temperatures, the petrolatum being more viscous, the diffusion of ions is slower, until at a certain temperature it should last through the interval between the end of the charge and the beginning of the discharge. At lower temperatures, it should last longer, but should be weaker. Hence, at a certain temperature, the diffusion of ions should occur at such a speed as to make the apparent capacity a maximum. This temperature was found to be in the vicinity of the melting point, 50 deg. cent. In the case recorded in Fig. 4, the apparent capacity as measured with direct current, is about seven times the capacity as measured with alternating current. At yet lower temperatures the ionic diffusion is so slow, due to the viscosity of the petrolatum, that it should have little effect upon the apparent capacity. This condition was found at temperatures below 20 deg. cent.

If the petrolatum is sufficiently viscous the ionic diffusion which follows a discharge may continue long after the completion of the capacity test, and, if the condenser plates are kept insulated from one another, this redistribution of ions will result in residual charges on the plates. The residual charge one minute after the initial discharge was measured and the value at 80 deg. cent. arbitrarily taken as unity in order to show the relative values at different temperatures. These values are plotted in Fig. 4, and show that the residual charge reaches a maximum at a temperature slightly below the melting point. This would be expected from the theory of ionic diffusion because the residual charge should be most evident when the petrolatum is soft enough to permit diffusion but not so fluid as to allow this diffusion to be complete before the minute interval has elapsed.

Thus far we have considered only ions of molecular dimensions. Electrons will behave differently by virtue of their ability to travel through conductors. Electrons will be attracted to the positive electrode, but unlike the ions of molecular dimensions will not remain in the petrolatum. They will be drawn into the electrode and charging circuit and a corresponding number will appear on the negative electrode.

If the charging potential be removed, the electrons will diffuse through the petrolatum. If the electrodes be connected through a galvanometer, the moving electrons will set the electrons in the circuit moving in opposite direction to the discharge current, thereby reducing the apparent capacity and on later discharge, making the residual charge appear to be negative. These effects predominate only at such temperatures as correspond with very low viscosity, when the diffusion of molecular ions is so rapid as to produce no appreciable effect upon capacity measurements. In Fig. 4 this begins to occur at about 90 deg. cent.

The ionization theory of the residual charge of petrolatum does not explain the entire residual charge in a cable, this being due largely to the juxtaposition of the particles of oil and cellulose at whose surfaces charges are induced by virtue of their different specific capacities.

Function of Paper in Impregnated Paper Cables

An experiment was made to ascertain the effect upon the dielectric strength of petrolatum, of interposing various numbers of sheets of paper between

testing electrodes. The experiment was made in an oil-testing cup having flat surfaced cylindrical electrodes ½ in. in diameter. The results are plotted as Curve A in Fig. 5, which shows clearly that in spite of the fact that after inserting the paper the oil was more highly stressed, due to the introduction of a dielectric of higher specific capacity, its dielectric strength increased as it was divided into thinner laminas by the introduction of more sheets of paper.

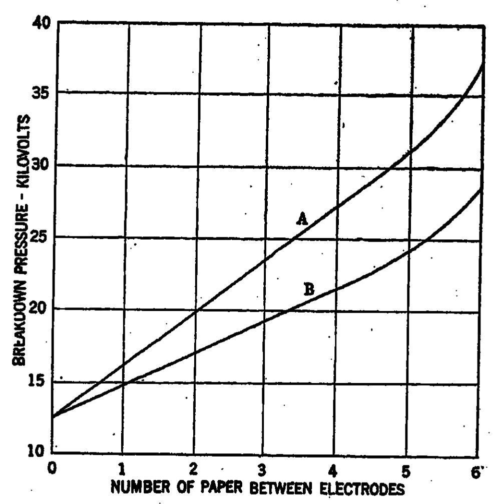

Fig. 5

If the paper be severely creased, and the crease viewed under a microscope, the line of the crease will be revealed as a hedge of fibres sticking out of the surface. In a cable, such projecting fibres will not act as barriers to ions trying to get through the paper, as they are loose and lie along, not across, the path of such ions. Hence we should expect badly creased paper, or paper with loose fibers, to be a less effective baffle to the ions and therefore to be less effective than smooth, tight paper in raising the dielectric strength of oil. An experiment similar to the last described was made with the only difference that badly creased paper was used. The results are shown by Curve B Fig. 5. It will be noted that both curves show a decided upward tendency, and further experiments, with different oils and papers have shown that this upward tendency continues as the number of papers increases, but experimental difficulties with the high voltages required to breakdown a wide gap, prevented obtaining a smooth curve for a much larger number of papers. Isolated experiments, however, indicate that the ratio of the breakdown voltages for uncreased and creased papers, keeps on increasing as the number of papers is increased, until it is at least two.

An interesting experiment was made with a radio frequency generator which showed in a very simple way the effect of serious creases upon the dielectric strength of impregnated paper. A plate of metal was connected to one pole of the generator and a movable wire connected to the other pole. The latter was held above the plate at such a distance that when about 17,000 volts were applied between wire and plate luminous white streamers extended between them. A sheet of oil-impregnated paper was then laid on the metal plate, with the result that the white streamers stopped immediately. When the wire was brought a little nearer the plate, faint purple streamers spread out from the wire, and flattened out over the paper. The crease in the paper was then brought within three cm. (horizontally) of the wire, the wire being one cm. above the paper. White streamers then spread from the wire to the plate through the crease as shown in Fig. 6.

Another sheet of impregnated paper with many creases was substituted for the first sheet and the wire moved slowly at right angles to the creases. Streamers jumped from crease to crease, never puncturing the uncreased paper.

A similar experiment made with unimpregnated paper, showed that the streamers were not attracted by the creases and proved that the harmful effect of creases is due to their effect upon the insulating properties of the oil rather than upon that of the paper itself.

The conclusion to be drawn from these experiments is that the electrical breakdown of impregnated paper is due to ionic motion in the oil, which is obstructed by the paper fibers.

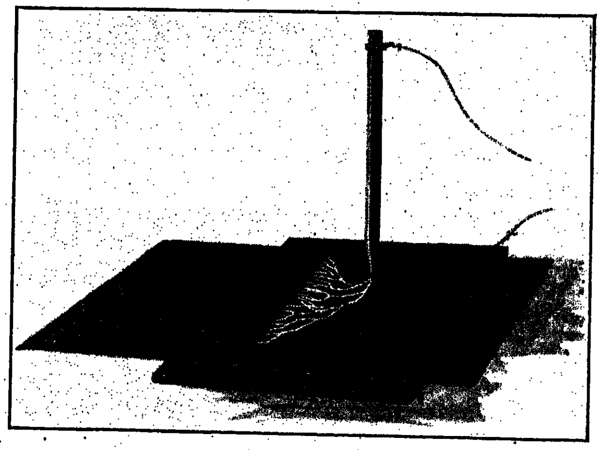

Fig. 6

Conclusions

Three sets of experiments have been cited and a theoretical explanation of each set has been given.

The first experiments indicate that when the power factor of impregnated paper insulation has been lowered as far as possible by the removal of air and moisture, there remains an element of power factor which depends upon the resistivity of the oil. This element is far too great to be explained on the basis of leakage current but may be explained as due to current which passes inductively through the capacity of the cellulose fibers and conductively through the oil.

The second experiments indicate that the oil used in impregnated paper insulation normally contains free ions in considerable quantities.

The third experiments indicate that the failure of impregnated paper insulation may be due to the establishment of streams of ions in the oil.

It would be logical to deduce from these considerations that in designing and using high-voltage cables particular care should be taken to impose every possible restraint upon ionic motion in the oil.

The practical means of accomplishing this are as follows, it being assumed that manufacturing processes will eliminate all air, vapor, and moisture:

1st. Use paper of a quality and thickness that will have the maximum baffling effect.

2nd. Apply the paper so that it will exert the maximum baffling effect.

3rd. Avoid sharp bends or other severe mechanical strains in manufacturing and installing.

4th. Use oil of a quality to make the dielectric loss fairly low.

Appendix I

Theory of Energy Loss in a Pair of Leaky Condensers in Series

A pair of leaky condensers in series may be represented for purposes of calculation by a pair of perfect condensers in series, each condenser being shunted by a non-inductive resistor.

Consider a pair of perfect condensers having capacities c_1 and c_2 and a pair of resistors having resistances r_1 and r_2 arranged as in Fig. 2, and suppose a sinusoidal e. m. f. of E volts to be imposed between the terminals A and C.

Let
$$a_1 = (2\pi f r_1 c_1)^2 \quad (1)$$
$$a_2 = (2\pi f r_2 c_2)^2 \quad (2)$$

Then the cosines of the imperfection angles of the parts $A\,B$ and $B\,C$, will be as follows:

$$k_1 = \frac{1}{\sqrt{1/a_1 + 1}} \quad (3)$$

$$k_2 = \frac{1}{\sqrt{1/a_2 + 1}} \quad (4)$$

and the sines of the imperfection angles will be as follows:

$$s_1 = \frac{1}{\sqrt{a_1 + 1}} \quad (5)$$

$$s_2 = \frac{1}{\sqrt{a_2 + 1}} \quad (6)$$

Let i_1 and i_2 be the currents in r_1 and r_2 respectively and I_1 and I_2 the currents in c_1 and c_2 respectively. Then the total power loss will be:

$$W = i_1^2 r_1 + i_2^2 r_2 \quad (7)$$

Let Z_1 and Z_2 be the impedances from A to B and B to C, respectively. Then

$$Z_1 = r_1 s_1 \quad (8)$$
$$Z_2 = r_2 s_2 \quad (9)$$

and the total impedance from A to C equals

$$Z = \sqrt{(Z_1 k_1 + Z_2 k_2)^2 + (Z_1 s_1 + Z_2 s_2)^2}$$
$$= \sqrt{Z_1^2 + Z_2^2 + 2 Z_1 Z_2 (k_1 k_2 + s_1 s_2)} \quad (10)$$

Combining **8** and **9** with **10**

$$Z^2 = r_1^2 s_1^2 + r_2^2 s_2^2 + 2 r_1 r_2 s_1 s_2 (k_1 k_2 + s_1 s_2) = \frac{r_1^2}{a_1 + 1} + \frac{r_2^2}{a_2 + 1} + 2 r_1 r_2 \frac{1 + \sqrt{a_1 a_2}}{(a_1 + 1)(a_2 + 1)} \quad (11)$$

As the drop from A to B is the same in amount by either parallel path and as the drop from B to C is the same in amount by either parallel path

$$i_1 r_1 = \frac{I_1}{2\pi f c_1} \text{ or } I_1 = i_1 \sqrt{a_1} \quad (12)$$

$$i_2 r_2 = \frac{I_2}{2\pi f c_2} \text{ or } I_2 = i_2 \sqrt{a_2} \quad (13)$$

If I be the total current through the circuit

$$I = E/Z = \sqrt{I_1^2 + i_1^2} \quad (14)$$
$$I = E/Z = \sqrt{I_2^2 + i_2^2} \quad (15)$$

Combining **12** and **14**

$$E/Z = \sqrt{i_1^2 (a_1 + 1)}$$

and combining **13** and **15**

$$E/Z = \sqrt{i_2^2 (a_2 + 1)}$$

whence

$$i_1^2 = \frac{E^2}{Z^2 (a_1 + 1)} \quad (16)$$

$$i_2^2 = \frac{E^2}{Z^2 (a_2 + 1)} \quad (17)$$

Inserting the values from **16** and **17** in **7**

$$W = E^2 \frac{\dfrac{r_1}{a_1 + 1} + \dfrac{r_2}{a_2 + 1}}{Z^2} \quad (18)$$

Combining **18** with **11**

$$W = E^2 \frac{\dfrac{r_1}{a_1 + 1} + \dfrac{r_2}{a_2 + 1}}{\dfrac{r_1^2}{a_1 + 1} + \dfrac{r_2^2}{a_2 + 1} + \dfrac{2 r_1 r_2 (1 + \sqrt{a_1 a_2})}{(a_1 + 1)(a_2 + 1)}} \quad (19)$$

It is of interest to note that if $a_1 = a_2$ the above equation reduces to

$$W = \frac{E^2}{r_1 + r_2} \quad (20)$$

indicating that the loss, in this case, is the ohmic loss due to leakage current only.

The power factor $\cos\theta$ may be derived as follows:

By definition

$$\cos\theta = \frac{W}{E\,I} = \frac{W\,Z}{E^2} \tag{21}$$

Combining equations **18** and **21**

$\cos\theta =$

$$\frac{\dfrac{r_1}{a_1+1} + \dfrac{r_2}{a_2+1}}{\sqrt{\dfrac{r_1^2}{a_1+1} + \dfrac{r_2^2}{a_2+1} + \dfrac{2\,r_1\,r_2\,(1+\sqrt{a_1\,a_2})}{(a_1+1)\,(a_2+1)}}} \tag{22}$$

Appendix II

POWER FACTOR OF HETEROGENEOUS INSULATION

A non-homogeneous dielectric consists of a mixture of particles of different resistivities and specific capacities. When a potential difference is established across such a dielectric, it sets up both displacement and conduction currents. At the boundaries between particles of different resistivities and specific capacities, the current may change from a conduction to a displacement current, or vice versa, just as at the plates of a condenser, the current changes from a displacement current into a conduction current as it leaves the dielectric and enters the plates. The total $i^2\,r$ loss may therefore be due not only to the leakage current but also to local conduction currents generated in particles of the insulation by the displacement currents.

A homogeneous dielectric may be represented by a capacity shunted by a resistance. When alternating voltage is applied across such a dielectric, the only energy loss that occurs is the $i^2\,r$ loss due to that portion of the current which passes through the resistance and this is the same for direct as for alternating currents.

A non-homogeneous dielectric may be represented by two or more shunted capacities in series. In the case of a dielectric consisting of two elements, if one of these capacities is high and the shunted resistance of the other is low, most of the current will pass inductively through that capacity and conductively through that resistance causing a high ohmic loss in the latter. This loss constitutes the major part of the dielectric loss and can occur only with alternating current.

It was shown in Appendix I that the power factor of two leaky condensers in series may be represented by the following equation:

$\cos\theta =$

$$\frac{\dfrac{r_1}{a_1+1} + \dfrac{r_2}{a_2+1}}{\sqrt{\dfrac{r_1^2}{a_1+1} + \dfrac{r_2^2}{a_2+1} + \dfrac{2\,r_1\,r_2\,(1+\sqrt{a_1\,a_2})}{(a_1+1)\,(a_2+1)}}} \tag{22}$$

The quantities a_1 and a_2 in this equation each contains the product of the resistance and capacity of one of the elements of the dielectric. But this product may be expressed in terms of resistivity ρ_1 or ρ_2 and specific capacity K_1 or K_2 by the following well known relations:

$$\left\{\begin{aligned} r_1\,c_1 &= \frac{\rho_1\,K_1}{36\,\pi \times 10^{11}} \\ r_2\,c_2 &= \frac{\rho_2\,K_2}{36\,\pi \times 10^{11}} \end{aligned}\right. \tag{23}$$

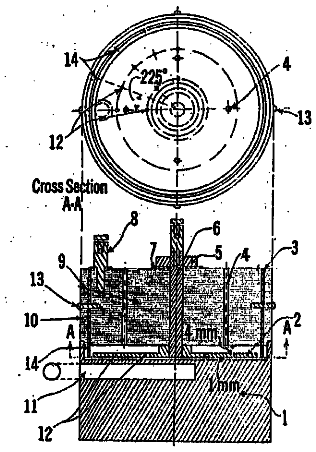

FIG. 7—ELECTROLYTIC CELL FOR LIQUID INSULATION

No	No Req.	Material	Description
1	1	Brass	Bowl 9.4 cm. in diameter with lip 9 mm. high & 2 mm. in thickness (see 11)
2	1	"	Circular plate 8 cm. dia. 2 mm. thick with collar 1.6 cm. dia. 4 mm. thick (see 12)
3	1	"	Cylinder 8.4 cm. inner dia. 1 mm. thick., axial length = 4 cm., with flap for binding post.
4	4	—	Holes bored through "9" parallel with axis, at radial distance of 5 cm. 2 mm. dia.
5	1	Brass	Nut to same thread as "6"
6	1	Steel	Pin 6 mm. dia. 5.2 cm. long threaded upper end to fit "5" & drilled & tapped to take "8"
7	1	Brass	Washer 3.5 cm. dia., center hole 6 mm. dia. 1 mm. thick.
8	2	"	Binding posts 1.25 cm. long & 6 mm. dia. (wire hole 2.5 mm. dia.)
9	1	Insul. Material	Circular block, axial length 3.8 cm. 8.4 cm. dia. (see 4)
10	1	"	Ring. axial length 4 cm. & 4 mm. thick with flange cut out bottom end 3 mm. deep to fit "1"
11	1	—	Thermometer hole bored 5.8 cm. deep & 8 mm. dia.
12	8	—	Holes bored through "2". 1 mm. dia. at radial distance of 1.5 cm. from center
"	16	—	Holes bored through "2". 1 mm. dia. at radial distance of 3 cm.
13	4	Brass	Screws. 1 cm. long
14	16	—	Vent holes. 1 mm. dia.

Inserting these values in equations (1) and (2):

$$\left\{\begin{aligned} a_1 &= \left(\frac{f\,\rho_1\,K_1}{18 \times 10^{11}}\right)^2 \\ a_2 &= \left(\frac{f\,\rho_2\,K_2}{18 \times 10^{11}}\right)^2 \end{aligned}\right. \tag{24}$$

If, as is approximately the case in impregnated paper, the thickness of the two elements, paper and oil, averages about equal, the resistances r_1 and r_2 may be replaced by resistivities ρ_1 and ρ_2. Hence, equation (22) may be expressed as follows:

$\cos\theta =$

$$\frac{\dfrac{\rho_1}{1+a_1} + \dfrac{\rho_2}{1+a_2}}{\sqrt{\dfrac{\rho_1^2}{1+a_1} + \dfrac{\rho_2^2}{1+a_2} + \dfrac{2\,\rho_1\,\rho_2\,(1+\sqrt{a_1\,a_2})}{(1+a_1)\,(1+a_2)}}} \tag{25}$$

If ρ_1 and ρ_2 are as great as they are usually found to be, the *ones* may be omitted without appreciable error, the equation then reducing to the following simple form.

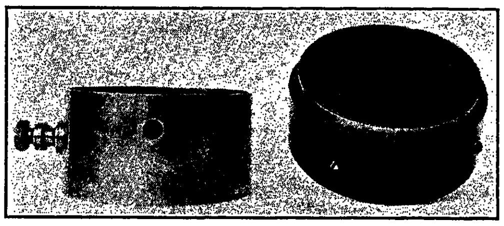

Fig. 8

$$\text{Cos } \theta = \frac{A_1^2/\rho_1 + A_2^2/\rho_2}{A_1 + A_2} \qquad (26)$$

Where
$$A_1 = \frac{18 \times 10^{11}}{f K_1}$$

$$A_2 = \frac{18 \times 10^{11}}{f K_2}$$

Appendix III

Cell for Resistance and Capacity Measurements

The resistivity of petrolatum was determined by measurements of a film 1 mm. thick and 8 cm. in diameter. The design of the cell, in which measurements were made, is shown in Fig. 7, and its appearance in Fig. 8.

The general arrangement of the testing circuit is shown in Fig. 9. With this apparatus the resistivity of an oil can be determined over a range of temperature from 30 deg. cent. to 105 deg. cent. in three-quarters of an hour.

The heating of the cell is accomplished by placing it on an electric hot-plate. With a reasonably sensitive galvanometer a sufficiently great deflection can be obtained to ensure an accuracy of 10 per cent. This may seem to be a large error, but the authors have known cases where different laboratories, using different types of cells, could not check such measurements within 50 per cent.

Capacity measurements were made with direct current by the ordinary ballistic galvanometer method, and with alternating current by a new method involving the use of a guard ring. The diagram of connections is shown in Fig. 10. C_1 is the cell connected in the Wheatstone bridge circuit. The resistance R_g is in series with the guard ring of the cell to prevent a serious arc in case the oil should fail under the application of voltage. The detector G is a Weibel electromagnet moving-coil galvanometer. The mutual inductance M, the resistance R and the capacity C are parts of the moving-coil circuit of the galvanometer and serve to stabilize the deflections and to produce critical damping. The shield circuit, R_s and C_3, was adjusted by connecting the galvanometer to post A and varying R_3 until the galvanometer showed no deflection when the key K was reversed. After this adjustment had been made the bridge could then be

accurately balanced by connecting the galvanometer to the post B and varying the resistance R_1.

For measuring the specific capacity of oil, a substitution method was used. The first balance was obtained with only air in the cell and then a second balance with the oil in the cell. The ratio of R_1 obtained in the first balance to that obtained in the second balance, is the specific capacity of the oil.

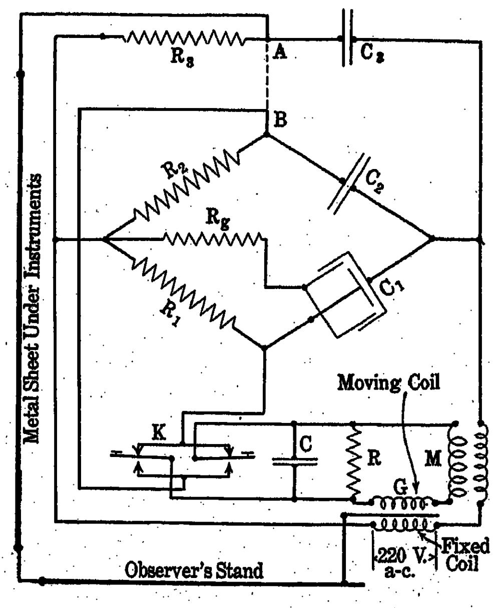

Fig. 10

To check the accuracy of the method, the capacity of the cell with air was measured by substituting for the cell a condenser of known value. The measured capacity was found to be 0.000099 microfarads as compared with 0.000098 microfarads calculated from the dimensions of the cell.

The specific capacity of an oil could be measured over a temperature range of 30 deg. to 105 deg. cent. in an hour with an accuracy of about 3 per cent.

Discussion

Potential Gradient In Cables

Discussion of the Logarithmic Formula, Its Modification and Effect of Internal Heat

Review of the Subject.—*If the dielectric of a single-conductor concentric cable is homogeneous, the voltage gradient at any diameter x is given by*

$$\frac{d\,v}{d\,x} = \frac{0.868\ V}{x \log_{10} \dfrac{D}{d}}$$

where $\frac{d\,v}{d\,x}$ *is the voltage gradient or dielectric stress, V the voltage between conductor and sheath, D the diameter over the dielectric and d the diameter over the conductor.*

A complete discussion of the above formula is followed by considerable experimental data and curves accumulated from many breakdown tests.

Results of tests on cables with large ratios of dielectric diameter to conductor diameter are included and a modification of the above theoretical formula is discussed. The modified formula is checked by tests on a special cable which was constructed for this purpose.

A new relation between the rupturing gradient at the surface of the conductor and the ratio D/d is suggested and curves of experimental data given.

Breakdown tests on three-conductor cables are included and the calculated rupturing stresses compared with those for single-conductor cables.

Special cables were constructed so that measurements could be made of voltages between layers of insulation. From data obtained from these tests, curves are given showing the change in potential gradient as the internal heat of the cable is increased. Curves are given showing the effect of a change of temperature on the dielectric strength, the stresses and the factor of safety of cables.

A complete description is given of the low-capacitance electrostatic voltmeter used in the temperature-potential-gradient tests.

CONTENTS.

INTRODUCTION

In a paper presented before the Institute in 1914[1] two of the authors gave the relations of testing voltage to the allowable stress and to the geometry of cables. The rules and constants given at that time were the results of data and experience covering a number of years. Since that time we have been conducting numerous experiments in order to determine more specifically the relations which exist among the maximum allowable gradients, the applied voltage and the geometry of cables. Tests have also been conducted to determine the effect of the conductor heating on the potential gradients in cables.

It should be appreciated that it is not a simple matter to determine the laws governing the breakdown voltage of dielectrics because the results are usually so erratic. The breakdown voltage for various sections cut from the most carefully made cable varies over wide limits even under the same conditions of test, owing to the fact that it is practically impossible to make homogeneous insulation. When a weak spot yields to the stress, more stress is immediately concentrated on the remaining layers, and the cable punctures. This action is cumulative and tends to produce erratic results, even under the best of conditions. The breakdown voltage is also a function of the rate of application of voltage, length of cable tested, etc. We have taken every precaution to prevent inconsistent results, by raising the potential at the same rate in every case, by using the same lengths of cable, and by taking the average of at least five readings for each test.

We are presenting the results obtained from numerous experiments and indicating the laws which breakdowns, etc., appear to follow in these tests. We do not claim that these laws are final, but on the contrary we feel that considerable more data must be obtained before any such laws can be accepted as final. In order to conduct a series of tests which will give satisfactory results, a large number of cables having the same dielectric, but with fixed outside diameters and variable conductor diameters, and also cables with fixed conductor diameters and variable outside diameters must be carefully made and tested. The fact that this involves considerable time and expense has prevented more data of this character being obtained.

If the dielectric of a single-conductor concentric cable is homogeneous, the voltage gradient at any diameter x is given by

$$\frac{d\,v}{d\,x} = \frac{0.868\ V}{x \log_{10} \dfrac{D}{d}} = S \qquad (1)$$

where S is the dielectric stress or potential gradient, V the voltage between conductor and sheath, D the diameter of the dielectric, and d the conductor diameter.

1. W. I. Middleton and Chester L. Dawes "Voltage Testing of Cables," TRANS. A. I. E. E., Vol. XXXIII (1914), page 1185.

Presented at the Annual Convention of the A. I. E. E., Niagara Falls, Ont., June 26-30, 1922.

If x is expressed in mils, S is given in volts per mil. The stress is obviously a maximum at the surface of the conductor, where $x = d$. If the conductor diameter d, is small as compared with D, the stress S at the surface of the conductor will be large, even with a thick wall of insulation, owing to the concentration of the dielectric flux at the conductor surface. As the diameter of the conductor d increases, D and V remaining fixed, S at first decreases, because of the less concentration of dielectric flux with increasing conductor diameter. When $d = D/2.72$, where 2.72 is the Napierian logarithmic base, S becomes a minimum. The gradient then increases with further increase in d, owing to the lesser thickness of the wall of the dielectric. The relation of the gradient S at the surface of the conductor and the ratio of the conductor to the dielectric diameter for fixed values of V and D is shown in Fig. 1. The minimum gradient occurs when $d/D = 0.368 = 1/2.72$. The curve, however, is quite flat near the point of minimum gradient. Obviously, S is infinite when $d = O$, and when $d = D$.

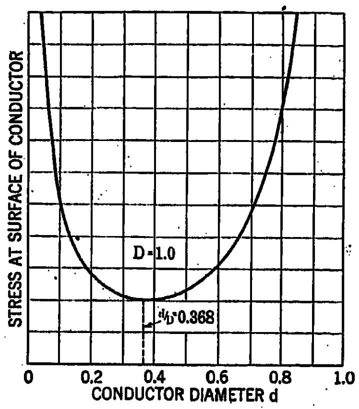

FIG. 1—RELATION BETWEEN STRESS AT SURFACE OF CONDUCTOR AND CONDUCTOR DIAMETER
Impressed voltage and insulation diameter fixed.

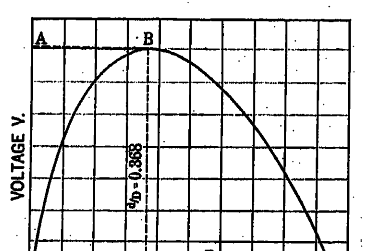

FIG. 2—RELATION BETWEEN ALLOWABLE VOLTAGE AND CONDUCTOR DIAMETER
Maximum stress and insulation diameter fixed.

If the allowable gradient S at the surface of the conductor and the diameter of the dielectric D, be maintained constant, the voltage which may be impressed on the cable

$$V = \frac{S}{0.868} \, d \log_{10} \frac{D}{d} = 1.15 \; S \; d \log_{10} \frac{D}{d} \qquad (2)$$

Fig. 2 shows the relation between V and d, with S and D ($= 1.0$) fixed. The maximum voltage which may be impressed under these conditions, and yet not overstress the dielectric at any point, occurs when $D/d = 2.72$ or when $d/D = 0.368$. The voltage V is obviously zero when $d = O$ and when $d = D$.

When D/d is equal to or less than 2.72, equations (1) and (2) are generally accepted for determining the voltage, the stress, etc. Our experience has always been that these equations give very consistent results. When D/d exceeds 2.72, however, the layers of insulation adjacent to the conductor can be subjected to gradients far in excess of those which the insulation can normally withstand and yet complete rupture does not occur because the gradient in the remaining layers is not sufficient to cause them to rupture.

We have subjected rubber to dielectric stresses three and four times the value at which it normally ruptures by applying voltage to cables having a very small conductor diameter.

The applied voltage was sufficiently high to produce high stresses in the rubber adjacent to the conductor, and yet not rupture the cable. Examination under a high-powered microscope of the rubber after being subjected to these stresses for considerable time, failed to reveal any change in the physical structure of the dielectric.

CABLES HAVING CONSTANT OUTSIDE DIAMETERS BUT VARYING CONDUCTOR DIAMETERS

In order to investigate the effect of large ratios of dielectric to conductor diameters on dielectric stresses we had several special cables made up. It was necessary to make these of rubber as it is difficult to use wrapped insulations, such as paper and cambric, with the small conductor diameters which we used. Moreover, rubber is a more homogeneous dielectric than either of the other two.

The first two sets of cables were made with the object of determining the effect upon breakdown voltage of having a constant outside diameter and variable conductor diameter. The outside diameters were 12/32 in. or 375 mils (9.49 mm.).

With a gaseous dielectric and concentric cylinders having diameter ratios exceeding 2.72, the dielectric at the surface of the inner conductor becomes ionized when the voltage gradient at its surface becomes sufficiently high. This produces corona at the surface of the inner conductor, and its effective diameter is increased by corona formation, as is well-known. Theoretically, this can occur until the corona diameter equals $D/2.72$, when complete rupture occurs without further increase of voltage. These effects will be modified somewhat by the ionization of the air outside the corona diameter.

So far as we know, this effect can only occur in solid

dielectrics when there are pockets of occluded gases, and even then the effect cannot be large. In well-made cables we feel that the effect of corona formation on stress distribution is negligible.

Assume that the values of V given by curve $O\,B\,C$, Fig. 2, produce a gradient at the surface of the conductor equal to the disruptive strength of the dielectric. When the impressed voltage exceeds the values given by the portion $O\,B$ of the curve, the dielectric near the conductor is obviously stressed beyond its disruptive strength. So far as the writers know, corona cannot form in such a manner as to increase the effective diameter of the conductor. Many theories as to the effects which this condition of overstress produces in the dielectric have been advanced, such as the carbonizing of the dielectric, etc.

In the cables constructed for investigating this effect, conductors ranging from No. 24 A. W. G. giving a value of $D/d = 18.65$ to No. 3 Stranded (A. W. G.) giving a value of $D/d = 1.44$ were used. Breakdown tests were made on short lengths, the results of which are tabulated in Table I.

TABLE I.

Set No. 1. $D = 12/32$ in. $= 0.375$ in. (9.49 mm.)

Size cond. A. W. G.	Cond. diam. (d) mils	Ratio D/d	Ratio d/D	Break-down voltage	Gradient at cond. surface volts per mil
24 solid	20.1	18.65	0.0536	27,680	942
20	32.0	11.70	0.0853	29,480	748
14	65.0	5.77	0.173	33,940	592
..	90.0	4.17	0.240	35,280	549
8	128.0	2.93	0.342	39,140	568
6	162.0	2.31	0.432	33,490	493
5	186.0	2.02	0.496	31,760	487
2	258.0	1.45	0.688	23,830	494
3 strd.	260.0	1.44	0.694	27,950	587

The insulation showed a dielectric strength of approximately 500 volts per mil when D/d was less than 2.72.

The values of breakdown voltage given in Table I

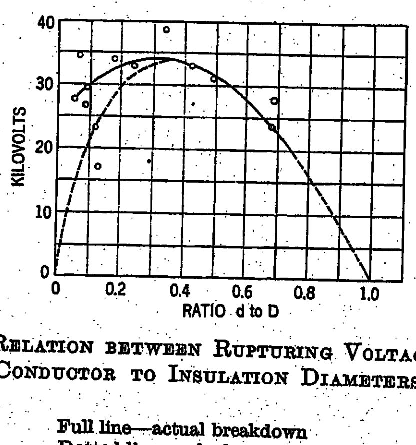

FIG. 3—RELATION BETWEEN RUPTURING VOLTAGE AND THE RATIO OF CONDUCTOR TO INSULATION DIAMETERS FOR DATA IN TABLE I.

Full line—actual breakdown
Dotted line—calculated breakdown
Maximum stress—500 V/mil

are plotted as kilovolts in Fig. 3, with the ratio d/D as abscissas. With two exceptions, the points lie on a smooth curve. The dotted curve shows the voltage which will give a constant gradient of 500 volts per mil at the surface of the conductor, as the conductor diameter varies. It will be noticed that the two curves coincide, over the range of experiment, for values of

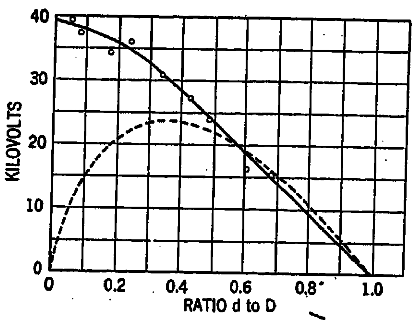

FIG. 4—RELATION BETWEEN RUPTURING VOLTAGE AND THE RATIO OF CONDUCTOR TO INSULATION DIAMETERS FOR DATA IN TABLE II

Full line—actual breakdown
Dotted line—calculated breakdown
Maximum stress—347 V/mil

d/D greater than 0.368 or 1/2.72. When the value of d/D is less than 0.368 the breakdown curve departs from the constant gradient curve, lying well above it. If the insulation loses its dielectric strength as soon as it becomes overstressed, the breakdown voltage should follow the curve $A\,B\,C$, Fig. 2, as was pointed out by the authors in their 1915 paper[2].

Our experience that the breakdown voltage usually followed the straight line $A\,B$ more closely than the the curve $O\,B$, Fig. 2, led us to adopt the following formula for cables having conductor diameters less than $D/2.72$

$$S = \frac{0.868\,V}{d_c \log_{10} \dfrac{D}{d_c}} = \frac{5.44\,V}{D} \qquad (3)$$

where $d_c = \dfrac{D}{2.72}$

TABLE II.

Set No. 2. $D = 12/32$ in. $= 0.375$ in. (9.49 mm.)

3	229.0	1.637	0.610	16,750	297
2	258.0	1.453	0.688	15,720	326

The cables whose breakdown characteristics are given in Table I and Fig. 3 follow this law very closely. The breakdown voltage actually becomes less when the conductor diameter becomes less than $D/2.72$, showing

2. loc. cit.

that the insulation between the conductor and the diameter $D/2.72$ adds nothing to the dielectric strength of these particular cables, but rather causes it to be less.

Table II gives data on another set of cables (No.2), similar to that shown in Table I. These cables were made of rubber having very nearly the same composition as that used in No. 1, but were cured by a different method.

Fig. 4 gives the relation between d/D and breakdown voltage for this set of cables. The dotted curve is calculated on the basis of 347 volts per mil, the average of the gradients at the conductor surfaces for the last four cables, whose ratio of outside to conductor diameter was less then 2.72.

Although the dielectric of these cables is nearly the same as that of set No. 2, except for cure, this set of cables has markedly different dielectric characteristics. The dielectric stress calculated for large values of d/D is only about 0.7 that for the first set of cables and yet with small values of d/D it has much greater dielectric strength. That is equation (3) is not applicable to these cables. A comparison of the results obtained with these two cables demonstrates the difficulty of obtaining consistent results under all conditions.

Cables Having Constant Conductor Diameters but Varying Outside Diameters

In order to determine the effect on the dielectric strength of cables of increasing the wall of insulation with a fixed conductor diameter, another set of cables was made up. In this set a No. 24 A. W. G. conductor having a diameter of 20.1 mils (0.51 mm.) was used. The diameters of the insulation varied from 3/32 in. (2.38 mm.) to 10/32 in. (7.94 mm.) giving values of D/d ranging from 4.69 to 15.55.

The results obtained with these two sets of cables were used to determine the breakdown constant K of the insulation.

Dividing equation (1) by 0.868 gives

$$1.15\, S = K = \frac{V}{d \log \dfrac{D}{d}} \qquad (4)$$

This equation is used to calculate K when D/d is less than 2.72. When D/d is greater than 2.72 equation (3) is likewise used.

$$K = \frac{V}{d_e \log \dfrac{D}{d_e}} = \frac{6.27V}{D} \qquad (5)$$

The constant K is the dielectric strength of the insulation multiplied by the constant 1.15. If the breakdown voltage follows these laws the values of K obtained by using equations (4) and (5) should be practically constant. As the values of D/d for all the cables in Table III were greater than 2.72, only equation (5) was used in the computation of K, for these particular cables.

TABLE III.

Set No. 3—No. 24 A. W. G. Cond. Diam. (d) = 20.1 mils (0.510 mm.)

Outside diam.	Ratio D/d	Breakdown voltage	k
3/32 in.	4.69	9,930	663
4/32	6.22	13,600	681
5/32	7.77	17,800	715
6/32	9.33	23,000	769
8/32	12.45	27,300	685
10/32	15.55	34,200	685

The values of K calculated, using equation (5) and given in Table III, are plotted in Fig. 5.

With small values of D/d, K increases slightly. For large values of D/d, K is practically constant. The breakdown voltage of this set of cables followed the law given by equations (4) and (5) very closely.

Effect of Stress on Permittivity

It is well-known that the dielectric constant or permittivity of a dielectric increases under dielectric stress. We felt that this fact might offer a partial explanation, at least, of the ability of the inner layers of cables to withstand voltage gradients far in excess of the normal rupturing gradients of the dielectric, and yet apparently show no signs of rupture.

If the capacitance of that part of the cable nearer the conductor increased a sufficient amount, there would obviously be a less percentage of the total voltage across these layers under high stress, hence the cable would automatically grade itself.

To determine whether or not there was any considerable change of capacitance under these conditions, a special cable was made up. The dimensions and cross-section of this cable are shown in Fig. 6. Our idea was to make a cable having a very heavy wall of insulation and also an extremely high value of D/d. Between the conductor and outside, a concentric conducting cylinder was made into the cable as a means of determining the potential at some intermediate distance

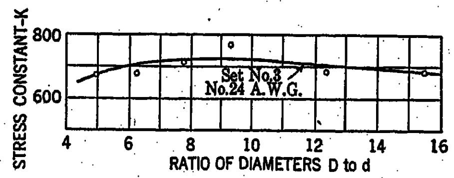

FIG. 5—Relation between Stress Constant K and the Ratio of Insulation and Conductor Diameters for Cables in Table III

between the conductor and the outer surface of the insulation. Because of greater ease of manufacture, a 0.038-in. (0.97 mm.) lead sheath was used for this intermediate conducting cylinder. The copper was No. 12 A. W. G. having a diameter of 0.081-in. (2.06

mm.). The inside diameter of the lead was 0.328 in. (8.34 mm.) giving 4.05 as the value of D/d for this inside portion of the cable. This value of D/d is well above the critical value of 2.72 and any phenomena developing under these conditions should be apparent

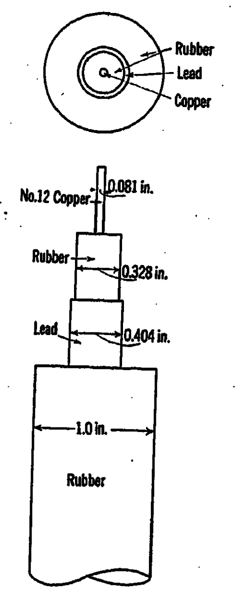

Fig. 6—Cable with Intermediate Sheath

in this cable. The outer diameter of the lead was 0.404 in. (10.3 mm.) and the cable diameter was 1.0 in. (25.4 mm.) giving 2.48 as the value of D/d for this outer portion of the cable. The ratio of outside to conductor diameter is only slightly less than the critical value of 2.72.

Approximately 100-ft. lengths of this cable were immersed in water. The electrostatic capacitance was then measured with low-voltage, 25-cycle, alternating current by means of a deflecting dynamometer, the cable capacitance being obtained by direct comparison with a standard condenser.

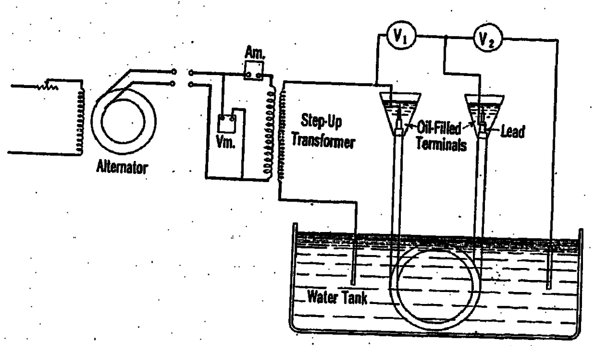

Fig. 7—Diagram of Connections for Stress Tests on Cable with Intermediate sheath

The cable was then connected to the secondary of a step-up transformer, the connections being shown in Fig. 7. The potential difference between the copper and lead and that between lead and ground was measured by means of two vibrating electrostatic voltmeters V_1 and V_2, a description of which has already been published by one of the authors.[3] The capacitance of these instruments is practically nil as compared with the capacitances across which they were connected, hence they did not disturb the potential relations within the cable.

Fig. 8 gives the results obtained from a typical test. The voltage, copper to lead and lead to ground, are plotted as ordinates with the total voltage from copper to ground as abscissas. The ratios between these two voltages remained practically constant until the voltage from copper to lead reached 22 kv. when there was a noticeable unsteadiness in the vibrations of both electrostatic instruments. As the applied voltage was being increased, the unsteadiness of V_1 became pronounced and at 22.8 kv. its reading dropped to zero, showing that the insulation between copper and lead had ruptured. Simultaneously, the reading of V_2 jumped to that corresponding to line voltage.

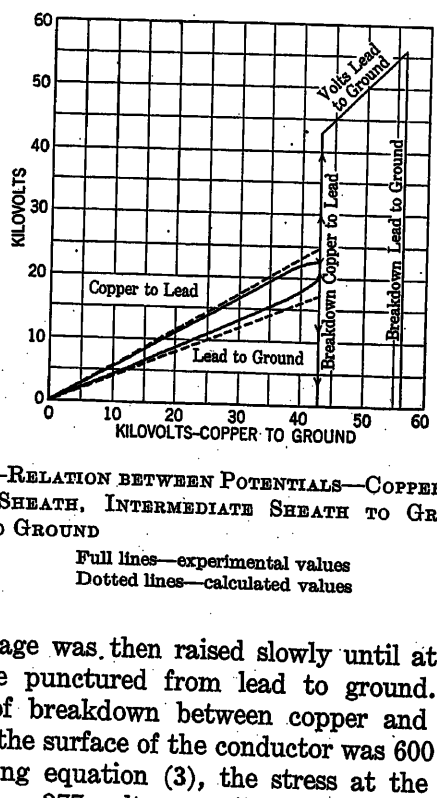

Fig. 8—Relation between Potentials—Copper to Intermediate Sheath, Intermediate Sheath to Ground, and Copper to Ground

Full lines—experimental values
Dotted lines—calculated values

The voltage was then raised slowly until at 56.5 kv. the cable punctured from lead to ground. At the instant of breakdown between copper and lead the stress at the surface of the conductor was 600 volts per mil. Using equation (3), the stress at the diameter $D/2.72$ was 377 volts per mil. The stress at the surface of the lead when the entire cable broke down at 56.5 kv. was 308 volts per mil. Three tests similar to the above were made, and the cable broke down copper to lead at practically this same voltage, the voltages being 23.8 kv. and 26.0 kv. In the subsequent tests the breakdown voltages from lead to ground were much higher than 56.5 kv., the average being approximately 70 kv.

The voltage between copper and lead and that from lead to ground were then calculated, using the measured values of alternating-current capacitance. The cal-

3. Trans. A. I. E. E., Vol. XXXV (1916), page 133.

culated voltages are shown by the dotted lines, Fig. 8. It will be noted that the increase of capacitance of the inner portion of the cable, which was under high stress, over that of the outer portion of the cable, which was under only moderate stress, is only of the order of 5 per cent except at the instant of breakdown, when it is slightly greater than this. This 5 per cent change in capacitance agrees very closely with other measurements which we have made to determine the change of capacitance caused by electrostatic stress. We feel that these tests demonstrate that the stress across the inner layers of a cable having a large ratio D/d is not relieved to any considerable extent by a change of capacitance produced by the stress. It also demonstrates that for this particular cable, the wall of insulation within a diameter of $D/2.72$ adds nothing to the dielectric strength of the cable.

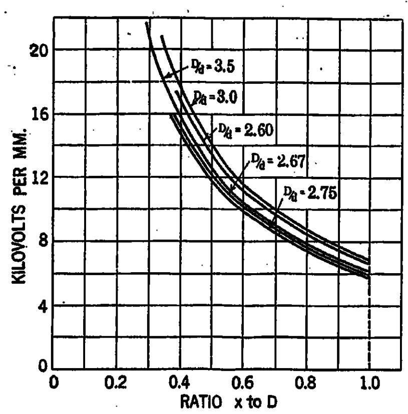

FIG. 9—RELATION BETWEEN GRADIENTS THROUGHOUT THE WALLS OF INSULATION AND THE RATIO x/D
Breakdown tests of F. Fernie.

LAW OF BREAKDOWN FOR VALUES OF D/d GREATER THAN 2.72

As was stated earlier in the paper, our object in making these numerous tests was, if possible, to determine some relation between the breakdown voltage and the stresses within the insulation for large values of D/d.

In an article appearing recently in *Beama*,[4] F. Fernie submits test data showing that several different cables, tested by him, all rupture with practically equal potential gradients at the outer surface of the insulation. The results are tabulated in Table III of his paper. The authors have examined this paper very carefully. In checking his values of gradient given in the last column of Table III, we find several values in error. The values of stress calculated by us, using his data, are not so nearly equal as his figures indicate. However, even then the difference can be readily accounted for by the erratic nature of breakdown tests already discussed. Even if these cables did break down at values of gradient at the outer surface of the insulation which were practically equal, we do not feel that it is at all rational to consider the breakdown voltage a function of dielectric strength of the outer layers where the gradient is a minimum.

4. F. Fernie, "Insulation Experiments," *Beama*, Sept. 1921, page 244.

Fig. 9 shows the calculated gradient throughout the insulation of each cable at the instant of breakdown. The gradient is plotted with kv. per mm. as ordinates and values of x/D as abscissas for each cable, where x is any diameter within the insulation. With fixed values of d and D and homogeneous insulation, the stress at each diameter x is inversely proportional to x (Eq. (1)). Therefore, each of these curves is a rectangular hyperbola. That is, the gradient at each point of Curve 1, Fig. 9,

$$S_1 = \frac{K_1}{(x/D)} \tag{6}$$

and the stress at each point on curve 2

$$S_2 = \frac{K_2}{(x/D)} \tag{7}$$

where K_1 and K_2 are constants.

For any given value of x/D

$$S_1/S_2 = K_1/K_2 \tag{8}$$

That is, the ratio of ordinates of any two curves for each value of x/D is constant for all values of x/D. If the gradients at the outer surfaces of the insulation of two cables are equal, they will be equal at all values of x/D for the two cables. If cables break down for equal values of gradient in the outer layers, the gradients in the inner layers for each value of x/D, as far as a given curve extends, must be equal.

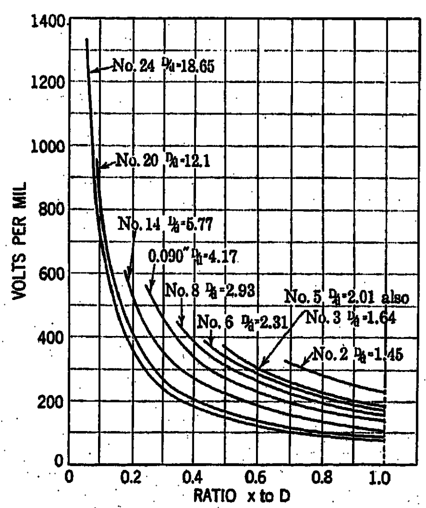

FIG. 10—RELATION BETWEEN GRADIENTS THROUGHOUT THE WALLS OF INSULATION AND THE RATIO x/D FOR CABLES IN TABLE II

An examination of Fig. 9 shows that the cables broke down for nearly equal values of gradient at the ratios of x to D between 0.33 and 0.39 which correspond practically to the critical ratio of D to d of 2.72.

We find that if the values of gradient at the outer surfaces of our cables No. 1 and No. 2 be plotted as

ordinates and d/D as abscissas, in one case a perfectly straight line results, and in another the plot is slightly curved. We do not feel that this is important, however, as it is merely the result of higher gradients existing within the inner layers of the cable.

On analyzing the tests made on the sets of cables

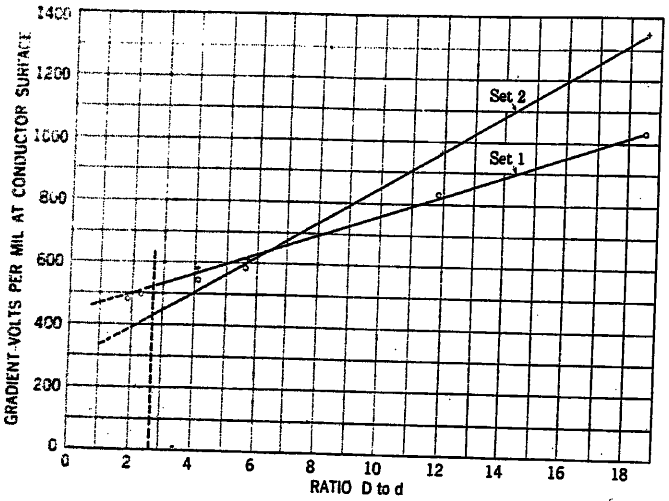

FIG. 11—RELATION BETWEEN CONDUCTOR STRESS AND RATIO OF INSULATION TO CONDUCTOR DIAMETERS FOR CABLES IN TABLES I AND II

No. 1 to No. 3 inclusive, the gradients throughout the insulation as ordinates and values of x/D as abscissas for each cable were plotted. A typical example for set No. 2 is shown in Fig. 10. The insulation is assumed homogeneous in every case.

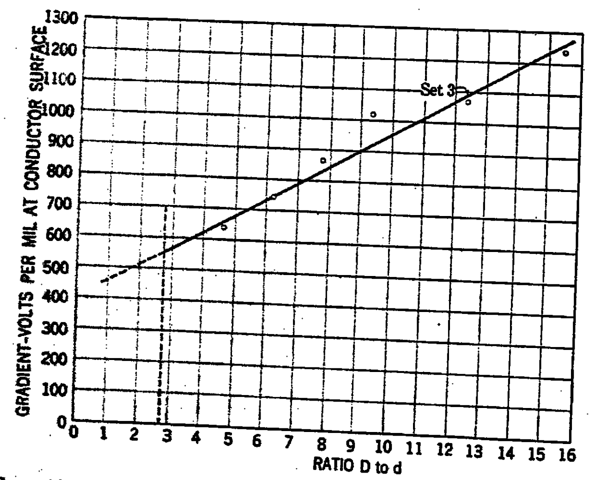

FIG. 12—RELATION BETWEEN CONDUCTOR STRESS AND RATIO OF INSULATION TO CONDUCTOR DIAMETERS FOR CABLES IN TABLE III

The upper extremity of each curve is the gradient at the conductor surface at the instant of breakdown. It will be noted that if a curve be drawn through these upper extremities, a curve resembling a rectangular hyperbola results. Therefore, if these gradients at the conductor surface be plotted with the reciprocal of d/D or D/d as ordinates, the plot should be nearly a straight line.

Fig. 11 shows these plots for the cables in sets No. 1 and No. 2. It will be noted that the points, particularly at the larger values of D/d, lie on practically a straight line. It should not be expected that every point will lie in a smooth curve, as, has already been pointed out, dielectric breakdown tests are certain to be more or less erratic. Each line, Fig. 11, intercepts the ordinate $D/d = 1.0$ at a value of gradient only very slightly less than the rupturing gradient of the respective dielectric of the set of cables which it represents.

The equation of these lines is obviously

$$S = K + A\,x \tag{9}$$

where S is the gradient at the surface of the conductor at breakdown, K is the intercept on the S-axis, A is a constant and $x = D/d$.

Fig. 12 gives similar plots for the cables in set No. 3 having conductors of No. 24 A. W. G. and varying walls of insulation.

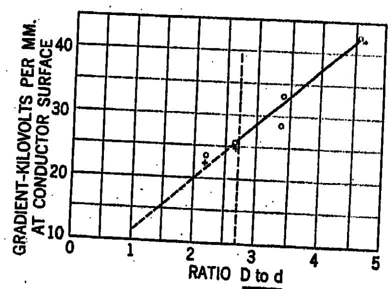

FIG. 13—RELATION BETWEEN CONDUCTOR STRESS AND RATIO OF INSULATION AND CONDUCTOR DIAMETERS FOR CABLES IN F. FERNIE'S PAPER

Fig. 13 gives similar curves using values obtained from F. Fernies' paper.[5] The plot given by these points is a straight line within the precision of results obtained from any set of breakdown tests. The intercept on the ordinate $D/d = 1.0$ gives a value of gradient about 0.7 the rupturing gradient of the insulation.

All the test data which we have available seem to indicate that for any given dielectric a straight-line law exists between the gradient at the conductor surface at breakdown and the ratio of outside to conductor diameters (D/d) for values of D/d greater than 2.72. However, we feel that further investigation is needed along this line, before this relation be accepted as final.

STRESSES IN THREE-CONDUCTOR CABLES

At the present time, there are two common methods of calculating the maximum stress in a three-conductor cable.

In the first method, which is the one used by most engineers until recently, the maximum stress for a three-conductor cable was calculated by the same formula as that used for a single-conductor cable of the

5. loc. cit.

same size of conductor and having a wall of insulation equal to the total wall between the conductors of the three-conductor cable.

The second method is by means of a formula recently published in the JOURNAL and PROCEEDINGS of the A. I. E. E.[6] Here again the stress in a three-conductor cable is calculated by the same formula as for a single-conductor cable, but the wall of insulation is assumed to be equal to the distance between the conductor surface and the center of the three-conductor cable. A correction factor is involved, dependent upon the relation between the conductor insulation and the conductor diameter.

In order to determine which one of these two methods of calculating stress in a three-conductor cable was the more accurate, a series of breakdown tests was made on single- and three-conductor cables.

The rupturing stress for the insulation should be approximately the same with both the single and three-conductor cables.

Of the two foregoing methods, the one which should be accepted as standard is the one which gives the rupturing stress of the insulation of a three-conductor cable more nearly equal to that of a single-conductor cable, having the same kind of insulation.

Tables IV and V give the results of breakdown and calculated stresses for single and three-conductor paper cables.

The breakdowns were all made at 60 cycles and by raising the voltage at the rate of approximately 1000 volts per second. The single-conductor cables were broken down with single-phase voltage between conductor and lead and the three-conductor cables with three-phase voltage between conductors, the lead sheath being grounded and connected to the neutral point of the Y-connected transformers.

It should be noted that the rupturing stresses of the three-conductor cables when calculated by the old method are nearly the same as for the single-conductor

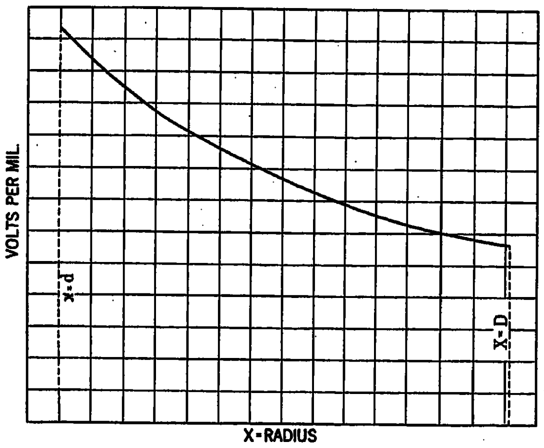

Fig. 14—Typical Potential-Gradient Curve

cables, while the stresses calculated by the new method are considerably lower.

Effect of Internal Heating on Voltage Gradient within Concentric Insulation

The general shape of the potential gradient or stress curve for a homogeneous wall of concentric insulation calculated by the logarithmic formula, equation (1), is shown in Fig. 14.

If the wall of insulation is not homogeneous, but made up of multiple layers of insulating materials having different dielectric constants, the voltage distribution throughout the wall may be calculated by the formula

$$V_0 = V_1 + V_2 + V_3 + \ldots V_n$$

$$= \frac{2Q}{K_1}\log_e r_1/r + \frac{2Q}{K_2}\log_e r_2/r_1 + \frac{2Q}{K_3}\log_e r_3/r_2 + \ldots \quad (10)$$

$$\frac{2Q}{K_n}\log_e r_n/r_{n-1}$$

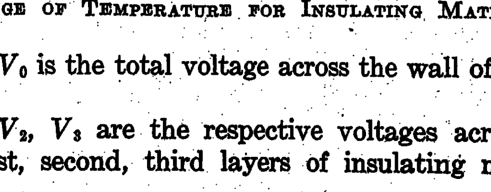

Fig. 15—Per Cent Change of Dielectric Constant with Change of Temperature for Insulating Materials

where V_0 is the total voltage across the wall of insulation

V_1, V_2, V_3 are the respective voltages across the first, second, third layers of insulating material

Q is the electrostatic charge on the surface of each layer of insulating material

K_1, K_2, K_3 are the respective dielectric constants of the layers of insulating material

r is the radius of the conductor

$r_1, r_2, r_3, \ldots r_n$ are the radii of the layers of insulating material.

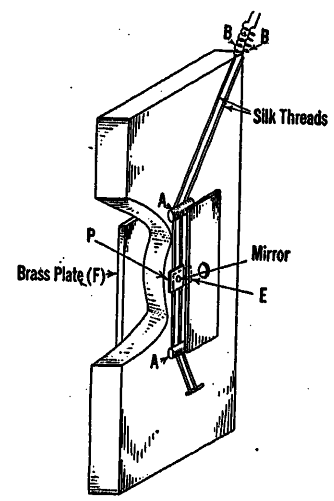

Fig. 16—Low-Capacitance Electrostatic Voltmeter

By employing multiple layers of insulating materials with the proper relative values of dielectric constants, it is possible to reduce considerably the maximum voltage stress at the surface of the conductor and increase the stresses in the outer layers of the insulation.

This method of insulating cables is commonly referred to as "grading" and theoretically results in a

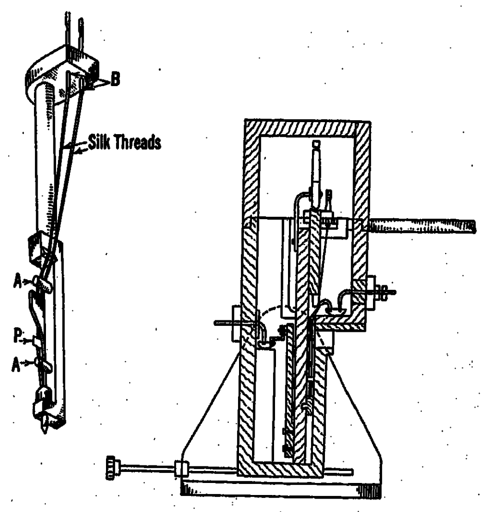

Fig. 17—Low-Capacitance Electrostatic Voltmeter

cable that will withstand a higher impressed voltage than a non-graded cable, other factors being equal.

Several excellent papers[7] have been published on the subject of "grading of cables."

H. S. Osborne, Trans. A. I. E. E., Vol. 29, 1910, page 1553.

An insulated cable carrying current must dissipate energy in the form of heat, and the source of this energy is the $I^2 R$ loss in the conductor. The heat flows from the conductor to the surrounding medium with the result that the conductor is at a much higher temperature than the outside of the insulation.

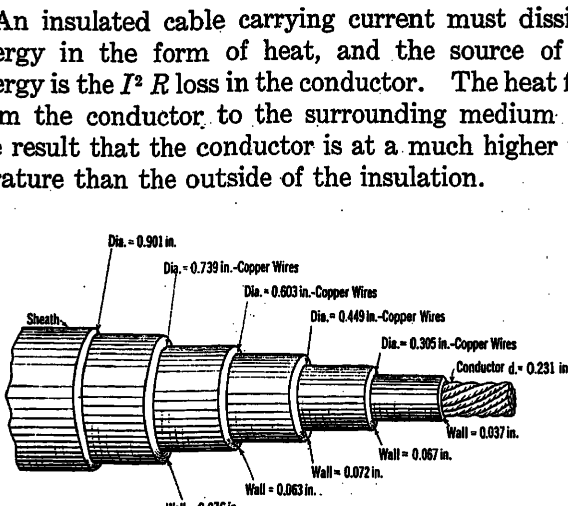

FIG. 18—DIMENSIONS OF NO. 4 STRANDED PAPER-INSULATED STRESS SAMPLE

The dielectric constant of insulating materials increases very considerably with increase of temperature.

In Fig. 15 there are curves showing the average increase of dielectric constants with temperature for the three most common cable insulating materials.

Therefore, theoretically, the insulation nearest the conductor of a cable carrying current should have a higher dielectric constant than the insulation farther from the center with the result that the voltage distribution throughout the wall of insulation should change as the temperature increases.

The following tests were made to determine whether or not the voltage distribution followed the theoretical law, and if so, how much change occurred as the temperature was increased.

The instrument used for voltage measurements was a modification of one described by Prof. C. L. Dawes in a discussion on voltage measurements at New York in 1916.[8]

Figs. 16 and 17 show the general scheme of the voltmeter.

Two silk threads are stretched tightly between two supports *A A*, the proper tension being secured by the springs *B B*. A thin brass plate (*P*) approximately 6 by 11 millimeters is cemented at one end to the two silk threads half way between the supports. On this brass plate is a small mirror for reflecting a beam of light.

In front of the plate *P*, another brass plate *E* is fastened, in the center of which is a small hole through which a beam of light enters to and leaves from the mirror. These two brass plates are connected together electrically by a flexible metal filament for one terminal of the instrument. The other terminal of the instrument is a small plate *F*, secured to the other side of the hard-rubber barrier. This barrier acts as a dielectric to prevent breakdown between the terminals.

8. TRANSACTIONS of A. I. E. E., Vol. XXXV, Part 1, page 133.

Because of the inertia and high damping of the moving plate, it does not vibrate, as in the original instrument, but gives a steady deflection with constant voltage. It is immersed in oil to prevent corona and brush discharge and also for damping purposes. The deflection of the instrument is nearly proportional to the square of the voltage impressed between its terminals and consequently the deflection is always in the same direction.

The capacitance of this instrument between terminals is extremely small, approximately 0.0000017 microfarad or 1.7 micro-microfarads.

At times when the instrument was too sensitive for the voltages to be measured, multiplying capacitances of either 3.1 micro-microfarads or 12 micro-microfarads were used to keep the deflection within the range of the scale.

Two short samples of single-conductor cable were manufactured upon which measurements could be made —one sample with paper insulation and one sample with varnished cambric insulation. Each sample consisted of a No. 4 A. W. G. stranded copper conductor with a total wall of insulation of approximately 9/32 in. (7.1 mm.), and a lead sheath. At four different points in the walls of insulation, layers of No. 36 A. W. G. bare copper strands were spiraled the length of the sample between layers of the insulating material. Figs. 18 and 19 show the dimensions and locations of the copper strands.

Thermocouples were placed in the conductors and in the lead sheaths of both samples so that it was possible to know accurately the temperature of each.

Sixty-cycle alternating current was applied to the samples from a current transformer and voltage measurements were made with an impressed voltage between conductor and lead of 10,000 volts.

The minimum capacitance between successive layers of copper strands was 950 micro-microfarads. It is

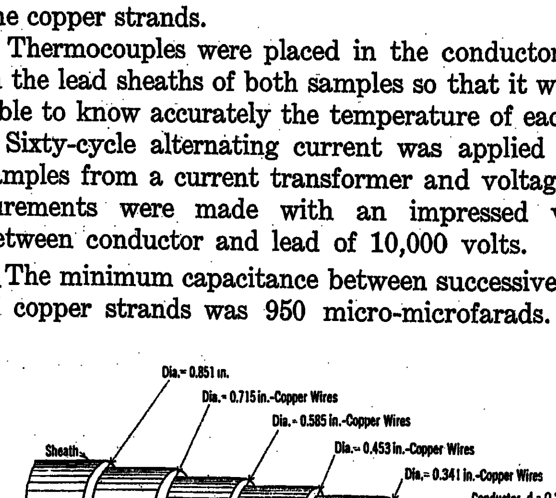

FIG. 19—DIMENSIONS OF NO. 4 STRANDED CAMBRIC-INSULATED STRESS SAMPLE

evident that because of its small capacitance the electrostatic voltmeter already described could be used to measure voltages between layers of copper strands without disturbing the voltage distribution through the wall of insulation.

The voltage measurements were so made that one

side of the voltmeter was constantly at ground potential.

Tables VII and VIII show the results of 1000-cycle capacitance tests made on the samples at the various temperatures.

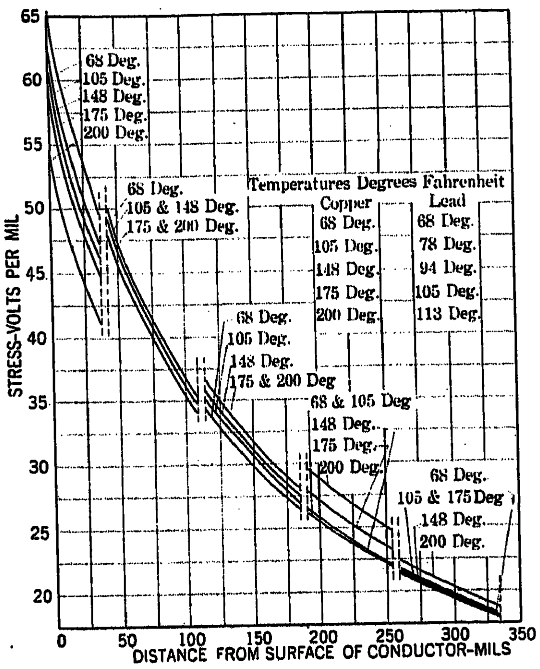

FIG. 20—EFFECT OF COPPER TEMPERATURE ON POTENTIAL GRADIENT OF PAPER CABLE

Four-stranded 0.295-in. wall impregnated paper
Temperature in degrees fahrenheit

The increase of capacitance for the paper cable is small, being only 11.3 per cent for the wall of insulation nearest the conductor and 6.1 per cent for the wall farthest from the conductor. The capacitance measurements indicate that any change in voltage distribution with increase of internal temperature is small, and, except in cases where the insulation is working very close to the breakdown stress of the material, the decrease of maximum stress is of very small value.

The actual voltage distribution through the wall insulation cannot be calculated from low-voltage capacitance measurements because the capacitance of insulating material under high-voltage stress is somewhat higher than when the stress is practically zero as has already been pointed out.

Table IX and Table X show the voltage as measured between the grounded lead sheath, and the layers of copper strands.

Tables XI and XII show the voltages between successive layers of copper strands as calculated from the data in Tables IX and X.

Figs. 20 and 21 show the potential gradient curves plotted from the data in Tables XI and XII. The curve for each copper temperature is indicated and the corresponding lead temperature is shown in the accompanying chart.

The first tests were made after the samples had been kept in the laboratory for several days so that the total wall of insulation was at room temperature. The potential gradient curves for these temperatures are smooth and continuous, the maximum stress on each layer being the same as the minimum stress on the preceding layer. This might be considered a good check on the accuracy of the apparatus used.

While both the paper and varnished cables show a decrease of maximum stress with an increase of internal temperature, there is quite a marked difference in the two sets of curves.

The most marked change of stresses in the cambric cable is between the second and third layers, while the change for the paper cable comes much nearer the conductor, between the first and second layers. There is no apparent reason for this, except possibly a difference in thermal resistivity. Some difference between the results obtained with the paper cable and those obtained with the cambric cable might be expected. This is due to a change in the physical state of the impregnating compound used in the paper cable with a rise of temperature, while the physical state of the insulating material of the cambric cable remains practically constant.

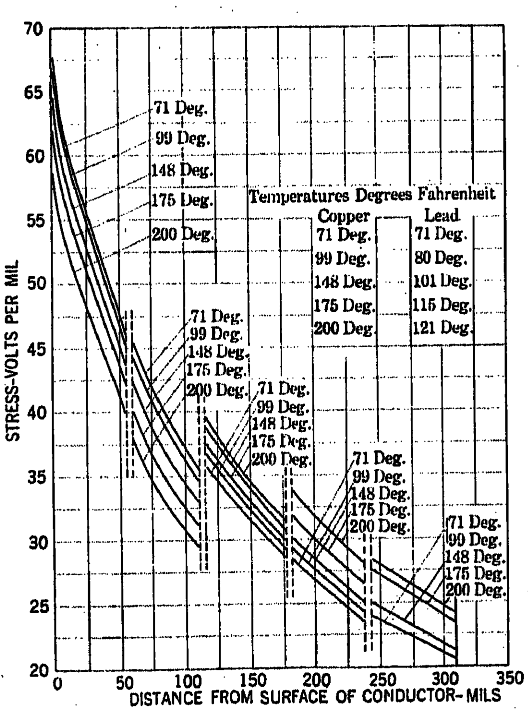

FIG. 21—EFFECT OF COPPER TEMPERATURE ON POTENTIAL GRADIENT OF CAMBRIC CABLE

Four-stranded 0.270-in. wall varnished cambric
Temperature in degrees fahrenheit

The maximum voltage that can be safely impressed across a wall of insulation depends upon the dielectric strength of the insulating material. The factor of safety for an operating cable is the ratio of the dielectric strength of the insulating material to the maximum stress produced by the working voltage. Either an increase in the dielectric strength or decrease in the

maximum stress results in an increase of the factor of safety.

$$\text{Factor of Safety} = \frac{\text{Dielectric Strength}}{\text{Maximum Stress}}$$

If both the dielectric strength and the maximum stress of a cable be changed the effect on the factor of safety would be the ratio of change of dielectric strength to the change of maximum stress.

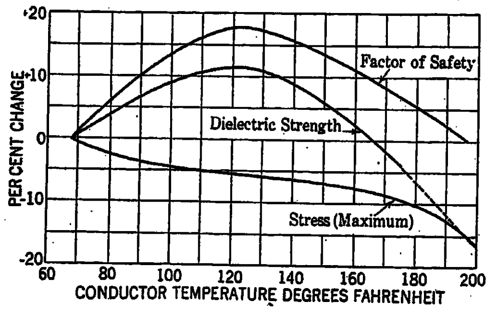

FIG. 22—EFFECT OF DIELECTRIC STRENGTH AND DIELECTRIC STRESS ON THE FACTOR OF SAFETY OF PAPER CABLES
Per cent change in maximum stress vs. conductor temperature
Per cent change in dielectric strength vs. temperature
Per cent change in factor of safety vs. conductor temperature
Paper-insulated cable

Fig. 22 shows the per cent change in maximum stress for the paper cables as the temperature of the cable is increased. There is also shown the per cent changes in dielectric strength with temperature change for impregnated paper insulation as determined from many breakdown tests. The ratio of the changes in dielectric strength to the changes in dielectric stress is plotted to show the changes in the factor of safety.

Fig. 23 shows the dielectric strength, the maximum stress and the factor of safety curves for the cambric cable.

It is interesting to note that the factor of safety for these paper cables is 4 per cent higher at 185 degrees fahrenheit, the A. I. E. E. temperature limit, than it was at normal temperature at 68 degrees fahrenheit.

In studying and discussing the curves and data of this paper, it should be borne in mind that these results are only an indication of what happens in the dielectric because of the internal heat generated at the conductor. The quantitative values would be affected considerably by the conditions under which the cable is working, probably mostly by the relative copper and lead temperatures.

CONCLUSIONS

The experimental evidence given indicates that:

1. For values of D/d equal to or less than 2.72, the potential gradient within a wall of insulation follows the simple logarithmic formula. The maximum stress may be calculated by the formula

$$S = \frac{0.868\,V}{d \log_{10} \dfrac{D}{d}}$$

2. For values of D/d greater than 2.72, the layers of insulation adjacent to the conductor can be subjected to stresses far in excess of those which the insulation can normally withstand and yet complete rupture does not occur.

The following modified formula can be safely used to determine the breakdown stress for small conductors with a heavy wall of insulation

$$S = \frac{0.868\,V}{d_c \log_{10} \dfrac{D}{d_c}}$$

where $d_c = \dfrac{D}{2.72}$

3. The stress across the inner layers of a cable having a large ratio D/d is not relieved to any considerable extent by a change of capacitance produced by the stress.

4. Breakdown tests of a special cable with an intermediate sheath at the point $D/2.72$ indicate that the insulation within the diameter $D/2.72$ adds nothing to the dielectric strength of the cable.

5. For values of D/d greater than 2.72, our data indicate that for any given dielectric, a straight-line law exists between the gradient at the conductor surface at breakdown and the ratio D/d.

6. Results of the large number of breakdown tests which are given show that in calculating the maximum stress in three-conductor cables the wall of insulation should be assumed equal to the total insulation between conductors rather than between conductors and the center of the cable, the delta voltage being used in the computation.

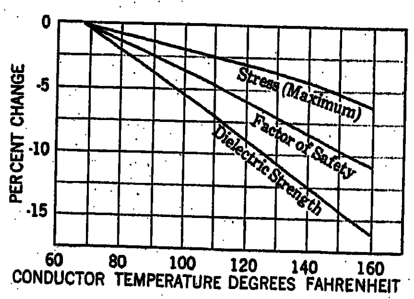

FIG. 23—EFFECT OF DIELECTRIC STRENGTH AND DIELECTRIC STRESS ON THE FACTOR OF SAFETY OF CAMBRIC CABLES
Per cent change in maximum stress vs. conductor temperature
Per cent change in dielectric strength vs. temperature
Per cent change in factor of safety vs. conductor temperature
Varnished cambric-insulated cable

7. Heat generated at the conductor of an insulated cable causes only a small change of capacitance of the insulation nearest the conductor and consequently only a slight "grading" of the cable. No dependence should be put upon the difference of temperature between conductor and outside of the cable to automatically grade the insulation.

Discussion

For discussion of this paper see page 611.

Corona in Air Spaces in a Dielectric

BY J. E. SHRADER
Associate, A. I. E. E.
Westinghouse Electric & Manufacturing Co., E. Pittsburgh, Pa.

Review of the Subject.—*The consideration of the extreme care necessary in preparing samples of a dielectric for test for electrical properties led to the investigation of the effect of air spaces, purposely formed of definite thickness and location, upon the power factor. This work in a way is an extension of some work done by Clark and Shanklin and Shanklin and Matson several years ago on air spaces in high voltage cables and wrapped armature coils. In their investigation the effect of assumed air spaces of indefinite thickness, extent, pressure and location was shown by plotting effective resistance from the formula* $R = \frac{E^2}{W}$ *against potential gradient. A characteristic curve was obtained, a sharp inflection point in the curve being interpreted as indicating the starting point of corona.*

In the work by the writer, various materials were investigated both with air spaces excluded as much as possible, and with air spaces of definite thickness, extent, and location at atmospheric pressure. The results were plotted showing variation of power factor with potential gradient. A definite increase in power factor with potential gradient indicated the starting of corona. The thicker air space with a given thickness of dielectric showed the more abrupt change in power factor, and this took place at a lower potential gradient. By plotting power factor against voltage, a maximum was shown indicating that a saturation of ionization was approached which resulted in a decrease in power factor.

By plotting effective resistance assuming the resistance to be in series with the dielectric and to be given by the formula $R = \frac{W}{I^2}$ *a very definite change in R as well as in power factor indicated the beginning of corona. The curve obtained in this way did not possess superior advantages over the plot for power factor for indicating corona and had the disadvantage that the points were somewhat scattered on the upper range of potential gradient.*

The results of the investigation show that:

1. It is extremely difficult to exclude air spaces from a dielectric so that it does not result in corona formation. Corona is shown by a more or less abrupt change in power factor with potential gradient.

2. The abruptness of the change in power factor with potential gradient depends upon the thickness of the air space, the thicker the air space the more abrupt the change.

3. The thicker the air space for any given thickness of dielectric the lower the potential gradient to produce corona.

4. The potential gradient to produce corona not only depends upon the thickness of the air space but also upon the extent of the air space as shown by observations on different areas of air space of the same thickness.

5. A maximum of power factor is reached with potential gradient indicating that saturation of ionization is approached after which the value of power factor decreases with potential gradient.

When measuring dielectric losses and power factor of insulating materials, it is of great importance that air should be excluded from the surfaces of contact with the electrodes and from the interior of the material. At low stresses, the losses and power factor are found to be lower than they should be because of the highly insulating air space. Likewise, the effective area of the material is smaller and consequently the measurements of the electrical properties are incorrect. At higher stresses, the gas spaces become ionized and corona formation results with the attendant increase in losses and power factor.

The phenomenon of corona formation in connection with loss measurements in high voltage cables and armature coils was observed by Clark and Shanklin[1] and was further studied by Shanklin and Matson[2]. In high-voltage cables and armature coils, air spaces no doubt exist which result in corona formation when overstressed.

In the case of materials built up in the form of cables and coils, it is practically useless to speculate from loss measurements as to the thickness or extent of the air space, its pressure and location. No assumption can safely be made even as to the partial pressures due to entrapped air and the vapors from the materials themselves.

It has been recognized that when an insulating space is filled with a composite dielectric such as a solid material and air having quite different dielectric constants the result is that the dielectric strength of the combination is lower than either one separately. For instance, when air which is a good dielectric and mica which is an excellent dielectric are used in combination, the result is a poorer dielectric than either used separately. This is due to the fact that an increased number of lines of force are concentrated in the air space which has the lower permittivity and this results in breakdown which throws a greatly increased stress upon the mica.

Air in a dielectric in the form of a cable, a wrapped armature coil or test piece with specially applied electrodes, may exist in two ways. Either, it may be in the form of an air film or bubble between layers or between the dielectric and the conductor, or it may be in the form of occluded gases in the interstices of the material. Both no doubt, produce losses at high-voltage stresses, though it is generally believed that air in films or bubbles gives rise to the greater part of the losses. It is impossible to separate the effect of occluded gases since the gases cannot be eliminated except by heat and vacuum, nor can they be excluded except by filling the spaces by some impregnating

1. Clark and Shanklin, A. I. E. E. Trans. Vol. XXXVI, 1917, p. 447.
2. Clark and Matson, A. I. E. E. Trans. Vol. XXXVIII, 1919, p. 489.

Presented at the Annual Convention of the A. I. E. E. Niagara Falls, Ont., June 26-30, 1922.

compound. By this process, however, the dielectric properties of the original sample are changed.

Though it is a difficult problem to study the effect of occluded gases on the losses of a dielectric material, the effect of various air spaces, which is by far the greater source of losses, may be studied by actually testing materials in which definite spaces are made and in which their locations are definitely established. It must be understood that the effect of occluded gases is also included in this effect, though in comparison with the former, it may be considered practically negligible.

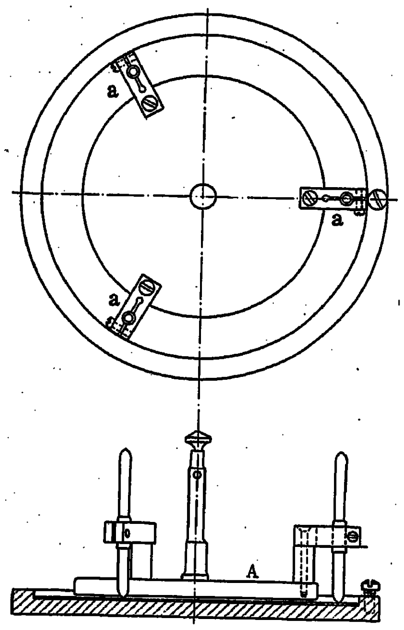

Fig. 1—Testing Electrode

The samples of insulation tested in connection with the effect of air spaces in this investigation, were all in the sheet form. In all cases except for glass, the surface of the material was made plane by fastening to an accurately plane brass disk. In the case of glass, the plane plate was floated upon mercury, the precaution being taken to free as nearly as possible any entrapped air from the under surface. The top electrode applied to the sample was so made that it could be adjusted for any desired air space between it and the specimen. This is shown in Fig. 1. The electrode *A* was a brass disk 7. 5 cm. in diameter with carefully rounded edges and polished surface. This was fitted with three arms *a, a, a,* through the outer ends of which passed three insulating quartz rods which formed a tripod support for the electrode. The quartz rods extended well out from the edge of the disk so that the insulating support was far removed from the electric field, since it is very essential that no dielectric having a different permittivity should be introduced in the air space in an electric field.

The air spaces of uniform thickness were formed between the upper disk and the dielectric by adjusting the quartz rods with spacers. The rods were then clamped in place by tightening the screws in the arms provided for that purpose, as shown in the diagram.

The loss measurements from which the power factor was determined were made with a sensitive electrostatic wattmeter. The current was measured by a sensitive electrometer shunted across a part of the non-inductive resistance of the wattmeter. The testing transformer was of 5 kw. capacity and the voltage was known to have a good sine wave. The voltage was varied by potential taps from the secondary of the transformer except where readings were desired at voltages between these steps. In this case, the voltage from the next step to the transformer, was varied by applying voltages to the primary by a potentiometer arrangement. The current in the potentiometer was quite large so that wave distortion was not introduced. Alternating voltages of 60 cycles were used throughout this investigation.

When materials with air spaces were tested, the potential gradient was increased to a point where there was a quite abrupt change in the losses and the current. The abruptness of this change was dependent upon the thickness and extent of the air space. Graphically the formation of corona is very clearly indicated by plotting power factor which involves both watts loss and current against potential gradient. The potential gradient was taken as volts per centimeter between the plates. For all materials having appreciable air spaces the power factor is low before corona forms, after which it rises rapidly to a maximum and then

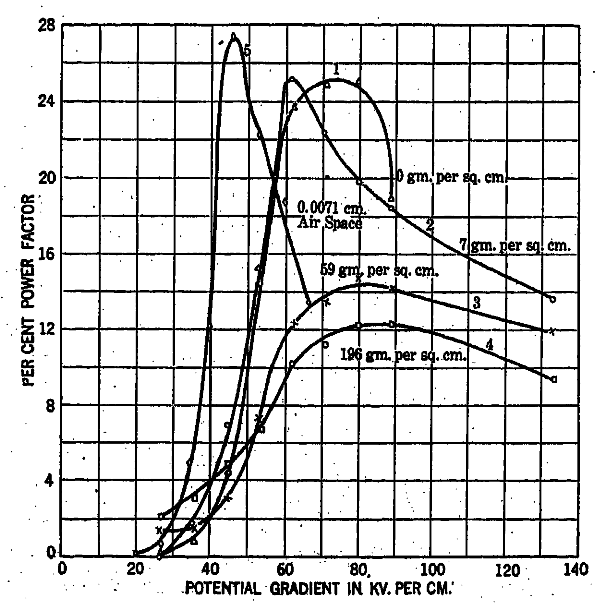

Fig. 2—Corona in Air Spaces

60 Cycles

White India mica, 0.026 cm. thick.

Variation of power factor with pressure on specimen.

again decreases with potential gradient, the sharpness of the fall depending upon the thickness of the air space.

A number of materials were tested with variations of air spaces and the results are shown by the following curves.

A sheet of White India mica about 11 cm. in diameter and 0.023 cm. thick, was selected for test. The specimen was clear and fairly free from air spaces between laminations. It was first tested by placing

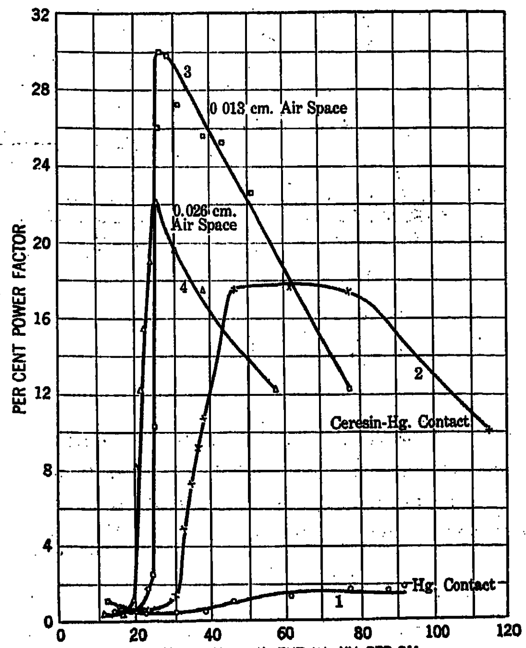

FIG. 3—CORONA IN AIR SPACES
60 Cycles
White India mica, 0.026 cm. thick.

the mica upon the brass plate and then laying the other electrode on the top surface. The tests were then repeated placing different weights upon the upper electrode. The variation of power factor with potential gradient for various pressures from zero where the weight of the electrode was just supported by the quartz rods to 196 grams per square centimeter are shown in Fig. 1. In these curves, the thickness of the air spaces were not known, though it can be presumed that they decreased with pressure. Curve 5 was obtained by raising the upper electrode a distance of 0.007 cm. above the mica. In each of these cases, there was an air space on each side of the mica presumably of equal thickness except for the last where the greater air space was on the upper side. In general, the power factor at low voltage was always greater for the greater pressure or thinner air space. Likewise, the potential gradient to produce corona was lower for the smaller pressure or thinner air space.

The change in power factor with potential gradient was more gradual the thinner the air space. With a thicker air space, 0.007 cm., the change in power factor was quite abrupt. It is also observed that in all these curves a maximum power factor was reached, after which the power factor decreased in value. In this test, the specimen of mica was not perfectly flat so that the air spaces were not of uniform thickness. A test for power factor was now made with mercury electrodes care being taken to eliminate as far as possible any air films. The result is shown by Curve 1, Fig. 3. It is to be observed that the increase in power factor did not take place until a value of 40 to 45 kilovolts per centimeter was reached. At that point, the increase was not great but the curve clearly gives evidence of an air film either at the surfaces of contact or between laminations. The sample was now fastened to the lower plate by melting a layer of ceresin upon it and pressing the mica upon it by a one half-ton press. Small air spaces were still clearly shown in the surface of contact even though the whole had been heated for some time at about 100 deg. cent. and had been pressed as stated. This fact illustrates how difficult it is to free a test piece from air spaces. The result of the test with mercury contact on the top surface is shown in curve 2. The abrupt change in power factor now occurred at a lower value, about 30 volts per cm. A flat-topped maximum was quickly reached after which

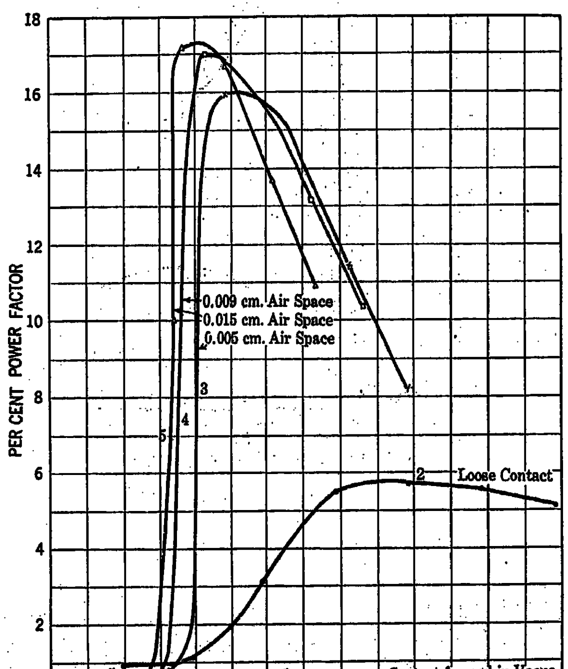

FIG. 4—CORONA IN AIR SPACES
60 Cycles
Ceresin wax layer, 0.025 cm. thick

the power factor decreased. For an air space of 0.013 cm. the corona started at 22 kv. per cm. and a sharp maximum of 30 per cent power factor was reached at 27 kv. per cm. With a 0.026-cm. air space, corona started at about 19 kv. per cm. and a sharp maximum was reached at 26 kv. per cm. The maximum for this

greater air space was not so great as for the 0.013-cm. air space, which is somewhat contrary to what was generally found. This may have been caused by a change in surface conditions due to the previous application of voltage.

In Fig. 4, are shown the results for a ceresin wax layer 0.025 cm. thick. Curve 1 was obtained by melting the ceresin wax in vacuo in a shallow plane-bottom tray and lowering upon it in vacuo the upper electrode adjusted for the desired thickness. The vacuum was then released and the specimen was allowed to cool. In this way, it was thought that the sample was completely rid of moisture and that air spaces were not included. The results of tests are shown in Curve 1. The curve shows only a very slight uniform rise of power factor up to 140 kv. per cm. Another layer melted in vacuo

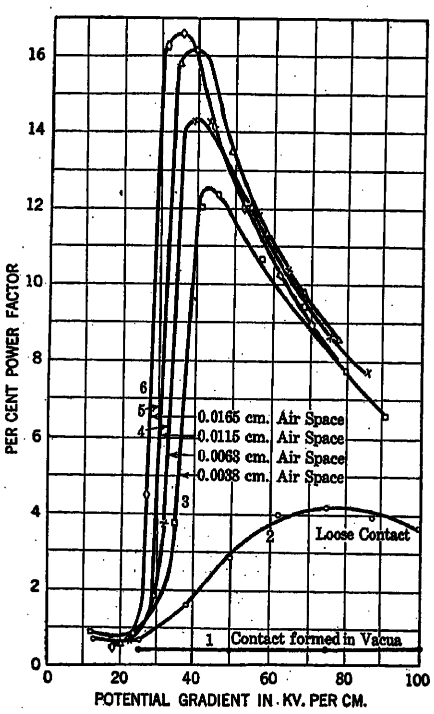

FIG. 5—CORONA IN AIR SPACES

was prepared in the shallow tray and was placed upon a level surface and allowed to solidify. In this way a smooth layer of uniform thickness was obtained. Curve 2 was obtained by laying the upper electrode loosely upon the layer of wax. Curves 3, 4 and 5 were obtained with air spaces 0.005, 0.009 and 0.015 cm. thick, respectively. As shown by these curves corona formed at lower potential gradients for the thicker air spaces. Likewise, for the thicker air space, the maximum value of power factor was greater, as one would expect if the greater loss took place in the air space.

In Fig. 5 are shown the results of tests for a thicker layer of wax (0.041 cm.) prepared in the same manner

as above. The results are much the same as in the previous test except that for the thicker layer corona took place at a lower potential gradient and the values of the maxima were slightly lower. Fig. 6 shows re-

sults for a still thicker layer of wax (0.056 cm.). For this thicker layer the potential gradients for corona formation were at still lower values, but the maxima of power factor were lower. Further, with this thicker layer of wax, there is a greater variation in the maxima

of power factor for the different thicknesses of air spaces.

In Fig. 7 are shown the results for condenser paper impregnated in ceresin. Curve 1 was obtained by

drying and impregnating and placing the upper electrode on the material in vacuo. In this way all moisture and air should have been completely removed. The curve shows that the power factor is independent of potential gradient. Curve 2 was obtained by placing the upper electrode loosely upon the impregnated condenser paper. Curve 3 was obtained with the same specimen with a 0.013-cm. air space between the impregnated paper and the upper electrode.

istics, the curve for the thicker air space showing corona at a lower potential gradient but both having about the same maximum value of power factor.

Fig. 9 shows the curves obtained with a glass plate

0.140 cm. thick. All the curves were obtained with the plate floated upon mercury with especial care taken to exclude as far as possible any air films on the bottom surface. Curve 1 for mercury contact also on the top surface shows slight corona formation at 21 kv. per cm. Curve 2 for loose plate contact shows corona at a lower value, about 12 kv. per cm. With air spaces of 0.013 and 0.026 cm., corona was shown at about 11 kv. per cm. The difference between the values of potential

gradient to produce corona was small because of the thinness of the air space in comparison with the thickness of the glass plate.

Fig. 10 shows the results for treated cloth 0.023 cm. thick. The cloth and plate were given a very thin coat of varnish and pressed together and placed in an oven at 100 deg. for two hours. At the end of this time, they were placed under a one half-ton press and allowed to cool. By this treatment, the varnish was not completely dried as shown at the end of the experiment. Curve 1, obtained with mercury contact on the upper surface, shows a minimum of power factor with potential gradient followed by a maximum after the beginning of corona. Curve 2, for loose contact, shows only a slight minimum if any but a much greater maximum. Curves 3 and 4 show a very abrupt change in power factor at about 25 and 23 kv. per cm. respectively. With these curves as with others, the falling off of power factor with potential gradient after the maximum was reached was more rapid with the thicker air space. In these curves where the power factor is larger at low voltages, the effect of air spaces in lowering the power factor before corona forms is more clearly shown.

Fig. 11 shows the results for two layers of treated cloth each rubbed with a slight amount of vaseline and each pressed tightly to a surface of each plate. The sample was not heat-treated in any way. Curve 1 was obtained by laying one plate upon the other with the surfaces of the two sheets of treated cloth in loose contact. Curves 2 and 3 were obtained with air spaces of 0.013 and 0.026 cm. between sheets respectively. These curves are less in agreement with the general types of curves previously obtained, due, no doubt to change in condition of the specimen during continued application of voltage.

Fig. 12 shows the results for manilla paper 0.021 cm. thick, vacuum dried, and impregnated with petroleum jelly. This material was supplied through the courtesy of the Habirshaw Electric Cable Co. Curve 1 was obtained with one sheet of paper. The excess of petro-

leum jelly was removed and air bubbles were excluded and pressure was applied to secure close contact. The curve shows that the power factor was practically independent of voltage. At slightly higher potential gradient, breakdown occurred but there was no noticeable corona formation up to that point. Curves 2 and 3 were obtained with air spaces of 0.013 and 0.026 cm. respectively. The potential gradient was not

raised to the point where a maximum power factor was obtained, but the curves show a corona formation for the thicker air space at a lower potential gradient. Curve 4 was obtained by placing upon the lower sheet of paper a second sheet having a hole 7.7 cm. in diameter. Upon this second sheet was placed symmetrically a brass disc about 10 cm. in diameter. In this way a confined air space 0.021 cm. thick was formed. The characteristics of this curve are not different from what had been obtained with the unconfined air space.

The curves in Fig. 13 were also obtained with the manilla paper impregnated with petroleum jelly. Curve 1 was for three layers closely pressed together by a one half-ton press. The curve shows that all air spaces were not eliminated. Curve 12 shows the results

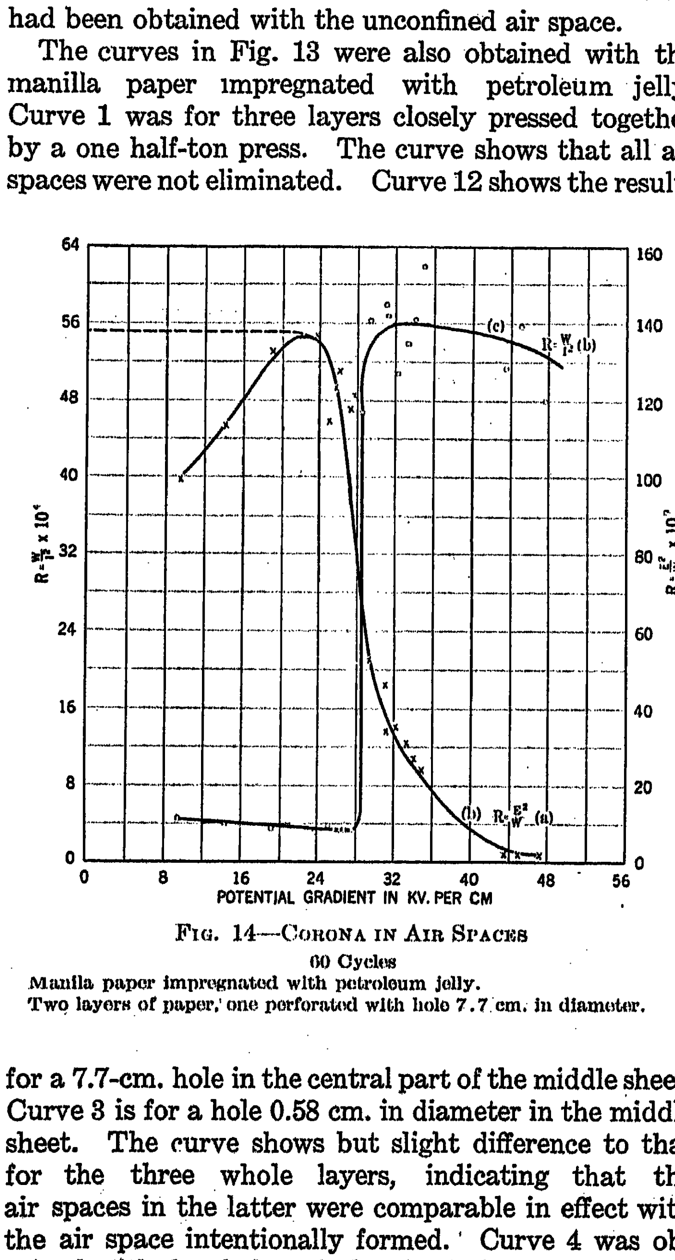

FIG. 14—CORONA IN AIR SPACES

Two layers of paper, one perforated with hole 7.7 cm. in diameter.

for a 7.7-cm. hole in the central part of the middle sheet. Curve 3 is for a hole 0.58 cm. in diameter in the middle sheet. The curve shows but slight difference to that for the three whole layers, indicating that the air spaces in the latter were comparable in effect with the air space intentionally formed. Curve 4 was obtained with five holes of the same size grouped near the center of the space beneath the upper electrode. Curve 5 was obtained with fifty-one holes of the same size laid out in regular pattern in the middle sheet between the electrodes. This curve does not differ greatly from Curve 2 for one large hole 7.7 cm. in diameter. In all these curves for the same thickness of dielectric, corona formation is indicated at the lower voltage for the greater area assuming the thickness of air space the same. Curve 5 which was carried to a higher potential gradient than Curve 2 shows a marked increase in power factor above 46 kv. per cm. This may have been due to heating as the voltage was in the neighborhood of breakdown.

In the work referred to by Clark and Shanklin[1] they plotted effective resistance considered in parallel with the dielectric against potential gradient where they defined effective resistance by the expression $R_{eff} = \frac{E^2}{W}$ where E is the potential in volts and W is the watts loss. These investigators state that the characteristic form of curve is hard to obtain because of the exactness with which E is obtained, the square of which appears in the formula. If it is assumed that the effective resistance is in series with the test sample and the value of this quantity is obtained by the expression $R_{eff} = \frac{W}{I^2}$ where W is the loss and I is the current much more definite curves may be obtained though they are quite different. As an example, the data from which Curve 4, Fig. 12 was obtained were used to calculate the effective resistance by the two formulas. These are shown in curves a and b, Fig. 14. It is shown that the characteristic curve obtained by Clark and Shanklin, indicated by the dotted curve, is not obtained though no great trouble was taken to obtain very accurate values of E. This curve, however, is as near the form of the characteristic curve obtained by Clark and Shanklin as any which have been plotted by the writer. Curve b calculated by the formula $R_{eff} = \frac{W}{I^2}$ is quite definite and shows quite sharply the starting point of corona. Further the points below the starting point of corona are quite definite in comparison to those for the same data plotted in curve a. The points in the upper range of the Curve b, on the other hand, are not as definite as those in Curve a. The points in Curve a by the formula probably are indefinite more on the account of inaccuracy in the measurement of W than of E, since at low-potential gradients the losses are quite small and a large per cent of error may be made in measuring a very small quantity. Because the points are definitely determined for power factor, over the whole range of potential gradient, and since this plotting shows definitely the starting point of corona, the writer in this investigation chose this method of plotting results to show the starting point of corona caused by the ionization of air spaces in a dielectric.

In this paper so far, as well as in the paper by Clark and Shanklin, no attempt has been made to analyze the mechanism of the phenomena observed. No doubt the mathematical relations of the quantities involved

could be worked out but that is outside the scope of the present paper. Physically, the relations shown in this paper may be expressed as follows: For any combination of air and a dielectric tested at low voltage, the losses should be in the dielectric, since the number of free ions in the air are small compared to the number in the dielectric. The losses in a good dielectric such as those used in these experiments should be in the nature of hysteresis losses rather than true ohmic losses, and would best be represented as a resistance in series with the dielectric. As the potential gradient is raised the free ions in the air space, though few in number at the start, soon acquire sufficient velocity to ionize other gas molecules in their path by the process known as ionization by collision. In this way, the ionized gas molecules are greatly multiplied until a point is reached where the characteristic discharge known as corona takes place. At this point the greater proportion of the losses occur in the air space and a large increase in current and losses are observed, the relation being such as to greatly increase the power factor. As the potential gradient is increased more ionization due to the increased velocity results and this produces greater losses and greater power factor. However, a point is reached in potential gradient where the greater proportion of gas is ionized so that further increase in potential gradient does not produce a corresponding increase in ionization. At this point then the change in the rate of increase of losses decreases and a lowering of the power factor is observed. According to this theory then these changes should be more pronounced with the thicker air space since the rate of multiplication of the ions is proportional to the distance they travel in the air space. This is in agreement with the observed results. With a thin air space, the free ions do not acquire a sufficient velocity to produce other ions in their path, hence corona is not observed at as low a potential gradient as for a thicker air space. Hence for a thin air space a higher potential corresponding to a higher velocity of the ions is necessary for corona formation, as has been shown in this investigation.

It is realized that the scope of this work may be extended and application be made to practical problems in which something is known of the actual conditions existing. Only the simplest conditions have here been considered, for it has been realized that the subject of losses in insulating materials is sufficiently complex under these conditions and that the introduction of many variables which may be eliminated only introduces confusion and speculation.

Discussion

For discussion of this paper see page 611.

The Action and Effect of Moisture in a Dielectric Field

BY DELAFIELD DU BOIS
Associate A. I. E.E.
Safety Insulated Wire and Cable Company, Bayonne, N. J.

***Review of the Subject.**—In studying the subject of dielectric loss in electric cables the author has become convinced that the moisture content of the dielectric is the dominant factor determining the a-c. resistance. Evershead's explanation of the action of moisture in a fibrous dielectric seems plausible but leads to the conclusion that moisture causes a decrease of a-c. resistance with increasing voltage, whereas the experience of the author is that with a fairly well dried dielectric a-c. resistance is independent of voltage, and that decreasing the moisture content still further gives higher and higher a-c. resistance, with no limit in sight. It seems obvious, therefore, that Evershead has not fully covered the subject. In order to get a picture of the action of moisture in a dielectric field the author has assumed a simply hypothetical case and tried to follow it to its logical conclusions. He assumed a pure dielectric of a homogeneous and plastic nature between parallel electrodes and subject to electric stress. He then mentally placed a very small globule of conducting moisture in the dielectric and watched the action. Under constant potential stress the moisture elongated into a thread-like filament until it bridged the dielectric. But under alternating stress the moisture globule, if sufficiently small stretched out only a short distance and then no further, no matter how high the voltage. This showed how the a-c. resistance could be independent of the voltage and yet depend upon moisture.*

Following up the analysis the author was surprised to find that such a dielectric, containing particles of moisture would show absorption and residual charge and many other characteristics of actual insulation. He also found that certain unusual test data, obtained while testing cables, could be explained as due to a breaking up of the moisture filaments by evaporation. The author does not claim that the paper that follows meets the complexity of actual insulation, but rather that it adds to our conception of the importance of moisture in its effect upon a dielectric field.

CONTENTS

THE phenomena observed when investigating and testing insulation can be classified into two groups. The first of these groups would comprise all the phenomena that a perfect insulator or pure dielectric would have. The second group would comprise all the phenomena of imperfection, such as leakage, dielectric loss, etc. In an attempt to account for the observed phenomena of this second group, it seemed advisable first to study a simple hypothetical case and to trace out the phenomena that might in that case be expected.

The case chosen was that of a pure dielectric between parallel plate electrodes and containing, embedded in it, minute particles of conducting moisture. The case was considered both with constant potential and alternating potential across the electrodes and with variations of voltage, temperature and frequency.

It is not claimed that the analysis that follows is complete, as a complete mathematical treatment would be extremely complex. The analysis shows, however, that a dielectric with many particles of moisture embedded would have all the characteristic phenomena actually found in insulation. The inference is, therefore, that all of these phenomena, of the second group, can be explained as due to the presence of moisture in the insulation.

CONSTANT POTENTIAL FIELD

Consider first the forces that would act upon any single one of many particles of conducting moisture in a dielectric field with constant potential across the electrodes. Obviously if such a particle elongated into a filament of moisture, stretching in the direction of the dielectric field, it would reduce the energy of the field by shortening dielectric flux lines. It follows that a dielectric force would act upon the particle to

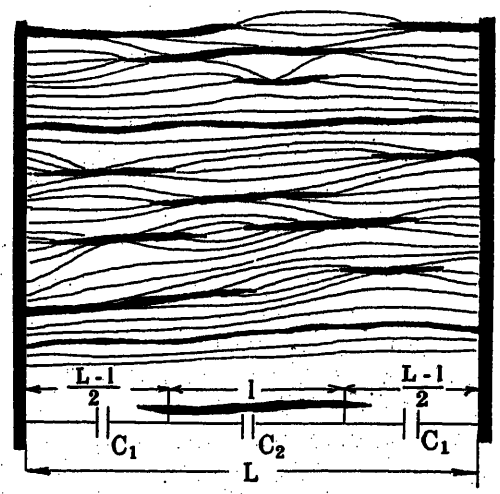

FIG. 1

produce such an elongation. We may designate this force as F_1

$$F_1 = \frac{E^2 \, d\, C_1}{d\,(L - l)} \qquad (1)$$

where C_1 is the capacitance between an end of the filament and the nearest electrode and E_1 the voltage

Presented at the Annual Convention of the A. I. E. E., Niagara Falls, Ont., June 26-30, 1922.

across this capacitance. L and l are the length of the dielectric and the length of the filament respectively, as shown in the diagram, Fig. 1.

C_1 and $\frac{d\,C_1}{d\,(L-l)}$ can hardly be expressed mathematically as they depend not only upon the dimensions of the single moisture particle or filament considered, but also upon the dimensions and arrangement of the other moisture particles and filaments in the dielectric.

As the filament elongated l would increase and C_1 would increase, increasing F_1, but as C_1, increased, and the filament included more and more lines of dielectric force, a current would flow through the filament and this current, flowing through the resistance of the filament, would produce a potential drop along the filament E_2. F_1 can therefore be expressed as

$$F_1 = (E - E_2/2)^2 \frac{d\,C_1}{d\,(L-l)} \qquad (2)$$

E_2 would be a function of the rate of change of l with respect to time and also of the resistance of the filament. Since the volume of moisture does not change, we may assume for the resistance of the filament $R = \frac{l^2}{\gamma\,A}$ where γ represents the conductivity of the liquid and A the section of the filament when $l = 1$. A also is the volume of moisture of the particle. We may therefore write

$$E_2 = f_1\left(\frac{d\,l}{d\,t}\right) \times \frac{l^2}{\gamma\,A} \qquad (3)$$

and

$$F_1 = \left(E - f_1\left(\frac{d\,l}{d\,t}\right) \frac{l^2}{2\,\gamma\,A}\right)^2 \frac{d\,C_1}{d\,(L-l)} \qquad (4)$$

When current flowed through the filament, the drop of potential along the filament would set up a secondary field in the dielectric. This field would emanate from the filament exactly as magnetic lines of flux emanate from a straight bar magnet, and it would be nearly similar to the field that would be set up if the filament were replaced by two small electrodes in the dielectric, spaced a distance apart slightly less than the length of the filament and with a potential drop between them corresponding to the potential drop along the filament. The distance l may be considered as the distance that would separate such electrodes, and the capacitance of the secondary field C_2 would be the capacitance between such electrodes.

This secondary field would act to shorten the filament and the force of this field would be

$$F_2 = -\frac{E_2^2\,d\,C_2}{2\,d\,l} \qquad (5)$$

or by equation (3)

$$F_2 = -\left(f_1\left(\frac{d\,l}{d\,t}\right) \times \frac{l^2}{\gamma\,A}\right)^2 \frac{d\,C_2}{2\,d\,l} \qquad (6)$$

The actual dielectric field would at any instant be a resultant field of what are here called the primary and secondary fields.

As the filament elongated friction would act to retard the elongation. This force of friction would increase as the filament attenuated and would depend upon the section of the filament, upon the nature of the dielectric and upon the rate of flow; it can be expressed as

$$F_3 = -f_2\left(\frac{d\,l}{dt}\,l/A\right) \qquad (7)$$

Surface tension would also act upon the filament to contract it. If we assume that the force of surface tension

$$F_4 = -K\frac{d\,s}{d\,l}$$

where S is the surface of the filament, we may write

$$F_4 = -K\frac{\sqrt{\pi\,A}}{\sqrt{l}} \qquad (8)$$

Considering all of the above forces as acting upon the filament we can write, for an elongation $\frac{d\,l}{d\,t}$

$$\left(E - f_1\left(\frac{d\,l}{d\,t}\right)\frac{l^2}{2\,\gamma\,A}\right)^2 \frac{d\,C_1}{d\,(L-l)} - \left(f_1\left(\frac{d\,l}{d\,t}\right)\frac{l^2}{\gamma\,A}\right)^2 \frac{d\,C_2}{2\,d\,l} - f_2\left(\frac{d\,l}{d\,t}\,l/A\right) - \frac{K\sqrt{\pi\,A}}{\sqrt{l}} = 0 \qquad (9)$$

The relation $\frac{d\,l}{d\,t}$ to the other factors is obviously very complex but certain useful relations can be deduced from this equation by inspection.

It is obvious that if either A or γ is increased $\frac{d\,l}{d\,t}$ will also increase. In other words a large particle of moisture will elongate more rapidly than a small one. A moisture particle containing more impurity will elongate more rapidly than one with less impurity, and, since conductivity increases with temperature, a hot moisture particle will elongate more rapidly than a cold one. It also seems to show that if A is small $\frac{d\,l}{d\,t}$ decreases rapidly as l increases.

Forces F_2 and F_3 tend to slow down the elongation but can not stop the filament from elongating. Force F_4 would decrease as l increased. It would seem then that no matter how small the filament became, it would ultimately bridge the dielectric—even if it became atomic in section.

When the filament finally bridged the dielectric, the forces F_1 and F_3 would disappear, but the filament

would now carry leakage current and would assume a gradient equal to the dielectric gradient. The dielectric field due to the potential drop along the filament would, therefore, remain, and the forces F_2 and F_4 would remain. These forces would hold the filament taut, but could not disrupt it or pull it away from the electrodes, for, if at any place along the filament the filament became thin, preparatory to a break, the resistance of that section would increase and the voltage gradient along that section would also increase. The resulting dielectric field would exert a force along the filament that would tend to flood the thin section in the filament with moisture from the thicker sections.

The filament would carry current electrolytically, that is, current would flow by migration of ions, and if the temperature of the liquid increased the velocity of migration would increase and possibly the degree of ionization would also increase. It follows that the leakage current would be greater if the dielectric were hot than if it were cold.

With current flowing in the filament, heat would be generated along the filament and this would increase the temperature of the filament and thus increase its conductivity. With increased conductivity the heat generated would increase and the temperature become still higher. This would result in a vicious circle, were it not for the fact that heat conduction to the surrounding dielectric would also increase with increasing difference of temperature between the filament and the dielectric, so that a condition of equilibrium would usually be reached. With a very small filament the ratio of heat generated to cooling surface would be small and such a filament would remain very close to dielectric temperature. Such a filament would show a resistance practically independent of the voltage between electrodes. If, however, the filament were large, we might expect resistance to decrease as voltage between electrodes increased.

If the temperature of the filament became sufficiently high, evaporation would occur, disrupting the filament. Evaporation might result in a general drying up of the filament, the moisture either leaving the dielectric or else forming a new filament or filaments in the dielectric adjacent to the original filament. Another possibility would be that the evaporation, being greatest at some one point, the resistance of that point would increase. The point would then become a hot spot and evaporation would further increase—a vicious circle ending in a local disrupture of the filament and a pushing apart of the sections by the resulting puff of vapor. This would decrease the flow of current and consequently the vapor would at once condense and the filament would be reunited, not only by the dielectric forces appearing across the gap in the filament, but also due to the vacuum when the vapor condensed. As soon as the sections of the filament united, in fact as soon as the ends touched, the action would be repeated—but the average conductivity would be reduced. With very large filaments evaporation might prevent any stable bridging of the dielectric.

The voltage at which evaporation first occurred would depend upon the size and conductivity of the filament. The larger the filament and the better its conductivity the lower the voltage of evaporation.

The voltage at which evaporation first occurred would also depend upon the temperature of the dielectric. The higher that temperature the lower would be the voltage of evaporation.

If a dielectric contained many particles of moisture, each of these particles would start elongating into filaments, but if the number of particles were great many of them would link up as they formed. This of course would decrease the time necessary to bridge the dielectric. Since, then, the time to bridge the dielectric depends both upon the number of particles and upon their size, it follows that the greater the moisture content of the dielectric the smaller the time required for the filaments to bridge the dielectric.

If a bridge were formed by the linking up of filaments as they elongated from particles of moisture of different sizes and conductivities, the voltage gradient across the bridge would not, at first, be uniform but the dielectric stresses set up along the filament, due to the gradient, would be greatest where the filament was highest in resistance. The result would be that an internal flow of moisture would occur until the gradient was uniform throughout.

If a dielectric containing many particles of moisture had voltage, from a source of constant potential, suddenly applied across the electrodes, the first rush of current would be the changing current of the dielectric. The maximum value of this current and its attenuation would depend upon the constants of the dielectric and the circuit and, if it were not for the moisture held by the dielectric, this current would soon drop to zero. However, as soon as voltage was applied, filaments of moisture would begin to form and, in forming, would apparently increase the capacitance of the dielectric by shortening the lines of force. The changing current would, therefore, persist beyond the normal time though gradually decreasing, as more and more of the filaments bridged the dielectric and the rate of change in length of others became less. But not until all of the filaments finally bridged the dielectric, would the changing current become zero. Leakage current would at first be zero but, as the filaments began bridging the dielectric, leakage current would increase. This increase in leakage current would at first be rapid, as the larger filaments and the filaments that linked up easily formed their bridges, but as the rate of bridging and the size of the filament that bridged became smaller and smaller the increase in leakage would become slower. Leakage would become maximum as changing current became zero. The action is shown diagrammatically in Fig. 2.

If the moisture content of the dielectric were great the action in building out filaments would be rapid and the leakage large. In that case as shown diagrammatically in Fig. 3 the current would reach its final value very soon after the application of voltage.

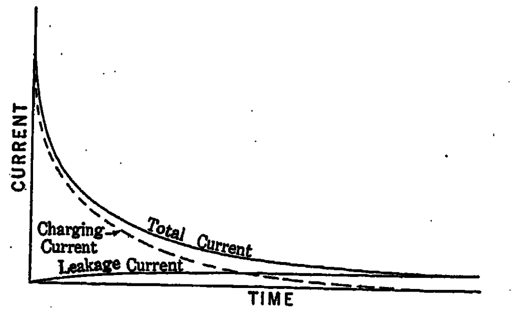

FIG. 2—"ABSORPTION" MOISTURE CONTENT SMALL

The phenomenon illustrated in Figs. 2 and 3 is apparently identical with what is usually called "absorption."

If a dielectric under electric stress, and bridged by filaments of moisture, were discharged by short circuit,

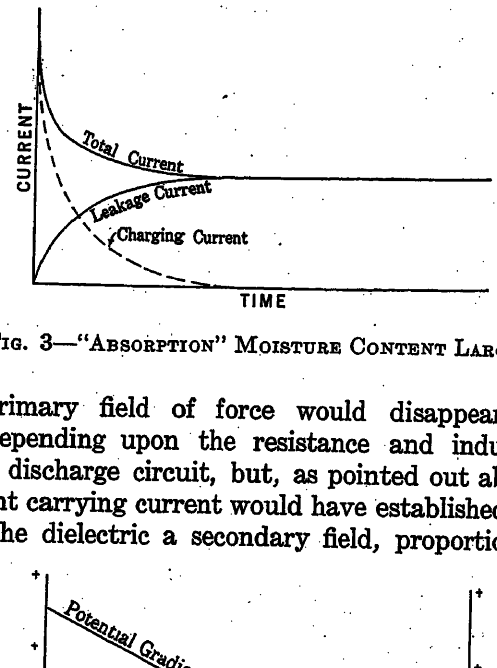

FIG. 3—"ABSORPTION" MOISTURE CONTENT LARGE

the primary field of force would disappear at a rate depending upon the resistance and inductance of the discharge circuit, but, as pointed out above, a filament carrying current would have established along it in the dielectric a secondary field, proportional to

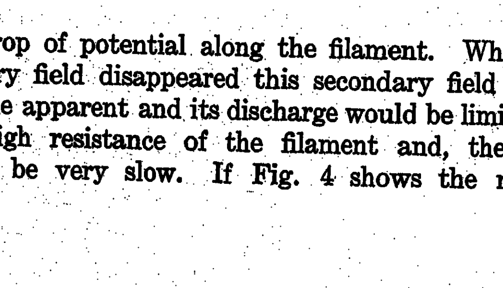

FIG. 4—NORMAL GRADIENT—DIELECTRIC CHARGED

the drop of potential along the filament. When the primary field disappeared this secondary field would become apparent and its discharge would be limited by the high resistance of the filament and, therefore, might be very slow. If Fig. 4 shows the normal gradient and flow of current along a filament under constant conditions in a changed dielectric field, the change in this gradient and current flow upon short-circuiting the electrodes would be as shown in Fig. 5.

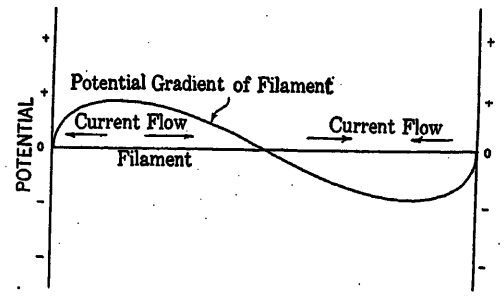

FIG. 5—FILAMENT GRADIENT—ELECTRODES SHORT-CIRCUITED

If left short-circuited long enough, the secondary field would become fully discharged and the gradient would disappear, but if, before that, the short circuit were removed the primary field would become reestablished

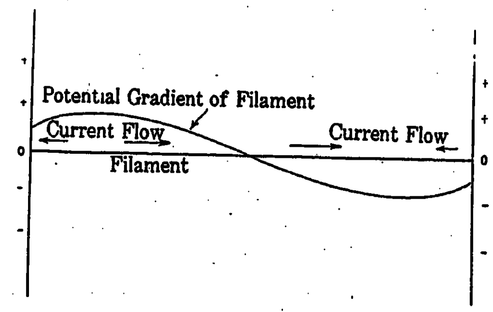

FIG. 6—SHORT CIRCUIT RMOVED—ELECTRODES RECHARGING FROM FILAMENT

by the secondary fields of all the filaments, as shown in Fig. 6 and 7.

The phenomenon illustrated in Figs. 4, 5, 6, and 7 is apparently identical with what is usually called "residual charge."

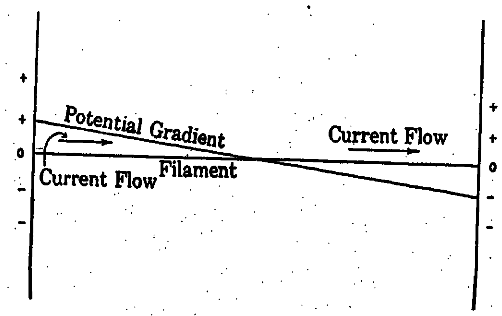

FIG. 7—"RESIDUAL CHARGE"

Discharge of the residual voltage would take place by leakage through the filaments until finally all difference of potential disappeared. When that occurred the force of surface tension would contract the filaments, but in contracting they would break up into small particles distributed along the paths of the filaments.

Alternating Field

As in the case of the constant-potential field already considered, particles of moisture embedded in an alternating dielectric field would be acted upon by four forces: F_1, a dielectric force acting to elongate them into filaments and due to the primary dielectric field; F_2, a contracting force due to secondary dielectric fields set up by the potential drop along a filaments; F_3, surface tension; F_4, friction.

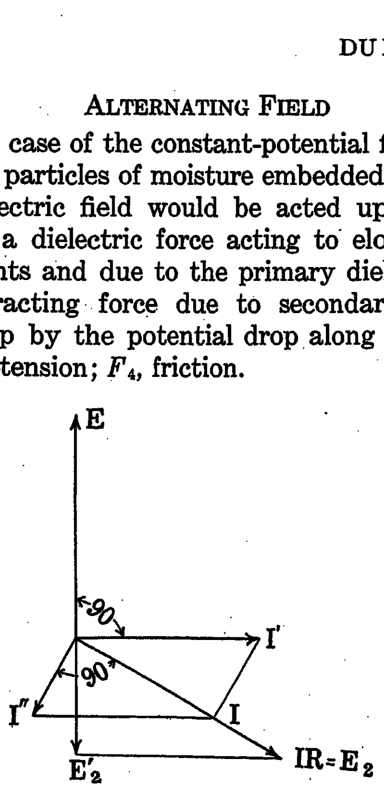

Fig. 8

The alternating field case is, however, rather more complicated than the other, because currents flow through the filaments whether the filaments are elongating or not. Thus, force F_2 is now not merely in the nature of a retarding force but acts to oppose force F_1 even if the filament is not elongating. Forces F_1 and F_2 are pulsating and not in phase.

To analyze the action, consider one filament of moisture, of many, in an alternating dielectric field. Alternating current I (see Fig. 8) would flow in the filament and this current can be considered as the resultant of two currents I' and I'', the first I' due directly to the main field, and proportional to the number of lines of force of that field entering the filament. This current would lead the electrode voltage E by 90 deg. I'', the second component of I is a current due to the secondary field set up in the dielectric by the voltage drop $I R$ along the filament. $I R$ is in phase with I and I'' leads this phase by 90 deg. It follows that E_2 leads E by more than 90 deg., and E_2 may be divided into two components, one of which E_2' is 180 deg. in phase from E. E_2', therefore, lessens the dielectric flux received by the filament and therefore lessens the force acting to elongate the filament. I of course, is proportional to the actual dielectric flux received.

The force F_1 would have a wave of double frequency and may be considered all positive. Its maximum values would occur when E was at full value either positive or negative. The force F_2 would also be of double frequency, and may be considered entirely negative. Its maximum values would occur when E_2 was at full value either positive or negative. The combination of these two forces would give a wave of force with both positive and negative values and with an intermediate phase. Due to friction, which in a small filament would be high, the filament could not respond to the rapid variation of the force cycles but would respond to the average resultant force F', of the force cycles of F_1 and F_2. If F' were positive in direction and exceeded the surface tension force F_3, the filament would continue to elongate, but elongation would cease if the forces F' and F_3 became equal and opposite in direction.

As the filament elongated its resistance would increase and, assuming that the total volume of moisture did not change, the resistance of the filament would increase in proportion to the square of its length. Although the current I might decrease as the filament lengthened, the voltage drop along the filament would be found to increase, and this would increase the force F_2. It would also swing the phase of the voltage E_2 further in advance of E and increase the component E_2' thus decreasing the force F_1. When the attenuation of the filament reached a certain degree the forces acting upon it would be in equilibrium and no further elongation would take place.

To show this a little more definitely it is convenient to consider the case from an energy standpoint, as all bodies, either conductors or insulators, in a dielectric field, tend to move or form themselves so as to take the max mum possible energy from the field. Thus if by elongating the energy loss in a filament would become greater, dielectric forces would tend to elongate the fi ament but the filament would not elongate if elongation meant a decrease of energy. The heat produced in the filament is a measure of the energy it takes from the field.

In Fig. 9, Let

$$1/r = g \qquad 2\,\pi\,f\,C_1 = b_1 \qquad 2\,\pi\,f\,C_2 = b_2$$

The admittance of the parallel circuit would be $y_2 = \sqrt{g^2 + b_2^2}$ and the impedance of the total circuit would be

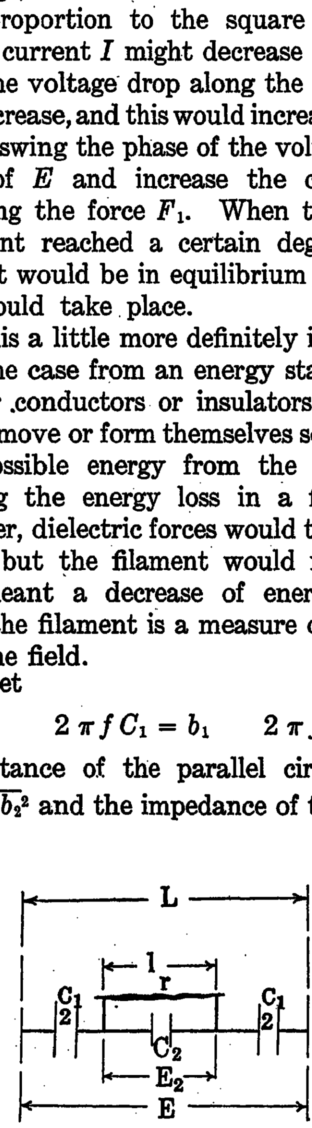

Fig. 9

$$z = \sqrt{\left(\frac{g}{g^2 + b_2^2}\right)^2 + \left(1/b_1 + \frac{b_2}{g^2 + b_2^2}\right)^2} \qquad (10)$$

It follows that since

$$E_2 = \frac{E_1}{y_2\,z}$$

and power loss in heating the filament $P = E_2^2\,g$

that
$$P = \frac{E^2 g}{\dfrac{g^2 + b_2^2}{b_1^2} + 2\dfrac{b_2}{b_1} + 1} \qquad (11)$$

As the filament lengthened out and l increased g, b_1 and b_2 would change in value

$$g = \frac{A\,\gamma}{l^2}$$

where γ is the conductivity of the liquid and A the sectional area at unit length, which equals of course the volume of the liquid

$$\frac{d\,b_1}{d\,l} \quad \text{and} \quad \frac{d\,b_2}{d\,l}$$

are actually rather complicated functions of L and l; and b_1 does not increase as rapidly as $L - l$ decreases, nor does b_2 decrease as rapidly as l increases, but if a value of l can be found giving P a maximum value on the assumption of direct proportionality it may be inferred that at some shorter value of l the filament would attain its maximum length.

Assume therefore $\quad b_1 = \dfrac{B\,F}{L - l}$

and $\quad b_2 = B/l$

when B is the value of b_2 when the filament is of unit length and F a factor of proportionality between the two fields.

The equation can now be written

$$P = \frac{\dfrac{E^2 A\,\gamma}{l^2}}{\dfrac{\dfrac{A^2\,\gamma^2}{l^4} + B^2/l^2}{\dfrac{B^2 F^2}{(L-l)^2}} + 2\,\dfrac{B\,(L-l)}{l\,B\,F} + 1} \qquad (12)$$

which reduces to

$$P = \frac{E^2 B^2 F^2 \dfrac{l^2}{(L-l)^2}}{A\,\gamma + \dfrac{l^4 B^2}{A\,\gamma}\left(1/l + \dfrac{F}{L-l}\right)^2} \qquad (13)$$

If L is taken as unity, and l is small with respect to L this reduces to

$$P = \frac{E^2 A\,\gamma\,B^2 F^2}{\dfrac{A^2\,\gamma^2}{l^2} + B + 2\,F\,B\,l + B\,F^2\,l^2} \qquad (14)$$

Differentiating this with respect to l and equating to zero gives

$$A^2\,\gamma^2 - F\,B\,l^3\,(1 + F\,l) = 0$$

F will not be a very large number and if l is small $\times\, l + F\,l$ can be considered unity and we may write

$$l_{max} = \left(\frac{A^2\,\gamma^2}{B\,F}\right)^{1/3} \qquad (15)$$

Obviously for small values of l, $B\,F$ must be greater than $A^2\,\gamma^2$.

Now putting this value of l in equation (14) gives

$$P_{max} = \frac{E^2 A\,\gamma\,B^2\,F^2}{3\,A^{2/3}\,\gamma^{2/3}\,B^{2/3} + B + B^{1/3}\,F^{4/3}\,A^{4/3}\,\gamma^{4/3}} \qquad (16)$$

and if $B\,F$ is to be large with respect to $A^2\,\gamma^2$ the term B will dominate the denominator and we can approximate the above formula by

$$P_{max} = E^2 A\,\gamma\,B\,F^2 \qquad (17)$$

From equation (15) it is obvious that the length to which a filament would elongate is a function of the quantity of its moisture and of its conductivity. Presumably if the quantity of moisture were sufficient or its conductivity sufficiently high the filament would bridge the dielectric. It should also be noted that the length of the filament is, according to this equation, independent of voltage. This of course is not strictly the case, as the force of surface tension has been neglected. The equation (15) must therefore be considered as giving the limiting value of l when A is very small. Undoubtedly for small voltages the effect of surface tension would be apparent but as the voltage increased the dielectric forces would dominate, and if γ remained constant the length of the filament would not change appreciably with voltage changes.

Equation (17) is the approximate equation of dielectric loss due to the presence of a very short filament of moisture in the dielectric but for larger filaments equation (17) will not hold. Most likely as l increased the factor B should decrease in importance until for a filament of length such as to bridge the dielectric the factor B would disappear and the loss would be

$$P = E^2 A\,\gamma \qquad (18)$$

where $\dfrac{1}{A\,\gamma}$ expressed the actual resistance of the filament, since we assumed the dielectric thickness, L, to be unity.

If the dielectric contained many particles of moisture of various sizes, doubtless some would bridge the dielectric, some would not elongate beyond a limiting or short value and some in elongating would link up with others forming longer filaments of limited length or else would bridge the dielectric.

With some filaments bridging the dielectric and others of limited length the total dielectric loss can be expressed as

$$P = E^2\,\gamma \int_{l=0}^{l=L} A'\,B'\,d\,l \qquad (19)$$

where A' is a function of A and l and expresses, for any length l, the total moisture in the dielectric, held as filaments, of length l; B' is a function of B and F with respect to l and varies from $B' = B\,F^2$ for very small values of l, to $B' = 1$ for $l = L$. B is also a function of l and would be 0 for $l = 0$. In this equation γ is as-

sumed to be the same in all filaments but if the filaments were of different temperature this would not be the case.

Dielectric Loss as a Function of Voltage

According to equation (**19**) the dielectric loss in a dielectric containing moisture increases as the square of the voltage indicating a constant "a-c. resistance" but as pointed out in the case of the constant potential field, the current flowing through the filaments generates heat, locally, and this may increase the temperature of the filaments, increasing the conductivity of the liquid of which they are formed, lengthening the filaments according to equation (**15**) and according to equation (**19**) increasing the loss. But, if the filaments are very small, radiation of heat to the surrounding dielectric would be rapid and might even cool the filaments down to the dielectric temperature between cycles. We would, therefore, expect that in a dielectric containing comparatively little moisture, dielectric loss would increase in proportion to the square of the voltage while in a comparatively moist dielectric the increase of dielectric loss with voltage would be at a greater rate. The phenomena of evaporation as explained in the case of the constant potential field would also occur in an alternating field and this might offset the increase in conductivity due to temperature rise as voltage increased. The evaporation, however, would only be apparent above some critical voltage. In other words, a dielectric containing moisture to such an extent as to increase in loss, as voltage increased, at a rate greater than proportional to the square of the voltage, would, above a certain voltage, show loss increasing at a rate more nearly proportional to the square of the voltage.

Dielectric Loss as a Function of Temperature

Assuming for the moment that the dielectric coefficient, k, is independent of temperature, then since γ, the conductivity of the liquid increases as temperature increases, it follows from equation (**19**) that the dielectric loss in a dielectric containing many particles of moisture would increase as the temperature of the dielectric increased. Furthermore as indicated by equation (**15**) an increase in γ would also cause a lengthening of all the filaments that did not already bridge the dielectric, and according to equation (**19**) this would cause a still greater increase of dielectric loss as temperature increased.

There seems, however, to be rather good evidence that the dielectric coefficient, k, is not a constant with respect to temperature. This will be brought out later, but assume for the moment that k decreases as temperature increases. B is proportional to k and so according to equation (**19**) a change in k will affect dielectric loss. In a comparatively dry dielectric a large part of the loss might occur in comparatively short filaments in which case the importance of B in the equation (**19**) for loss would be great. In such a dielectric the effect of the increase of conductivity as temperature increased might be somewhat offset by the decrease in k as temperature increased, though, as the filaments lengthened due to increasing temperature the importance of B as affecting loss would decrease. The result, in a very dry dielectric, might be that, when cold, dielectric loss would decrease as temperature increased but that, at a certain temperature, a point of minimum loss would be reached and that, for higher temperatures, loss would increase perhaps rapidly with temperature.

It has been stated above that dielectric loss is sometimes affected by evaporation, depending upon the moisture content and the voltage impressed. Another factor would be the dielectric temperature, for obviously if the dielectric were hot evaporation would occur at a lower voltage than if the dielectric were cold.

Dielectric Loss as a Function of Frequency

If a filament of moisture in a dielectric field were very short the importance of B as affecting dielectric loss would be great. B is proportional to frequency so the loss would be nearly proportional to frequency. If, on the other hand, the filament bridged the dielectric, the loss would be independent of frequency. In the case of many filaments of all sizes, dielectric loss would increase with frequency but in a degree depending upon the quantity of moisture and its distribution.

As an offset to the above is the fact that, as indicated in equation (**15**), the length of the filaments would decrease as frequency increased. This of course though tending to decrease dielectric loss would increase the importance of B and so increase the sensitiveness to changes in frequency.

With an increase of temperature, the variation of loss, due to changes in frequency, would be less as the increase of temperature would lengthen the filaments, and so give less importance to B.

Capacitance as a Function of Frequency

The capacitance of a dielectric containing embedded moisture elongated into conducting filaments would be greater than the capacitance of the same dielectric if no filaments were present, for although the effect upon the capacitance of such filaments as bridged the dielectric would be negligible, those filaments that partially bridged the dielectric would act to shorten the length of such lines of force as converged to them in crossing the dielectric. Thus the effect of these filaments would be the same as if the electrodes were moved nearer together. An increase in frequency would increase the factor B in equation (**15**) and shorten the length of these filaments; thus an increase in frequency should be accompanied by an apparent decrease in capacitance.

Capacitance as a Function of Temperature

As pointed out above, the effect of an increase of temperature upon the filaments that do not bridge the dielectric, is to increase their conductivity and

so increase their length. Obviously, this would increase the apparent capacity of the dielectric. But as stated above there is no reason to assume that the dielectric coefficient k is independent of temperature. It is a measure of the energy required to produce some atomic change, and the condition of an atom changes with temperature.

W. Grover[1] of the Bureau of Standards has found that the capacitance of paraffined paper condensers changes with temperature but with rather a complex relation to phase angle. It will be shown later that in the dielectric we are considering the larger the phase angle the greater the moisture content. Grover finds that, for a very small phase angle, the capacitance decreases as temperature increases—for a larger phase angle capacitance is nearly independent of temperature and for a still larger phase angle capacitance increases as temperature increases. A very small phase angle is equivalent to saying very few filaments and these of short length. Such filaments, although they would, presumably, increase in length as temperature increased, would, in lengthening increase the capacitance of the dielectric but slightly. If in this case the capacitance were found to decrease with an increasing temperature our only explanation seems to be that a decrease of k must have taken place. A larger phase angle would indicate more moisture, that is more filaments and longer filaments. When due to an increase of temperature, such filaments elongated, their effect upon capacitance would be more pronounced and might dominate over any change due to a change in k. It follows that when investigating k as a function of temperature, the moisture content should be as small as possible; in other words the phase angle should be small. In this case Grover found that capacitance decreased as temperature increased. The conclusion seems to be that the dielectric constant k actually does decrease as temperature increases.

Phase Difference and Power Factor as Functions of Voltage Temperature and Frequency

The phase angle of the changing current of a condenser would be

$$\tan^{-1} \theta = \frac{b}{g} = r_{ac}\, 2\, \pi\, f\, C$$

if however the phase angle is large we can assume for the power factor

$$\cos \theta = \frac{1}{r_{ac}\, 2\, \pi\, f\, C}$$

and since $r_{ac} = \dfrac{E^2}{P}$ $\quad \cos \theta = \dfrac{P}{E^2\, 2\, \pi\, f\, C}$

The term "phase difference" may be defined as 90 deg. $- \theta$.

1. The capacity and phase difference of paraffined paper condensers as functions of temperature and frequency. W. Grover, *Bulletin of the Bureau of Standards*, Vol. 7, No. 4, 1911.

The dielectric loss P and capacitance C have both been analyzed above as functions of voltage, temperature, frequency and moisture content, and as these are the only variables in the equation of power factor that would be influenced by moisture content it seems hardly necessary to fully develop their ratio. In general we might expect P to change more with moisture content and conductivity of the moisture than C and it would follow that in a comparatively dry dielectric, power factor would be lower and phase difference smaller than in a comparatively moist dielectric.

In any actual insulation the action of entrapped moisture would be more complex than in the simple case considered above. It is doubtful however if any usual insulation would be dense enough to prevent the penetration of filaments of moisture provided the filaments were sufficiently small, and they may of course be even atomic in section. The impossibility of freeing insulation from every trace of moisture is apparent when we consider the moisture content of the air. If we attempt to drive out moisture by high temperature we vaporize the moisture but even with vacuum we cannot get all of the vapor out. There seems to be an action of occlusion that holds to the moisture and brings in new moisture when possible from the air. If very high temperatures are used in drying, many insulations decompose and usually one of the products of decomposition is water.

The idea that moisture forms the conducting paths in insulation is not at all new, Evershead[2], by means of a very ingenious model studied the action of moisture as affecting the insulation resistance of fibrous insulating materials. This is of course a more complex case than the simple one considered above, since the fibers of the material would hold moisture strongly by capillary action. Evershead concludes that only a small part of the total moisture forms high resistance paths and that most of the moisture lies dormant in cells and fibers of the insulation. According to Evershead, an increase of electrical stress floods the conducting paths with moisture taken from the reservoirs of dormant moisture and so decreases the resistance as voltage increases. Evershead accounts for this flooding of the moisture paths by the action of electrical endosmose which gives a movement towards the cathode only. Electrical endosmose is essentially a phenomenon of a dielectric liquid and not of a conducting liquid, and it hardly seems possible that moisture in commercial insulation would be pure enough to be considered as a dielectric. Conducting moisture on the other hand would elongate into filaments, the force acting in both directions, both towards anode and cathode. Possibly both actions may take place.

In the above analysis we have considered only the actions that would take place, due to moisture, in a uniform dielectric field. If the field were not uniform,

2. The Characteristics of Insulation Resistance. *Journal of the Institution of Electrical Engineers*, Dec. 15, 1913.

as for instance in the insulation of an electric cable, it seems obvious that the moisture would have a tendency to migrate towards the more intensely stressed portions of the field. One result of this would be an easing off of the gradient where it was steepest. It may possibly be that an actual benefit is derived from the

Single-conductor No. 0000, 20/32-in. paper cable.

moisture in a cable if the potential gradient at the conductor is excessive.

Almost all of the characteristics that it was found should be expected in the hypothetical insulation that has been considered above have been described before as characteristics of ordinary insulation. Perhaps the

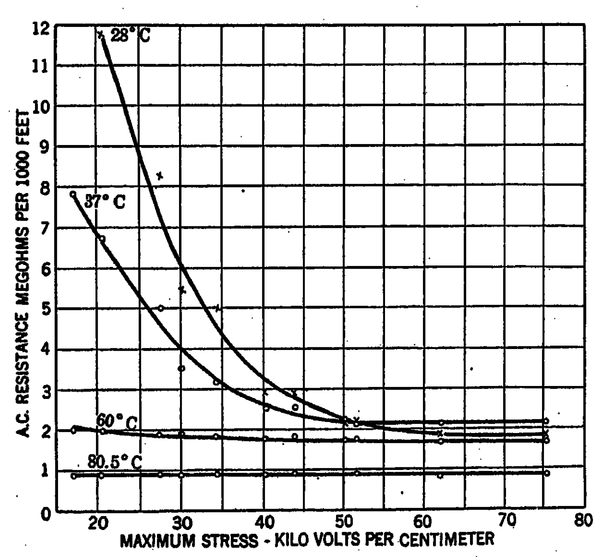

Fig. 11—A-C. Insulation Resistance

Single-conductor No. 0000, 20/32-in. paper cable.

characteristics described above as due to evaporation may be considered novel. Among many tests made on cables and other insulation, the author has occasionally found variations that it seemed probable were caused by evaporation. Such a test is given in the appendix.

Appendix

The curves shown in Figs. 10, 11 and 12 were plotted from dielectric loss measurements made upon a single conductor cable insulated with paper and impregnated with mineral oil. This was a special experimental length of 200 feet and it was given less drying than would have been given to a commercial cable of similar design. The curves plotted from the results of the test show the typical characteristics which we have learned to associate with insufficient drying. In a cable where the drying is more complete we find that dielectric loss is proportional to the square of the voltage and that, at any given temperature, power factor and insulation resistance do not change greatly as voltage changes. In this case, however it is only at high temperature that insulation resistance and power factor do not change with voltage. At low temperatures, insulation resistance decreases with

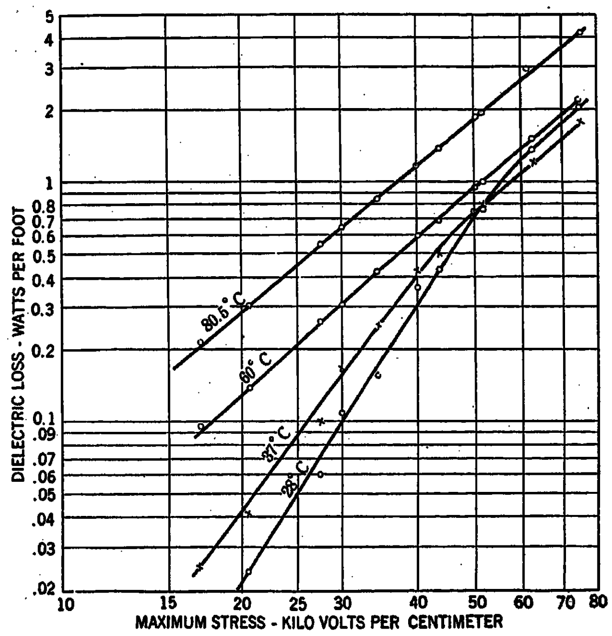

Fig. 12—Dielectric Loss
Single-phase, 60 cycles.
Single-conductor No. 0000, 20/32-in. paper cable.

increasing voltage and power factor increases with increasing voltage. The lower the temperature the greater the rate of change. But in each case if the voltage is sufficiently high a condition of constant insulation resistance and constant power factor is reached. The voltage to bring about this condition depends upon the temperature and is greater for low temperatures than for high.

The explanation for these curves according to the theory given in the above paper is as follows:

Many of the moisture paths or filaments of moisture are, in this case, so large that their sur aces, which dissipate heat, are small with respect to the heat generated in them by electric currents. The moisture therefore becomes hotter than the surrounding dielec-

tric, the actual temperature depending upon both the dielectric temperature and the voltage. Therefore as voltage increases the temperature and conductivity of the moisture increases and the filaments of moisture lengthen. Due to both these causes, a-c. resistance decreases and power factor increases with increasing voltage. But if the temperature of these large filaments becomes sufficiently high, they will be disrupted by evaporation. The cooler the dielectric the greater must be the rise in temperature to reach an evaporating temperature. Therefore the cooler the dielectric the higher must be the voltage to produce evaporation. Evaporation breaks up the large filaments, thus changing the slope of the curves to the horizontal lines that are characteristic of comparatively dry dielectric, in which only small filaments are present.

In the case of the 80.5 deg. curves it would seem that the dissipating action of evaporation must have been complete well below the lowest voltage recorded in the test and that, therefore, the only indication of an excess of moisture is that the power factor is a little higher than might have been expected for a well dried cable.

In the case of the 60 deg. curve the dissipation of moisture, due to evaporation, is almost complete at the lowest test voltage but the last trace of the phenomenon is discernible.

The crossing of the 28 deg. and 37 deg. curves is interesting and apparently means that at 28 deg. a larger part of the total moisture was concentrated in the large filaments than at 37 deg. cent. so that, at the evaporating voltage, the moisture as a whole was hotter in the 28 deg. dielectric than in the case when the dielectric was 37 deg. The fact that at 28 deg. the oil is hard while at 37 deg. the oil is very soft may have bearing on the case.

At high voltages there is much less difference between the curves for different temperatures than there would be for a comparatively dry dielectric, but it must be remembered that the temperature of the conducting moisture paths is not the temperature of the dielectric, nor are the moisture paths in any case all at the same temperature. Above the voltage of dissipation by evaporation many moisture paths would be at evaporation temperature no matter what the dielectric temperature might be. Other paths in the dielectric would be at temperatures between the evaporation temperature and the dielectric temperature. Thus the 80.5 deg. cent. curves differ from the others at high voltage not because the hottest moisture is any hotter than in the other cases but because more moisture is hot.

Discussion

For discussion of this paper see page 611.

Rating of Cables in Relation to Voltage

Bibliography on Dielectrics

BY DONALD M. SIMONS
Associate, A. I. E. E.
Standard Underground Cable Company, Pittsburgh, Pa.

THIS bibliography was prepared at the request of the Subcommittee on Wires and Cables of the Standards Committee of the Institute, and is intended specifically to be a continuation of that published by E. H. Rayner, *Journal of the Institution of Electrical Engineers*, (England) 1912, Volume 49, p. 53, who describes his bibliography as follows:

The references given below are to articles in periodical literature only. With few exceptions they deal with the physics of dielectrics from the point of view of energy loss and electric strength.

The first section includes papers dealing with theory and experiments of a laboratory nature.

The second deals with instruments, chiefly electrostatic voltmeters and wattmeters, suitable for measurements on high-voltage circuits.

The third section includes papers on atmospheric phenomena at high voltages at or above ordinary pressures, more especially such as describe experiments of engineering interest.

In the fourth section are references to similar experiments in oils.

The fifth section consists chiefly of papers dealing with the electric strength of materials and energy loss in insulation. Articles on cables are included which discuss insulation problems; but such as deal merely with capacity, inductance, etc., have been omitted.

The number of articles on the subject of porcelain and porcelain insulators has increased so much since the publication of Rayner's bibliography, that an additional Section, namely Section V, has been included on this subject in the present bibliography, changing the general section into Section VI.

Niagara Falls, Ontario, June 29, 1922

E. B. Meyer: As already stated by one of the writers, the general opinion in the past seemed to be that when the voltage of a circuit was increased the only requirements so far as safe operation was concerned, was to add more insulation to the cable.

Recent experience and research has developed the fact that the quality of the insulation and of the compounds used for impregnation have an important bearing on the safe operation of underground cables.

The thickness of insulation applied on cables has apparently been determined heretofore by a cut and try method. In several installations with which I am familiar, cables recently purchased have less insulation applied than some of the older installations operating at the same voltage. This seems to bear out the fact that either more insulation than necessary was originally provided, or that improvements in the quality of dielectrics have been effected.

In the operation of underground cable systems of voltages under 9000 comparatively little trouble is experienced. However, as soon as we pass this point and get into the range of voltages close to 20,000 which is becoming more extensively used, the number of failures per unit length of cable show a large increase over the number experienced at lower voltages.

In looking over the last report of the Underground Systems Committee of the National Electric Light Association in which was included a record of the cable failures during the year 1921 on cable systems at voltages ranging from 6600 to 25,000 volts, it is interesting to note that the average number of cable failures excluding those caused by electrolysis or external injury on a total of nearly 5000 miles of cable was slightly over 10 failures per 100 miles.

In a large number of systems in this classification operating at voltages over 15,000 the failures ran about 25 failures per year per 100 miles of cable. It is really seen from these figures that in order to reach what might be termed the "ideal condition" as cited by Mr. Roper in which he states that the burnouts of high-voltage cables should be no larger than for the lower transmission voltages and should not exceed one or two per hundred miles per year, radical changes and improvements will be necessary both in the construction and methods of handling underground transmission cables of the higher voltage class.

F. W. Peek, Jr.: I will limit my discussion to the data by Fernie given in Table I of Mr. Simons' paper. These data were obtained by measuring the break-down voltage on cables with inner conductors of various radii. The maximum stress or gradient on the insulation of such a cable is always at the surface of the inner conductor; the minimum stress is at the sheath or outer cylinder. The stress or gradient calculated from the break-down voltage varies with the size of the inner conductor. The apparent strength of the insulation is greater for the smaller sizes of conductor. Exactly the same result is obtained with oil and air. The apparent strength of air for various sizes of conductors is readily obtained from the well established relation

$$g_v = 30 \left(1 + \frac{0.30}{\sqrt{r}} \right) \text{kv./cm.} \qquad (1)$$

Where r is the radius of the conductor in cm.[1]

Data from Table I are given below with some additional calculations.

Data from Table I				Calculated from Equation (2)		g_v for air from equation (1)
R cm.	r cm.	Max. Stress at Cond. g_v kv/cm.	Stress at Sheath kv/cm.	Max. Stress at Cond. g_v kv/cm.	$R' = 1.1\sqrt{r}$	
1.13	.243	428	92	320	0.8	48
1.79	.527	335	98.3	250	1.30	42
1.25	.369	288	84.3	280	1.00	45
1.41	.527	257	95.6	250	1.30	42
1.62	.737	240	108.7	240	1.70	40
1.16	.527	219	99.5	250	1.30	42
1.70	.817	189	90 6	220	1.80	41

In the last column the stress is calculated for the same conductor arrangement as for the cable for the purpose of comparison. The apparent strength is greater for the smaller conductors as is the case for this cable.

The physical meaning of equation (1) is that when breakdown occurs the stress is not constant at the conductor surface but is always constant and equal to 30 kv./cm. at $0.3\sqrt{r}$ cm. from the conductor surface. This constant value of 30 kv./cm. is the strength of air, but a finite thickness must be stressed at or above this value before break-down can occur. This thickness is $0.3\sqrt{r}$ cm.

The break-down values for the solid insulation from Table I may be represented by the same relation. Thus

$$g_v = 100 \left(1 + \frac{1.1}{\sqrt{r}} \right) \qquad (2)$$

This means that the solid insulation breaks down at a constant stress of 100 kv./cm. at $1.1\sqrt{r}$ cm. from the conductor surface. It so happens that the radii of the sheaths, R, for the cables used in Table I have values approximately equal to $1.1\sqrt{r}$. This makes it appear that break-down occurs for a constant value of stress at the outer conductors.

C. F. Scott: I have some appreciation of cables, in a general way, I am not an expert, I am not going into this discussion in the way that the preceding persons have done.

I will look at the whole matter from a different standpoint, that is, with reference to the place of the cable in commercial engineering work. We see the large power houses which have been constructed—we marvel at the advance which has been made in the last twenty years, since turbines began to be factor in power generation, and yet, in the large cities, the investment in the cables which lie beneath the street, is comparable with the investment in the power houses, and the continuity of service may be as much dependent on cables as it is on the operating machinery of the power houses.

What do we find with regard to the change in cables in the last twenty years? It is about twenty years ago, if I recall rightly, that a cable of some 25,000 volts was installed, and so far as I know, has been reasonably successful and has been in continuous operation since that time. Yet, the number of

1. Peek, "Dielectric Phenomena in High-Voltage Engineering", p. 47.

cable installations, which have exceeded that voltage, have been very few and very recent, and neither in quantity or quality have they proved, I think, that they are yet 100 per cent perfect; and the one particular point I want to make is that the advance which has taken place in cables from the technical and operating standpoint, has been very mild and feeble, compared with that in other branches of the electrical industry.

We had presented, a day or so ago, the fact that in telephonic transmissions, efficiencies equal to the older efficiencies were obtained with wires of 1/10 the size, and that this was accomplished with cables containing something like ten times the number of circuits that they used previously.

That immediately raises the question why power cables have changed so little. Has the cable not been something that has been turned out by the mile, according to very ordinary sort of specifications? Has not the type of work, as has been presented here this morning, which is the theoretical research type, been of very slow progress and has not the theory advanced too slowly? Has not the practical application of that theory and the results of the research work which has been done on cables, to make better cables, not been very slow? In a word, are we not ten to twenty years behind the times in the real advance in power cables, in comparison with what has been going on in other fields of the electrical industry?

If that is so, it is a challenge to the electrical profession, to the theoretical men, to the cable makers, to get very busy in order that the cable, may take its proper part in performing its very important function in power distribution.

C. F. Proos: In a paper read before the Association of Electrical Central Station Managers in Holland, on September 30th, 1921, (to which the following figure numbers refer) there were discussed certain factors that influence the dielectric loss in high-tension cables, with special reference to the tension at which ionization starts as influenced by changes of temperature.

The general characteristics of a paper insulated cable is shown in Fig. 1, where $\frac{W}{E^2}$ is given at different voltages. It will be noted that up to a certain value $\frac{W}{E^2}$ is constant; beyond that point $\frac{W}{E^2}$ changes due to the air becoming ionized; and at yet higher voltages it becomes nearly constant again, when the air is nearly totally ionized.

The time during which voltage is applied has influence on the measured value of dielectric loss, but only on the second part of the characteristic. Slow readings or low ionization give curves like No. III Fig. 5 instead of No. I.

Temperature has a large influence on dielectric loss as shown in Fig. 7. The curves show a minimum of losses, for all tensions, at nearly 37 deg. cent.

The ionization characteristic (Fig. 1) is changed by heating and cooling the cable. The ionization voltage runs up with temperature, and comes down, when the cable cools, to lower values than before. The higher the temperature reached, the lower the ionization voltage in the cooled cable, as shown in Fig. 9. There is a certain temperature of the heated cable, above which the ionization voltage in the cooled cable runs down rapidly (Fig. 10). Running the cable above this temperature makes the operating conditions dangerous, unless unusually thick insulation is used.

The power factor also changes with differences in temperature and is dependent on the range of temperature the cable has previously covered, as shown in Fig. 11.

In the original paper these results are discussed at length and it is shown that these changes in electrical values are caused and can be explained by the changes in volume and pressure of the small occluded air bubbles that are left in high-tension cables. Both the thickness and the pressure of the air bubbles change and ionization starts at different voltage in accordance with these changes. The expanding air pushes the fluid oil away at the spots of higher temperature which are also spots of highest dielectric loss and stress; these spots are dried out, the temperature rises and the resultant hot spot causes breakdown. The oil pushed away at high temperatures, does not come back to its former place when the cable has cooled down; the air occupies a bigger space than before, the pressure coming down accordingly. Hence at lower temperatures, the break-down voltage of the air bubbles is lower, and the heavy ionization which occurs is dangerous and may cause hot spots and consequent breakdown of the cable. Practise in Holland has confirmed this theory, several breakdowns having been noticed at the low temperatures which followed a period of heavy load on the distribution cables.

Ionization tension lowered by heavy loading of the cable comes back to former values in course of time. An average time for the recovery of a cable is 8 to 10 days. At higher temperatures recovery is faster. Curves taken on a recovering cable are shown in Fig. 12. It will be noticed from these curves, that the same cable can show nearly any possible form of characteristic according to the conditions (thermal and electrical) the cable has been subjected to before test. This explains most of the differences which have been experienced in checking dielectric loss measurements.

By special precautions taken in manufacture and in the materials used, the ionization stress in cables can be brought up to values of 40 kv./cm. or more and the influence of temperature changes can be reduced. (Figs. 14 to 19).

A cable always used at an operating voltage lower than the ionization voltage does not show hot spots; hot spots are caused by occluded air only, and will cause breakdowns sooner or later. Laboratory tests should be made on cooled cables after being heated up to operating temperatures. A proper knowledge of a cable's characteristics cannot be obtained unless its voltage characteristic is determined over a wide range of voltages. (Fig. 7). A test at one voltage only is insufficient; the ionization voltage must be known under all operating conditions.

The above tests were made at the Nedelandsche Kabelfabrik on lengths of 1000 feet or more with a special wattmeter at 50 kv./cm. The cables were heated by passing currents through the conductors, the sheaths being freely exposed to air. This is different from the American practise of putting cables in an oven until the insulation, is uniformly hot throughout, and more nearly represents operating conditions.

William A. Del Mar: In the course of preparing the Historical Summary, the Subcommittee noted that the first man to call attention to the importance of dielectric losses in cables was Mr. Philip Torchio. They found that in 1902 Mr. Torchio gave the results of measurements of dielectric losses on long feeder cables, and deduced the general laws which govern the variation of dielectric loss with voltage frequency and temperature.

Philip Torchio: Your reference to my work may be used as an illustration in answering Prof. Scott's very timely remarks which are more or less an attack on the slowness of American progress in cable development. As the Chairman states, I was the first to make tests and call attention to the importance of dielectric losses in cables in the Spring of 1902. My conclusions on the tests as I then reported were as broad and comprehensive and covering all features of the problem as we would enunciate them today, my report of 20 years ago stating that "the dielectric losses are approximately proportional to the frequency, to the square of the voltage and to a certain function of the temperature not yet determined. The temperature, however, increases considerably the dielectric losses."

I submit to Prof. Scott this fact, that while the fundamental principles of the importance of dielectric losses were clearly

enunciated in 1902, practically nothing was done in this country in following up the subject until about 10 years afterwards when, in 1912, Mr. Roper was confronted with certain high-tension cable failures due to heating, and he then became persistent in urging that the study of dielectric losses in cables be seriously taken up and pushed forward. In later years, other operating engineers who experienced similar troubles vitally contributed to exert pressure to push the research. In this manner, through the efforts of both manufacturers and users either through independent or cooperative work, we have arrived at the large progress reported in these papers.

In reviewing these developments, I believe Prof. Scott will recognize the fact that until the need for improvements is felt either on account of failures of existing apparatus or inadequacy to give service, the theoretical research does not become of pressing importance. On the other hand, as soon as the operator experiences trouble, immediately the research becomes extremely vital. Hence, our experience with the study of dielectric losses in cables illustrates the great importance of the necessity of cooperation between users and manufacturers. The manufacturer must carefully study the experience of the operator and, on the other hand, the operating engineer must closely analyze his troubles and give the manufacturer the benefit of such experience.

H. W. Fisher: The writer will confine most of his remarks to Mr. Roper's criticism of American manufacturers and praise of foreign ones. Through correspondence from abroad, the writer knows that most of the so-called very high-voltage cables, concerning which much has been written in the technical press, have been operating, if at all, at much less than the designated voltage. Europe has apparently many engineers who try to keep their names before the public by advertising when they can, unusual work which is contemplated or supposed to be done abroad. When for any reason installation or actual operation at the stated voltage is delayed, a false impression is given, not only to the foreign, but also to the American public, of the actual accomplishment of foreign cable manufacturers and operators.

The writer has had access to actual tests of dielectric loss made in some of the cables abroad, and intended to be used at 33,000 volts, and the dielectric loss was so high that he can state with confidence that Mr. Roper would not operate the cables on his 33,000-volt system.

To be more explicit, I will state that the dielectric loss of this cable was over twice that required by Mr. Roper for his 33,000-volt cables. The cable was very well constructed and the physical properties of the compound were excellent, making very remote the possibility of transfer of the compound from one part of the cable to another. The manufacturer of this cable is a large concern with an excellent reputation and from the above information, it would seem that they are willing to sacrifice to a certain extent, dielectric loss in order not to neglect the other important considerations of cable construction.

R. W. Atkinson: The great questions brought to my mind by the subject of this meeting are "*What are the limits of the operating voltage of the cable, imposed by the voltage stresses in it, aside from the secondary effect of heating produced by dielectric losses*"? and "*What is the proper relation of insulation thickness to working voltage and what is the effect on the required insulation of the fact that the stresses are not uniform but are greater at the conductor surface?*" I will formulate some statements which I believe will be found fairly close to the correct answer to these questions. These questions will be discussed primarily from the standpoint of long continued stresses, though the answers apply in some measure to stresses applied for shorter time.

In his discussion, Mr. Peek has outlined an answer to these questions which is substantially the same as that which I have prepared but I believe that the matter is of such importance as to well bear a repetition, especially as my discussion is from a somewhat different viewpoint.

A theory departing very much from previous ideas has been advocated by Fernie and has recently been given much publicity in this country. This theory has been effectively refuted in the paper presented this morning by Mr. Simons which leaves the way clear for the discussion to be made without further reference to it.

I will now consider the questions with which I have begun this discussion. Taking up the second question first, I believe the law for such dielectrics as are in the cables follows very closely that which has been developed by Whitehead, Peek and Ryan for air. That is breakdown will occur not when a certain average stress is reached nor yet when a certain maximum stress is attained but will occur when this maximum stress is imposed on a certain definite amount of the dielectric. The reason in the two cases is very similar. In the solid dielectric a condition of failure must be the liberation of a sufficient quantity of energy to cause disintegration of the dielectric at the point of failure. This disintegration may be mechanical, or due to heat, or to direct chemical changes and the electrical failure is likely to follow rather than precede these other changes.

As a direct result of this a cable with a large conductor though standing a higher total voltage will withstand a lower stress next the conductor surface than one with a small conductor, and the same thickness of insulation, but the difference is much less than would be calculated on the basis of maximum stress and indeed may be unimportant for fairly large changes of conductor size.

The answer to the other question follows directly. That is the dielectric strength will be substantially proportional to the thickness for the same ratio of maximum to average stress. The strength will not increase quite in proportion to the thickness because this distance through which the stress must exceed the critical value is of greater relative importance in thin insulation than in thick. By way of illustrating the magnitude of this effect, it may be cited that experiments with insulation 100 mils thick that have shown dielectric strength say eight times what might have been expected from ten mils, 1/10 as much, of the same material.

There is not time even to begin to outline reasons and data supporting this theory. I will give some cautions to prevent misapplication. One of the most common reasons that low values of average dielectric strength are found for thick masses of dielectric in proportion to those found for thin layers is the heating due to dielectric losses. In other cases there is a great concentration of stress with the thick mass due to the shape of the electrodes. Where means are not taken to prevent discharges over surfaces, the electrical oscillations produced thereby are likely to be proportionately higher for the higher voltage and for the thick insulation. In many cases the thick insulation though supposedly of the same quality, actually is of lower quality than the thin insulation. Thus, there are many ways in which tests will be relatively very unfair, to the thick insulation in spite of the fact that say the same precautions were taken in all cases. That is, on account of the greater difficulties introduced by the higher voltage many precautions must be taken that need not be taken for the lower voltage.

It must be borne in mind that there is essentially a large difference between tests made where the voltage is rapidly built up to the breakdown point than where voltage is applied for very long periods as in service or say in accelerated aging tests. It is believed that the same fundamental considerations will apply in both cases but that numerical values may be enough different to cause a very important difference in the ratios of strength for short time application and long time application for specimens of different thicknesses of insulation.

Where a cable has composite dielectric, it follows that the limiting voltage is reached when the critical stress is reached in a sufficient portion of either of the two dielectrics. This may be in the one having the greater stress. That is usually next the conductor—or it may be in the other if the ratio of the dielectric strength is greater than the ratio of the stresses. Incidentally,

it may be pointed out that all multi-conductor cables having insulation on the individual conductors and a belt or jacket overall, are essentially of the class of composite insulated cables inasmuch as the filler materials constitute an essential part of the insulation and may be the source of voltage limitation on account of their low dielectric strength, in spite of the lower stress there than in the main body of the insulation.

In 1920 Mr. Roper gave a paper showing the results of experience on the Commonwealth Edison system with lightning arresters. In a way his overhead system became an enormous laboratory and the results of these observations were epoch-making and, we understand, have revolutionized our whole ideas on the protection of distribution circuits and the development of new and far better types of arresters and even in the means used for testing and judging the worth of an arrester. He has now begun work with another part of his huge laboratory, this time with his underground system.

Mr. Roper is trying in this vast laboratory of his whether American cables can successfully meet conditions which have never before been met when we consider both the thickness of insulation for the working voltage and the service conditions. Speaking first of cables for operation at 25 kv. and less, vast quantities of American cables with thicker insulation have met successfully these conditions and there is a good deal of experience in Europe under their more favorable conditions with insulation thicknesses less than are common in American practise. But we know of no operating experience anywhere with these thin insulations combined with American operating conditions.

It is important to remember that, though laboratory and factory tests on this cable give reasonable assurance of successful operation, yet there is a very fundamental difference between such tests and the actual practical proof by large scale commercial operation. Laboratory tests have a very great value, in fact are the foundation of development, yet very misleading conclusions may be drawn from these when they are not backed by proper large scale experience.

Separate mention may be made of three-conductor cable for operating at 33 kv. More than one lot of cable in England is understood to have been placed in operation at 33 kv. during the present calendar year. These cables are understood to have an insulation thickness of one-half inch between conductors and the same amount between the three conductors and the sheath. All of these cables have round conductors. One English cable with thicker insulation and also an American cable have been in operation at this voltage for a greater length of time but the present interest centers in these newer cables. It is of interest to compare these with the American cables which Mr. Roper has installed during the last year for the same voltage. His cable with a 350,000 cir. mils sector conductor and 19/64 in. plus 7/64 in. insulation and 9/64 in. lead has a diameter of slightly less than 3 in. With sector conductor and the same insulation as used in this frequently quoted English practise, the diameter would be about 3.04 in., or with round conductors it would be 3.32 in. or about 12 per cent greater than that of the American cables. Thus though the British have used relatively thin insulation between conductors, they have been so conservative by use of thick belt insulation and unwillingness to use sector conductors that these much talked of cables are materially larger than the American cables and have more insulation as a whole. The comparison in favor of the American cable is still further emphasized by the statement that with round conductor and the insulation thickness used in English practise a 3-in. diameter cable could not have a conductor as large as 250,000 cm. instead of 350,000.

However, aside from the fact that European practise regarding insulation thicknesses is not so different from American practise as appears on the surface, or is sometimes mistakenly supposed or taken for granted, there is plenty of difference between European and American conditions to make comparisons very difficult. In two most important ways do the English make very sure that their cables are installed and operated so that they remain in exactly the original condition. In the first place, they take precautions about handling and bending the cable during installation that we understand are impractical under American conditions. Their cables are normally armored and it would be very difficult indeed to subject them to a serious amount of bending even if one wished to do so. It is true that English specifications are more severe in some particulars regarding bending test than is the American N. E. L. A. specification, though the English specification does not call for a low temperature at which the test is to be made, but we are not here concerned with the bending test which may be imposed under specifications. We are concerned with the actual installation conditions and with the fact that they are exceedingly careful to treat their cable with very tender care during installation and do not subject it to the degree of bending to which American cables are subjected. Thus the cable is installed in such a way that it remains in practically identically the condition in which it was originally made, and then it is operated with a maximum temperature of 55 deg. cent., or thereabout. This temperature limit is certainly not limited by dielectric losses unless these are far greater than is common in American practise. Under the favorable cooling conditions of installation directly in the ground, only very high dielectric losses indeed could cause limitations to this operating temperature. It is true that they are able to carry very heavy loads without exceeding this temperature but this limitation is quite surely because it is felt that the cables may deteriorate if heated to higher temperatures. This limitation may be nothing more than for instance the migration of the saturating compound due to fluidity at high temperature. If stresses are low we need not be concerned about that, but it is another matter if stresses are as high as allowable for cable in the original condition. We may very safely say then that whatever thickness of insulation is found satisfactory for conditions now obtaining commonly in American practise, a materially lower thickness will be equally satisfactory under conditions prevailing in England and other European countries, or conversely if our American operators can with like results use as thin insulation as can the Europeans, it means that they are getting better cables.

I believe that full study of the data will show that the American manufacturer has no cause to fear comparison of his recommendations or his product with those of European manufacturers. And let us give full credit to this operating company which is making this great experiment with its transmission system. Successful operation will be of material value to the operating companies of this country and to the industry in general. But let us conservatively remember that it is still an experiment, and let us not be too early in considering it out of the experimental field. And if this is concluded as a successful experiment let us remember the conditions under which it was made and not apply the results under still more severe conditions.

V. Karapetoff: This meeting represents a notable milestone in the development of cables and dielectrics. As an outsider, I note some tendencies which from my point of view seem desirable, and also a few remains of older undesirable tendencies in the methods of attack.

Perhaps the most desirable tendency is a steady, cooperative work, as contrasted with former sporadic individual efforts; also due respect to the work of preceding investigators, and a most excellent bibliography. This attitude alone vouches for the success of the enterprise.

Another desirable tendency is a change from looking upon a cable as a unit piece of apparatus, to a careful analytical study of its elements. I was once crossing the frontier between two European countries and had with me two presents, a fine silk shawl and a very heavy metal box. The customs inspector put them together on a scale, found the total weight, multiplied it by a coefficient, and told me what duty I had to pay. Many of the older experiments on high-tension apparatus remind me of that

summary proceeding. A piece of cable is "shot," a result is obtained, and presented to the public for future digestion. The tendency in the present papers is distinctly away from that pernicious practise. The dielectric is separated into paper, petrolatum, moisture, and what not, and the properties of these materials are treated separately in a more or less scientific and rational manner.

Finally, I welcome most heartily the tendency to speak of the phenomena in dielectrics in terms of the recent ionic and electronic theory of electricity. I appeal to my fellow-teachers to see in this tendency an encouragement of our endeavor to present electricity to our students in terms of the ionic theory. In a few years our graduates will not be able to read Institute papers unless they become familiar with the electron theory.

As to undesirable tendencies one is exemplified by the Fernie theory. It reminds me of those old empirical rule-of-thumb formulas, and is a dangerous step backward. I was glad to hear a speaker oppose this theory.

The other tendency which I rather deplore is to extrapolate theoretical formulas derived from stresses within the elastic limit, and to apply them to the phenomena at the rupture of a piece of insulation. What would we think of a specialist in strength of materials who would use the results of the theory of elasticity in discussing the ultimate strength of a column or a beam? Could he legitimately use a theory which does not apply there? Take a continuous beam on three supports; as long as the stresses are within the elastic limit, the load can be increased and all of the stresses will be in proportion. But load the beam beyond the elastic limit, for example so that the middle support begins to yield, and you will get an entirely different distribution of stresses, unforeseen by the theory of elasticity.

This is apparently done in some of the papers presented today. The logarithmic formula which holds for dielectric stresses within the elastic limit, is being applied to the discussion of stresses which lead to the failure of a cable. I hope that this inaccurate way of reasoning will be gradually eliminated from our papers.

I would suggest to the Committee the necessity of extending our terminology in this branch of electrical engineering. Whenever there is progress in the art, we must not be afraid to introduce new terms. I notice that Mr. Del Mar used in his introductory remarks the expression "imperfection angle." This I think is a legitimate and useful term for characterizing a given cable. A cable has an imperfection angle of 5 deg., against some other cable with an imperfection angle of 9 deg. etc. We also need a new term to distinguish cables in which the ratio of radii is below 2.72 and above 2.72. It is rather awkward always to mention this ratio. Let us call one of them type A, the other type B, or thin and thick insulation, or something else, but let us not be afraid to introduce new names for these two types of cables.

B. Welbourn: Perhaps the best answer I can give to Mr Fisher is to state one or two facts which are within my own knowledge as one of the engineers connected with cable work who has been right through the development from the early days of high-voltage cables in our country. We have a considerable quantity of 33,000-volt cable at work. In one installation, on which I have all the information, a large number of tests have established that the dielectric loss per mile at 50 cycles, with a conductor working temperature of 140 deg. fahr., 60 deg. cent., is exactly 2 kilowatt-hours. I think that you state your losses in terms of watts per foot, and unless my arithmetic is wrong, that is 0.38 watts per foot. I may say that considerably better results have been obtained since.

A cable manufactured by my company has been at work in England for the last two and one-half years, working with a stress of 5,530 volts per mm., as calculated by the Atkinson formula. There are 3-core cables in service working with 4400 volts per mm. I think you call it 44,000 volts per cm. in your phraseology. I can state definitely that 44,000-volt three-core cables are commercially possible.

A great advance has been made in our country with regard to the question of dielectric losses. Forty-four thousand-volt 3-core cables can be supplied which will have a power factor not exceeding 1 per cent, up to a working temperature of 130 or 140 deg. fahr.

A good deal of attention has been given today to Mr. Fernie's minimum stress theory. He is a friend and, until two years ago, was a colleague of mine. He developed his theory about 1914. and the results which he has published in the *Beama Journal* are based on experimental work done at least seven years ago.

At the time Mr. Fernie reached his conclusions, he caused a great deal of discussion in my company, as you may imagine and I might say that his results have never been accepted by my company. I think that much later work which has taken place since Mr. Fernie left the company, and went out of the cable business has shown that his theory has to be provisionally laid aside until a completely new lot of data can be accumulated on cables of the latest manufacture.

I would therefore suggest to Mr. Simons and the other gentlemen who have been discussing Mr. Fernie's theory that they lay it aside for a time, until they have done further experimental work on up-to-date cables.

I have been rather surprised in looking over your literature on cables, to see how little attention has been paid to the subject of the thermal resistivity of the insulation. It is the same in our country, but to the operating companies, and to the engineers who have to prepare the specifications for cables, I would strongly suggest that they call for very stringent guarantees on the thermal resistivity of the cables they are buying, whether they be for high or low-voltage work.

D. M. Simons: In considering Fernie's data, I mentioned that it was unfortunate that his tests did not include a greater range of the ratio R/r, or D/d. The paper by Messrs. Middleton, Dawes and Davis contains a valuable contribution in this respect, since their breakdown tests cover four times as great a range of D/d as Fernie's. It is interesting to see that their tests show that the minimum stress is by no means constant.

The authors have apparently concluded from the data of their Tables 1 and 2, that the maximum stress at breakdown is a constant for cables in which D/d is equal to or less than 2.72. This does not seem to be justified as a definite conclusion since there are appreciable variations in their test values, and in fact, the variations are about half as great as those of their average stresses.

I feel that the comparison of the maximum stresses in three-conductor cables as calculated by the so-called old and new methods is open to considerable criticism. In the first place, they assume in this comparison that the maximum stress at breakdown is a constant, and the same for single-conductor and three-conductor cables. Secondly, the so-called old formula for a stress in three-conductor cables gives obviously a stress considerably too high. The actual cable consists in one leg of two parallel cylinders with the delta voltage between them, and for this condition the old method substitutes one cylinder of the correct diameter, surrounded by a large concentric cylinder, with the same insulation thickness and the same voltage. It is well known that the maximum stress in the former case is always considerably less than the latter. The accuracy of the new method has been so thoroughly substantiated that the tests shown by these authors do not tend at all to disprove this method, but rather to show that the maximum stresses occurring at breakdown in the three-conductor cables tested by them were much lower than the maximum stresses in the single-conductor cables tested.

Mr. Welbourn has apparently obtained a meaning certainly not intended by Mr. Fisher's remarks. Mr. Fisher by no means intends to imply that none of the high-voltage cables mentioned

in the foreign press were in operation, since we have every reason to believe that certain ones are under full rated voltage.

On the other hand, he has attempted to point out that it seems quite sure that many of the described installations are not in operation. I might mention specifically the cut which appeared about a year ago in the *Electrician* showing a large three-core cable "for 66,000 volts." Our information seems quite definite that this cable is not in actual operation, but is merely a short experimental length.

Mr. Welbourn has apparently replied to Mr. Fisher's remark about the dielectric loss in a foreign cable by mentioning the very low dielectric losses in British cables, I am sure that Mr. Fisher's comment was by no means meant as a criticism, but quite the contrary, and that he merely desired to show that certain foreign manufacturers at least did not consider it necessary or advisable to go to extremely low dielectric losses.

J. B. Whitehead: In discussing the potential gradient at the surface of the central conductor of the cable it is perhaps worth while to recall that the value which we use is based on the elementary laws of electrostatics acting in a perfectly continuous medium, such as the ether.

We should remember that when we introduce a dielectric we may through the polarization modify the forces existing before its introduction. For we know that even a perfect dielectric is made up of discreet molecules and that under electric stress the component charges of these molecules are drawn apart. Remembering also the space separation between molecules themselves, it is not difficult to picture such a space arrangement of charges, around a circular conductor as would alter the value of the electric intensity pertaining to a continuous medium. For example we may imagine the dielectric in a single-conductor cable as arranged in concentric layers of molecular thickness, and the component charges separated radially under the electric field. In each layer the inside charge would be nearer the central conductor, and owing to the space separation, would tend to lower the normal value of the intensity in the next inner layer. The amount of this lowering would depend on the radial and circumferential space separation of the charges, but reasoning in this way, it is not difficult to picture the stress in the layer next the central conductor as being reduced to a value comparable with or equal to that in the layer next the sheath. This would account for the evidence that cable breakdowns do not always begin at the center, and would permit us to think that a perfect dielectric at least may have a definite dielectric strength. There is good reason to believe that the gradient necessary to ionize a molecule has a definite value. But air and oil and perhaps other dielectrics always do begin rupture at the center as in the corona. Does not this upset the foregoing suggestion? Not necessarily, for neither air nor oil is the perfect dielectric we have pictured. In each of them, in air particularly, free ions, that is, independent charges, are always present in a certain quantity. These charges, unlike the neutral molecules may move freely in the electric field and so may cause a still further modification of the gradient at the center. It is in some such phenomena as these that the explanation of the peculiar law of corona will ultimately be found. It is probable that we shall never attain the perfect dielectric, but it would appear that the stiffer cable compounds would offer less freedom of movements to independent ions, and so would be less liable to departure from the ideal structure in this respect.

Here, however, new troubles await us, for we encounter conducting filaments, moisture particles, and other departures from homogeneity, any one of which may cause a further modification of our fundamental expression for potential gradient. Consequently, it is of great importance as already pointed out by Professor Karapetoff, that in analyzing the problems presented in cable construction, every care be exercised to separate all the elements entering. The occurrence of corona, or more properly, ionization, in thin air layers, has been recognized for some time. Suspected only at first, its presence was next indirectly shown in the break in the dielectric loss curves of cables, and subsequently its presence has been made visually manifest in air layers between glass plates. Mr. Shraders' power factor curves on one sheet of insulation and an adjacent film accentuate sharply the influence of this state of ionization. It is important to note, however, that his curves are all plotted with the average potential gradient as abscissas, and consequently they do not express the behavior of the air alone, but only the combined behavior of insulation and air. It is for this reason that the rise in the power factor curves is gradual for the thinner air films, and steeper for films of increasing thickness. Ionization begins at a definite value of potential gradient, and consequently the power factor curves plotted against gradient in the film, would all of them show a sharp ascent at the critical gradient.

The sharp maximum of power factor indicates that above the critical gradient the normal charging current increases more rapidly than the ionization loss, and suggests that the principal loss is due to the process of ionization, rather than to a resulting resistance of the air film.

W. C. Hayman: Mr. Roper, in his paper, has given us some very good data on dielectric losses and stresses on paper insulated cables. His conclusion, however, that in low-loss cables the temperature is limited as in low-voltage cables by the temperature which the insulation will stand without deterioration, does not agree with results we have obtained from a number of tests. We have found that the breakdown voltage of low-loss cables decreases with increase of temperature. The average breakdown voltage will decrease between 25 deg, and 100 deg. cent. as much as 25 per cent.

We should also make a study of the effect of high temperatures on compounds used for impregnating high-tension, low-dielectric loss paper-insulated cables, before we make any change in the present standard temperature ratings.

Referring to Mr. Simons' paper regarding Fernie's theory, it would seem that more experimental data are necessary before we discard some of the older theories regarding stresses in the insulation. We have found from tests that breakdown voltage on small conductors is less than on large conductors where the insulation thickness is the same. As the breakdown varies so widely, however, on samples cut from the same cable, it is necessary to make a large number of tests.

William H. Cole: In cable specifications with which I am familiar, dielectric losses are specified to be relatively low, but no other essential quality is to be unduly sacrificed on that account. I believe certain manufacturers have been neglecting some of these other qualifications of good cables. In one case at least, while continued reduction in dielectric losses has been effected, the saturation of the paper dielectric has become less perfect. I do not refer to longitudinal migration of compound with which many engineers are familiar, but to continual radial absorption by the paper of compound from the filler spaces. Such cables are apparently well saturated when they are delivered and remain so while held in storage. After being in operation from one to two and one half years, some of these cables develop serious voids in the filler spaces, so that we are now meeting with trouble due to ionization in the central part of the cable.

Tests have been made which indicate that ionization has an oxidizing effect on the compound. Stethoscope tests show that the used cables have a larger percentage of voids, than unused sections from the same original lot.

On the whole it appears to be a question whether or not the manufacturer in arriving at low dielectric losses has acquired sufficient knowledge of the characteristics of his impregnating compound, how much compound he puts into his paper, how much he leaves in the filler spaces, and how long that compound will remain in the filler spaces. The importance of this subject was realized years ago—that compounds must not only be introduced into the cable to a sufficient extent to fill all voids, but

that there shall be no chemical or other action within the cable after the cable is placed in service.

On the subject of d-c. testing of cables the class of cable referred to failed recently under a d-c. routine test. The faulty section was carefully examined disclosing the radial absorption effect, the ionization of the voids and the oxidation of the compound. The cable under test had been in continual service, was supposed to be in a sound condition, and the operating pressure between conductors had been of the order of 24,000 volts. The d-c. test voltage was 10,000 volts or less than two times the a-c. operating pressure. On the basis of the factor of 2.4 the cable failed at a voltage much less than the d-c. equivalent to the a-c. operating pressure. The condition of the dielectric at the point of failure seemed to show conclusively that so called, "spitting" and re-healing of the dielectric had been taking place for some time under a-c. operation. The only conclusion to be drawn is that d-c. voltage is probably more effective in breaking down incipient faults than a-c. voltages and that the ratio of 2.4 between d-c. and a-c. holds good only for dielectrics in perfect condition.

It may be of some slight interest to know that tests on high dielectric loss cables have been made for the purpose of determining whether or not the potential gradient is very much altered by temperature gradients, and while it is of no particular interest today, since no one uses high loss cables willingly, it has been found possible, with sufficient fall of temperature between the copper and lead, to change the distribution of the potential, so that the outer layers receive very much higher stresses than would be calculated for uniform temperature. This may be a possible explanation why some of the old type high loss cables could become so badly charred before final breakdown.

G. B. Shanklin: Mr. Roper's study of current carrying capacity and critical temperature is based on an average duct radiation curve taken from a paper by W. S. Clark and myself read before the Institute in 1919. Available data on duct radiation constants are very meager and our curve was given merely as an illustration with no intention of introducing it as a standard. Since then a few additional data are available and a closer study of our original radiation curve indicates it to represent about 25 per cent better thermal conditions than actually exist in the average duct. Our original "hot spot" radiation curve more nearly represents the true average curve than our original average curve does.

It was with some misgivings, therefore, that I noted Mr. Roper had based his calculations on the average curve and it is surprising to find how well his practical observations and experiences check his calculations. I believe this is accounted for, at least, in part, by the fact that his dielectric loss values assume a uniform temperature through the cable cross section, equivalent to the copper temperature whereas, in actual practise the temperature is graded through the cable cross section, giving a lower dielectric loss than he assumed.

A standard average duct radiation curve would prove useful and if one is ever adopted it would be much better to represent the temperature drop from sheath to ambient soil. The curve would then be independent of the type of cable placed in the duct, except insofar as influenced by sheath diameter, which under ordinary conditions is a factor of no more importance than several others that are ignored in this "short-cut," approximate method.

Mr. Roper's statements regarding the variation of dielectric loss over lengths of cable might lead to misinterpretation. I believe he referred only to high loss cable of the rosin-oil-filled type. The better grades of low loss modern cable do not show such wide variations with length.

An interesting feature brought out by Mr. Roper's study of critical temperature is that, although the Institute temperature rule of 85 deg. cent. applies very well for the old type, high loss cable it is too conservative for the new type, low loss cable.

I have only one conditional exception to take with Mr. Roper's conclusions. He shows quite clearly that the quality of cable insulation has been improved to a point whereby there is little danger of cumulative heating under normal operating conditions. He also shows that this new type of cable meets the standard high-potential test with ease. On the strength of this advancement he recommends that insulation thickness be reduced. There is no doubt but that the thickness used in this country can be safely reduced, but I feel that Mr. Roper has overlooked one important factor, and that is internal ionization.

The state of the art has progressed to a point, now, where internal ionization will be the limiting feature in any further reduction or gain. It is to be regretted that more is not known about this feature. We know that when voids or gas spaces are present in a cable that ionization occurs when a certain value of stress is reached. The conditions under which this ionization is likely to occur in service, its nature, whether it continues indefinitely and the amount of damage it can do is not clearly understood. We are at present making a study of these factors and hope to throw some light on them in the near future.

Ionization cannot be ignored. No matter how compactly made a new cable may be and how tightly the sheath is applied, voids form in service. Expansion and contraction loosens the lead sheath, causing it to "crawl" to a more or less extent, thus forming voids. Under laboratory test conditions these voids just under the sheath are ionized at a stress on the insulation (minimum stress) of about 14.0 kv./cm. What occurs in actual operation when the minimum stress exceeds 14.0 kv./cm. we do not know yet. Our work thus far indicates that ionization usually starts first, next to the sheath and not next to the conductor as previously assumed, although we are not prepared to state this conclusively.

Mr. Simons' paper on the dielectric strength of cables is too theoretical and speculative to be of practical application. Papers of this type are interesting and help us form a better mental picture of what might happen in a cable at breakdown. What actually happens is another story and probably involves too many factors to be so simply explained.

The mechanics of breakdown in gases is now fairly well understood and the parallel problem of liquids is well on the road towards solution. Gases are homogeneous and readily applicable to theoretical study. It is but natural that they should first give up their secrets. Liquid insulations are not so homogeneous but far more so than solid insulations. Investigators began to make real progress with the mechanics of breakdown in liquids only after the factors introduced by foreign impurities, such as moisture, dust, etc., were recognized and eliminated.

The same principles will have to be applied to a study of the mechanics of breakdown in solids. One of the greatest difficulties is in obtaining even an approach to homogeneity in solids. We must first learn something about the theory of breakdown with simple homogeneous solids in a parallel field and explain why the breakdown stress usually depends upon the thickness of insulation. Later we can go to more complicated built up commercial insulations in parallel fields and finally to cables, in which the non-parallel dielectric field adds further complications. What is needed at present are more actual breakdown data on cables, such as published by Fernie, and the very interesting data presented at this meeting by Messrs. Middleton, Dawes and Davis.

The paper by Del Mar and Hanson impressed on two counts, as we have done work along similar lines. Their theoretical study of dielectric loss is clearly and remarkably put forth and agrees with measured results better than any of the several theories that have been advanced at various times.

Several years ago we found by trial that the equivalent dielectric circuit could be closely represented by an arbitrary circuit similar to their Fig. 2. The component which they designate in their formula as "resistivity of cellulose fibers," however, should be called, "unknown factor," for it must surely represent more than the resistivity of the cellulose fibers. (It

probably represents also the moisture resistivity.) The effect on dielectric loss of this component is small. I fully agree with their statement that dielectric loss is largely determined by the resistivity of the impregnating compound, for we have made numerous measurements that verify this in every particular and have found much the same relation between power factor and compound resistivity as given in their Fig. 3.

In one other respect, our work verifies theirs. The conductivity of compound alone, and hence, the power factor and dielectric loss of finished cable, gives every appearance of being mostly due to ionic conduction. It may not be true ionic conduction of the electrolytic type but it is some sort of uniform migration or transfer of charged particles such as metallic conduction. One of the best proofs of this is the almost exact agreement between d-c. and 60-cycles a-c. resistivity of compounds at temperatures above their melting points. Divergence occurs only at lower temperatures where the compound is in solid form. There is a sharp upward break in the resistivity curves when the solidifying temperature is reached.

The conclusions arrived at by Messrs. Del Mar and Hanson concerning dielectric strength are not so convincing. They attempt to explain the dielectric breakdown by this same theory of ionic conduction. If they are referring to slow breakdowns of the accumulative heating type their theory holds quite well, such failures should be called conduction breakdowns, but the term dielectric strength is recognized as applying only to those breakdowns that occur soon after the test voltage is applied and before accumulative heating takes command.

Under these conditions there is no relation between dielectric loss and dielectric strength of cables. Quite often cables having the lowest dielectric loss also have the lowest dielectric strength and vice versa. Still more convincing proof that the conduction and dielectric strength are unrelated is furnished by tests on the compound alone. Here, there are no cellulose fiber barriers, the charged particles have a free path between electrodes. One would naturally expect the relationship to be brought out more distinctly than in cables. The results, however, are even more divergent than in cables. Compounds having low resistivity often have high dielectric strength. If moisture or dust is added to a compound of high resistivity its dielectric strength can be reduced to a negligible value without effecting its resistivity at all. The resistivity of any compound varies enormously with temperature while its dielectric strength is effected hardly at all by temperature. This same temperature characteristic holds, approximately, for solid insulations.

I have studied dielectric strength for a long time, and have never found a theory that applied better than the old analogous theory of mechanical impact stresses and strains.

There appears to be a tearing apart of the molecular structure similar to mechanical rupture. Some materials are electrically brittle and some electrically elastic, analogous to mechanical brittleness and elasticity.

One of the most vital factors appears to be concentration of stress, set up by local high frequency. As an illustration, a poorly filled cable can be considered. Every one knows that a poorly filled cable has relatively low dielectric strength. This is due to concentration of stress, set up by local high frequency. When the applied voltage reaches a certain value, the voids in the cable cross section are ionized. At first it is merely a faint glow but as the voltage increases there is an increase in intensity of discharge and appearance of local high-frequency oscillation. The localized stress thus caused tends to start rupture and final breakdown. This might first start at the conductor, at the sheath or wherever the voids happen to be located.

Mr. DuBois, in his present paper advances a theory of dielectric loss somewhat at variance with that of Del Mar's and Hanson's. He attempts to account for dielectric loss as due to a certain peculiar behavior of moisture content. I believe if both theories were combined in their proper proportions a very good working theory would be produced. The whole trouble seems to be that Del Mar and Hanson ignored moisture while Du Bois over-emphasized it. It is only in cable not thoroughly vacuum dried that the moisture component of dielectric loss is comparable with that component produced by the conductivity of the impregnating compound. I am certainly inclined to agree with Del Mar and Hanson in their conclusion that the last named component predominates in modern, low loss cable. All of our experience points in that direction.

Messrs. Middleton, Davis and Dawes deserve a unanimous vote of thanks for their splendid paper and the admirable way in which they have handled dielectric strength, a subject involving many, as yet, unknown factors. Their empirical results are original and impressive. It will be interesting to see how well they stand the test of time and additional trials.

If Mr. Middleton had looked up a paper on cables presented before the Institute in 1917 by W. S. Clark and myself he would have found evidence supporting his conclusion that automatic grading due to voltage stress and temperature distribution is of negligible amount.

Mr. Shrader's paper on "Corona in Air Spaces in a Dielectric" does not leave much room for doubt concerning the cause of the peculiar and abrupt change in dielectric loss that occurs in practically all commercial forms of solid dielectrics when the voltage is increased. It is, as we have always contended, due to ionization of the entrapped gas. It is to be regretted that Mr. Shrader did not include data on permittivity, temperature, etc., which would have enabled those engineers who have worked along similar lines to make a better comparison between his work and theirs. His method of presenting results is, in every other way, exceptionally good, but I do not agree with his conclusions that these results cannot be theoretically applied.

J. L. R. Hayden: In our investigation on insulated materials during the last few years we made the same observations, which are in good agreement with Mr. DuBois explanations on the effect of moisture in insulating materials. We have been able to reproduce experimentally some of the phenomena discussed in the paper in such a manner that they can be visually observed. For instance, the action of moisture particles in forming threads and bridging between terminals, is illustrated in Fig. 1 of the paper. This can be shown conveniently in the following manner. As insulating materials we use a light colored viscous oil; as terminals two spheres of 2.5 cm. diameter and 1 cm. distant, and impress about 10,000 volts between the spheres, that is, much less than the voltage which the oil gap would stand. Then a small amount of moisture is dropped on the oil by a dropper, in small drops. These drops can be observed to drop slowly through the oil, until they approach the electrostatic field. Then they are rapidly sucked into the field, and each drop elongated into a thread, and the thread lengthens, until it bridges between the electrodes. Then a flashover and the thread is destroyed by turning into steam by the heating effect of the current through it. In this manner flashes occur for a considerable time in intervals of a few seconds by drops entering the gap, lengthening into threads and bridging the gap.

Very interesting and suggestive also are the motions of the drops, which depend on their position in the electrostatic field, and on the nature of the field, whether unidirectional or alternating.

N. L. Morgan: Mr. Simons has mentioned several theories which attempt to account for the breakdown of single-conductor cables having the radio R/r greater than 2.72 and he has also suggested another theory to explain the results obtained by Fernie. After reading his paper, I do not feel entirely satisfied with his explanation. I think that it is an advance over the other theories that have been suggested but do not think that it has been carried far enough.

I do not see how insulation can be overstressed and at the same time not destroyed. Several investigators have shown

that so-called "overstressed insulation" is really due to temperature rise, and the effect eliminated after a period of rest. It seems to me that the breakdown of single-conductor cables, having the ratio R/r greater than 2.72, is due to change of dielectric constant of the portion of the insulation near the conductor. As a voltage is applied to the cable, the stress in the portion of the insulation near the conductor increases and consequently the increasing dielectric loss causes the temperature to rise. Although the a-c. dielectric constant does not change below 50 deg. cent. it does vary considerably above 100 deg. cent. If, therefore, the inner portion of the insulation is several degrees hotter than the portion near the lead, we may have the equivalent of a cable with graded insulation and the cable would withstand higher voltages than would be expected.

This also explains Fernie's statement that small conductor cables withstand higher maximum stress than large conductor cables with the same insulation wall.

From the above one might think that the greater the dielectric loss of a cable is, the hotter it will get and therefore the greater will be the breakdown voltage of the cable. But as mentioned above, breakdown is really a charring of the dielectric, that is, a strictly physical phenomenon, and the cable with the greater dielectric loss will reach this charring temperature first.

When voltage is applied suddenly, the heat generated near the conductor where the stress is greatest has not sufficient time to be conducted away and the grading effect will be much more marked than if the voltage is increased slowly and the heat given time to be conducted to the sheath. That is, a cable will withstand a higher voltage when it is applied quickly than when the cable is subjected to long period test, which has been found to be the case in practise.

It seems to me that a satisfactory theory of dielectric breakdown, will not be arrived at until we take all the factors into consideration. The theory cannot be based on only one class of observations, but must be based on the temperature of the dielectric, its dielectric loss and constant, its insulation resistance, its specific heat, the thermal conductivity, its shape, its dimensions, and the inter-relation of these different properties. When all these things have been taken into account, then we will be in a position to formulate a theory of dielectric breakdown.

C. P. Steinmetz: An extensive investigation of this problem of the mechanism of the breakdown of solid insulation, has been carried out during the last few years in my laboratory by Mr. Hayden and his assistants, in which we derived the conclusion, or rather, are forced more and more to the conclusion that there exists no such thing as a definite breakdown voltage or breakdown gradient of solid insulation.

It seems to look more and more as if the electrical breakdown of solid insulation under electrical over-stress is not analogous to the mechanical breakdown of a structure under mechanical overstress, but is a phenomenon of an essentially different nature, and different character, and is related to the electrical characteristics of the third class conductors. I have discussed this type of conductor on a number of occasions, the so-called pyro-electric conductor. It is a type of conductor little studied. It is characterized by a volt-ampere characteristic in which over a certain range of current, the voltage decreases with increasing current; so that in such a conductor, if we impress a voltage and gradually increase it, the current passing through the conductor first increases proportionately to the voltage, then begins to increase more than proportionately to the voltage, and finally, the resistance decreases with increase of current at such a rate that the voltage does not further increase, but the current continues to increase. A further increase of current results in a decrease of the terminal voltage across the conductor, and with increase of current, the voltage decreases to a minimum. Beyond this the voltage may again increase slightly. That is, in such a conductor there is a maximum voltage point at a certain intermediate current. The results of our investigation seem to show that what we call a solid insulator, is, at least in many cases, a third-class conductor—a conductor of a type in which the current at the maximum voltage point is extremely low.

Considering then the solid insulator as such a third class conductor. By impressing constant voltage on it, and gradually increasing the voltage, you will find that the current, passing through the insulator, increases, first proportional to the voltage, and then more than proportional, until the maximum voltage point is reached, and there the current runs away, rapidly, practically instantly rises, up to the short-circuit current of the voltage supply, which means the destruction of the conductor by heat and the elimination of all that can be seen. We have succeeded, by limiting the power, to carry these volt-ampere characteristics of the insulator beyond the maximum voltage point, and observe that part of the volt-ampere characteristic, where the increase of current means a decrease of voltage, where, as we would speak of insulators, the insulator is over-stressed. We find that at the maximum voltage point, which would be considered in general as the breakdown voltage, the disruptive strength of the insulator is not impaired, and we may go materially above this, and still have the insulator unimpaired, no change, no damage. It is the unlimited concentration of energy, resulting from this characteristic at constant voltage supply, which leads to the destruction which we call breakdown.

But, by limiting the energy, we have been able to go beyond the maximum voltage, and we have been able to study the behavior of solid insulation in this range.

From this it follows that in dielectric fields where the shape of the field is such as to limit the energy which can be concentrated in an overstressed portion of the dielectric, as is the case, for instance, with a cable with a high ratio of external to internal diameter,—with such a structure a part of the insulation can be stressed above the so-called breakdown point of the insulator without changing the insulation.

In this case the logarithmic law of voltage distribution does not apply any more.

You see all these are conclusions which have been brought out very nicely in a number of these papers. Furthermore, it follows that the rupturing voltage of a solid insulator, with continuous voltage and alternating voltage, are in a constant relation, and this relation depends on the nature of the insulator, and this seems to offer a possibility of the study of actual voltage distribution in the insulator, not merely at breakdown where the voltage distribution really means but little, but before and after the breakdown, and so get some idea of the mechanism of the breakdown.

It follows, for instance, that with regard to the overstressed portion of the insulator, the voltage gradient does not collapse, but remains finite, though lower than in the portion of the insulator which is not overstressed.

We may consider the maximum voltage point of the solid insulator as third-class conductor, as the breakdown point. However, this maximum voltage point of the volt-ampere characteristic is not a constant, but depends on very many conditions. It depends on the nature of the insulator, on the energy developed in the insulator, or near the insulator; on the heat conductivity and on the heat storage capacity of the insulator and of all surrounding material, and also on changes taking place in the insulator with temperature, etc. Mr. Roper's paper was interesting in showing a number of features that bring this out, although I have not had time yet to numerically check up these figures.

There is still a large amount of work which will have to be done, before we can really be perfectly certain of this conception of the solid insulator as a third-class conductor, by which the electrical volt-ampere characteristics determine the behavior of the insulator in the electrostatic field. There will still have to be much experimental work done, and the conclusions which we derived therefrom, verified; but it is to be hoped, at a meet-

ing similar to this, it will be possible for Mr. Hayden to present a paper on the mechanism of breakdown of solid insulation.

G. A. Anderegg: In connection with the problem of dielectric loss in power cables it may, perhaps, be of interest to make a brief statement regarding similar losses in telephone cables at frequencies higher than those customarily considered in power circuits.

Telephone transmission ordinarily occurs at voltages far below the limiting strength of the insulation, and the entire power loss in such cables normally has no appreciable effect upon their temperature. In such cases the dielectric losses are of importance, therefor, not from the standpoint of heating or of breakdown strength but from the standpoint of attenuation, especially in case the cables are artificially loaded with inductance or are operated at the high frequencies used for "carrier" transmission, when the dielectric loss may add substantially to the total power loss and transmission loss. It is, therefore, important, especially in long loaded cables, to take special precautions to have the dielectric loss as low as possible.

It has long been recognized that the capacity and insulation resistance as measured with direct current by means of a galvanometer do not accurately represent these properties for a cable operated at frequencies of hundreds or thousands of cycles per second. Great numbers of measurements of capacity and dielectric loss of circuits in telephone cables have, therefore, been made by means of a specially designed bridge, briefly described by G. A. Campbell in the *Electrical World* and *Engineer*, April 2, 1904. It has been found convenient to express the results of dielectric loss measurement in the form of the conductance of the circuit; *i. e.*, the admittance of an actual circuit having capacity and dielectric loss is represented as if it consisted of a pure ideal capacity shunted by a conductance. To make a ready comparison of different circuits, it has been found convenient to consider for each the value of the "damping constant" $G/2C$, in which G is the conductance in micromhos and C the capacity in microfarads. This expression appears in one form of the attenuation constant for a loaded circuit, and when its magnitude is known for the desired frequencies it serves to indicate the quality of the insulation from the standpoint of dielectric loss.

With the types of insulation most commonly used in telephone cables it has been found that the conductance is approximately proportional to frequency throughout the ordinary range of telephone frequencies, though increasing somewhat more rapidly than proportional to frequency. It is independent of the applied voltage so long as this is kept well below the breakdown strength of the insulation, as is the case in normal telephone operation.

Since the conductance increases with frequency it follows that for a given effective voltage the dielectric loss is greater with a complex wave form than with a pure sine wave form, because the higher frequency components of the complex wave form act upon a higher conductance and, therefore, contribute a greater dielectric loss than they would if conductance were independent of frequency. This fact may have some bearing on the advantage of a good wave form for power transmission in cables.

In many telephone cables low capacity and low dielectric loss, rather than high breakdown strength, are controlling requirements. The design of such cables differs greatly from that of power cables, the commonest form of insulation being air and dry paper without impregnating material, only enough paper being used to give the spacing of wires needed to secure the desired capacity and the necessary firmness to make it possible to handle the cable successfully during installation. Such construction makes possible a very low dielectric loss. In some cases the power factor, or sine of the "imperfection angle" at 1000 cycles per second may be as small as 0.002, or sometimes even less.

Changes in design or treatment which tend to increase the insulation resistance for direct currents usually tend also to decrease the conductance for alternating currents an(crease the excess of the capacity at low frequencies ove1 high frequencies, though there are no definite relations these quantities. In the ordinary ranges of working tem: the conductance of the usual types of telephone cables i with increase in temperature, though in many cases tl temperature of minimum conductance, below which a decrease of temperature again results in increased cond Certain insulators, for example rubber compounds an percha, in many cases show a very markedly higher conc at temperatures approaching the freezing point of wa at more ordinary room temperatures, although their current insulation resistance is much greater at the lov perature.

W. D. A. Peaslee: With reference to the paper by Middleton, Dawes and Davis, there are several very int points brought out that add materially to the large an data that has accumulated during the last few years lead serious question as to the validity of our past theories wit to the mechanism of breakdown of a dielectric.

It would seem that it is time for a very serious consi of our past theories in the light of the accumulated evi the last ten years of investigation in the field of the dielectrics to see if there is not something fundamentall with our ideas regarding these materials. For sometim been drawn very positively to the feeling that there is thing as a dielectric, that the substances we have o

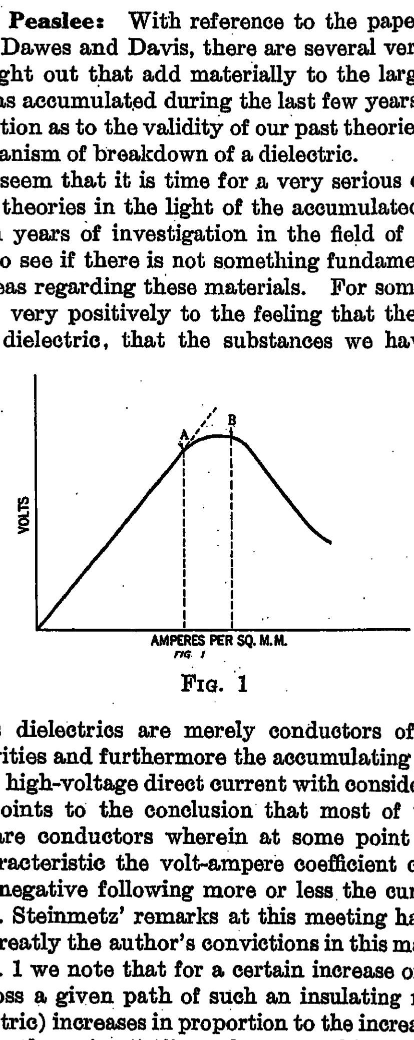

FIG. 1

regarded as dielectrics are merely conductors of eno high resistivities and furthermore the accumulating data by means of high-voltage direct current with considerabl available, points to the conclusion that most of the dielectrics are conductors wherein at some point of t ampere characteristic the volt-ampere coefficient chang positive to negative following more or less the curve s Fig. 1. Dr. Steinmetz' remarks at this meeting have s ened very greatly the author's convictions in this matter refer to Fig. 1 we note that for a certain increase of cur voltage across a given path of such an insulating mate called dielectric) increases in proportion to the increase in density. At the point "A" on the curve this increase from a strict proportionality, the coefficient steadily de until at B the coefficient has become O and an increase rent density does not entail an increase in voltage. Bey point B an increase in current density actually occurs decrease in voltage across the conducting path.

We have, in the past, rather accepted the mechanism o tric breakdown as expressed in the old rule "whenev finite period of time the dielectric flux in a given diele ceeds a certain critical value for that material the diel destroyed." I think that this theory is subject to very challenge in the light of present accumulated data. The ance of such a theory of breakdown has led to the discr in interpretation of observed data, such as have been bro in the paper by Fernie's "Minimum Stress Theory" a theories discussed in these papers.

Let us for a moment examine what occurs in a cable as

is applied between the conductor and sheath. Admitting for a moment the hypothesis that the so-called dielectric is merely a conductor of the class described of extremely high resistivity, assume a conductor of radius r surrounded by an insulating material whose volt-ampere characteristic is given in Fig. 1 which is in turn surrounded by a lead sheath whose inner surface is at a radius R from the center of the conductor. We will designate as x the radius of any point under discussion at any time. As voltage is applied between the conductor and sheath, a very minute current will begin the flow through the insulating material. The current density naturally is greatest at the surface of the wire, decreasing, at a given applied voltage, as we approach the lead sheath. As the voltage is increased the current flowing through the insulating material increases in proportion to the applied voltage until at the surface of the wire the current density reaches the value corresponding to point A on the curve of Fig. 1. As the voltage increases, the point at which current density equivalent to A exists, moves out from the surface of the wire to a point x within the insulating material. At this moment the insulating material between a radius R and radius x is carrying a current density corresponding to a point beyond the point A on the curve and we will say for the moment that the current at the wire surface corresponds to the point B when the current density at radius x corresponds to point A. Until the current density at the surface of the wire reaches a value greater than that density corresponding to point B, there is no part of the insulating material in which the conducting path is operating with a negative voltage current characteristic. The part from radius x to radius R is still operating at a current density corresponding to points somewhere between 0 and A on the curve. The result is a stability of the insulating sheath.

At this point, if the voltage is increased, the radius at which the current density corresponds to the point A will move farther towards the sheath. The radius at which the current density corresponds to point B will move out from the conductor surface into the insulating material. We will then have in the insulating material three zone conditions:

1. The point from radius x to radius R corresponding in current density to points between O and A.
2. A distance from radius x to radius x_1 carrying current densities corresponding to the part of the curve A-B.
3. Portion of the material from radius x_1 to the conductor surface in which the current characteristic has become negative and corresponds in current density to the part of the curve beyond B.

If at this point the total voltage current characteristic of the path from the conductor to the lead sheath is still positive, the insulating material is in stable equilibrium and breakdown will not result. However, the moment the composite voltage-current coefficient of the path from the conductor to the lead sheath becomes negative, the current begins to increase rapidly and the insulating material will be destroyed by heat. This is the so-called puncture voltage and is really not a puncture voltage but is a voltage at which with the given material and spacing, the composite volt-ampere coefficient of the path from the conductor to the sheath becomes negative.

The current herein discussed is the pure conduction current such as would be produced with the application of direct-current voltage. The capacity current flowing under alternating voltage serves merely to raise the temperature of the insulating material. Due to the negative temperature resistivity coefficient of many insulating materials however, this capacity current has a very decided effect on the voltage at which the current density in the insulating material becomes great enough to destroy the material by heating. This explains certain of the discrepancies in alternating and direct-current breakdowns of insulating materials. Under this theory also the effect of time of application of voltage in the breakdown voltage becomes apparent as merely the time element of an energy function.

It is well known that gaseous conduction presents characteristics of a conductor of the class described and that this conduction is an electronic or ionic migration. In a solid insulating material the ionic motion is restricted, but there is an enormously greater supply of electrons or ions available and it seems an entirely tenable theory that this conduction in materials of this class is electronic or ionic in nature. Viewed in the light of this hypothesis, Mr. Peek's Energy Distance Theory acquires wider meanings and the ratio of $\frac{D}{d}$ equals 2.72 takes on a rather definite meaning. Our older theories of the mechanism of a breakdown of a dielectric have led to contradictory theories and ideas and the mass of data that have been accumulating does not seem to admit of explanation throughout the entire field without rather startling hypotheses and exceptions being made.

I cannot accept completely the theory of an over-stressed dielectric still carrying a certain amount of voltage gradient by some mysterious virtue of its geographical position. When we examine this phenomena under the light of the above discussed hypothesis, a certain amount of light seems to be thrown on some of our more serious problems in the insulation field. I should be very glad to have others who have been studying this field examine this hypothesis critically as I believe there is some merit in the theory and considerable evidence to support it, especially from our researches of recent periods.

F. Fernie: The writer is greatly interested in Mr. Simons' interpretation of his (the writer's) experiments.

The conception of an over-stressed dielectric still carrying its share of the voltage is new to the writer, and he is inclined to abandon the "skin-resistance" theory in favor of it. Indeed the "skin-resistance" theory was only presented for want of something better. It has been suggested as a possible explanation that the dielectric constant of an insulation may alter under an electric stress; the writer's informant having some recollection of experimental work done on porcelain in this connection, but the writer has been unable to trace it.

As Mr. Simons points out, the difficulty in forming a conclusion is the lack of data.

The only results the writer has been able to find are in a paper by Dr. Klein abstracted from the E. T. Z. in *London Electrician* dated Dec. 26th, 1913.

The following table is taken from Dr. Klein's paper, which deals with single-conductor paper cables.

	3 mm. thickness of insulation			6 mm. thickness of insulation		
	A	*B*	*C*	*D*	*E*	*F*
Area in sq. mm.	16	50	240	16	50	240
Minimum	20.0	20.0	20.0	35.0	30.0	50.0
Mean	40.3	36.6	37.2	56.5	62.0	70.3
Max.	49.3	49.0	54.0	70.0	84.0	95.0
E_1	20.3	15.8	14.3	18.3	16.1	14.9
E_2	25.4	20.8	17.6	23.5	20.6	19.0

There were apparently 60 to 80 tests made on each size cable. The figures in the first 3 columns are the breakdown values in kv.: E_1 and E_2 are the maximum stresses at breakdown calculated from O'Gormans' formula (E_1), and Deutschs modification (E_2), in kilovolts per millimetre.

The minimum stresses calculated from Klein's E_1 figures are:

A	8.8	*D*	5
B	8.9	*E*	6.3
C	10.5	*F*	7.9

These figures are inconclusive, as is to be expected, when there is such a big diversity between the maximum and minimum values found for similar samples. Still by making a selection from Klein's figures, a good case could obviously be made for a constant minimum stress. Mr. Simons attributes such diverse results to "the inherent lack of uniformity of insulating materials." The writer disagrees with this view, and regards non-uniformity as ultimately a *surface tension* effect.

Probably everyone is familiar with an experiment by which potassium permanganate solution can be filtered with blotting paper so as to emerge nearly colorless. The same effect tends to take place in the impregnation of paper cables. If the paper is wound on rather tightly so that the compound is forced to go through the paper, rather than between adjacent layers, analysis will show that the compound which reaches the inner layers of paper is different from that on the surface layers. There are then a variety of reasons for non-uniformity: (1) Tension with which the paper is lapped; this may be varied in several ways, during the lapping of one length of cable. (2) Variation in the mixing of the compound ingredients; possibility of different phases; as solution of A in B, or solution of B in A. (3) Age of the compound, *e. g.* time elapsing since mixing and amount of stirring done. As is well known spirit varnishes are particularly sensitive in these respects. (4) Temperature of compound.

It may be concluded then that paper cable making is by no means an exact science, and cable makers are unable to predict exactly what the breakdown of a particular design will be, even from the purely empirical data gained from experience.

Returning now to the minimum stress theory the writer, reasoning from the behavior of concentric electrodes, concluded that the breakdown voltage between two adjacent conductors would depend on the stress on the insulation situated midway between them. He evolved the following formula for the breakdown voltage:

$$V_{rms} = \frac{K\left(2rx + \frac{x^2}{2}\right)\log_e\left\{\frac{x+2r}{2r} + \sqrt{\left(\frac{x+2r}{2r}\right)^2 - 1}\right\}}{\sqrt{x^2 + 4rx}}$$

x is the thickness of insulation between conductors, and r is the radius of the conductors. K is a constant for any one kind of dielectric. (In one series of tests with paper $K = 39$).

This formula has given fairly accurate results with some kinds of insulation, but the writer has not made nearly enough experiments to justify him in presenting it as "Highly probable." It is given here as of possible interest in connection with Mr. Simons' paper.

L. L. Perry: Mr. Roper shows, in Fig. 12, values of "Dielectric Loss Assumed for Purposes of Calculations." His method seems an excellent one and on comparing with his assumptions the results of tests made on some recent 3-conductor cables of 400,000 cir. mils used on 13,200-volt circuit, I have thought the results might be of interest to the Institute. As will be noted by accompanying curve, Fig. 2, at temperatures above 85 deg. cent. Mr. Roper's assumed characteristics give somewhat higher values than these tests show, and so are on the safe side. At temperatures below 85 deg. the tests on all but cable C-2 also show lower values than in Fig. 2 of Mr. Roper's paper.

It is thought Fig. 3 which gives the average power factor for each of the four cables tested, may be of interest, as presumably this should be about the same for different sizes of conductor at the same temperature.

In these tests the power factor curves when plotted to the arithmetical-logarithmic scales, as shown, follow closely the shape of the loss curves.

The power factor at any definite temperature varies but little with a change in voltage from 7000 to 17,500 volts, the variation above 85 deg. cent. from the average having a maximum of about 8 per cent, and below 85 deg. cent. about 25 per cent.

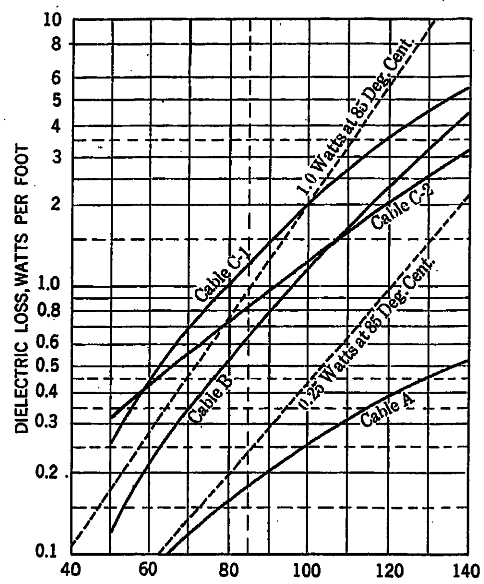

FIG. 2—DIELECTRIC LOSS FROM TESTS ON THREE MAKES OF CABLE COMPARED WITH ASSUMED LOSS

400,000 cir. mil., 3-conductor cable, 7 ft. 32 in. x 7 ft. 32 in. paper insulation—13,200 volts, 3-phase tests. Cables C-1 and C-2 of same make.

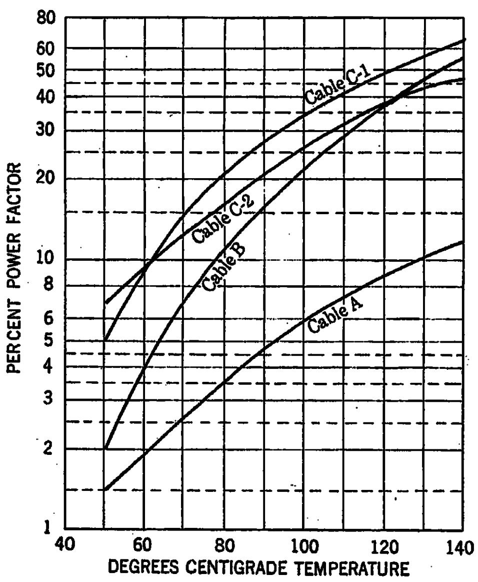

FIG. 3—AVERAGE POWER FACTOR OF DIELECTRIC LOSS IN TESTS

400,000 cir. mils., 3-conductor cable, 7 ft. 32 in. x 7 ft. 32 in. paper insulation—7000 to 17,500 volts, 3-phase tests. Three makes, C-1 and C-2 of same make. Note: Above 85 deg. cent. the tests showed a maximum variation in power factor at any temperature of only about 8 per cent from the average shown for voltages from 7000 to 17,500. For temperatures below 85 deg. cent. the maximum variation was about 25 per cent.

These are similar to the results in the power factor figures given in Clark and Shanklin's, A. I. E. E. paper of June, 1917.

W. A. Del Mar: Dynamo-electric machines and transformers are now susceptible of design with wonderful exactness. Designs made to any performance specifications would differ but little whether made by one manufacturer or another, and the performance would fulfill predictions with very little margin of error. This is because the theories of the magnetic circuit, of electromagnetic induction, and of the generation and flow of heat, are well understood and their bearing upon practical design are appreciated.

It is not so with electric cables whose insulation has seemed

to us as capricious, in its behavior, as the magnetic circuit must have seemed to dynamo designers in the days of the long-pole Edison dynamos.

It is hoped that this symposium will be the starting point for research which will be as epoch-making as Hopkinson's work on the magnetic circuit, which put dynamo design upon its present basis of exactness. The papers which have been presented do not record any startling discoveries, but taken in the aggregate, they show that cable engineers are alive to the problems before them and that both manufacturers and operators are closing in upon some basic facts and devising ingenious theories that may lead eventually to the solution of the major problems.

While not part of this symposium, Dr. K. W. Wagner's recent Institute paper should be studied in connection with the present group.

It is interesting to note that two papers are devoted to theories of dielectric loss; that they are both based upon imaginary microscopic views of the insulation, which reveal a heterogeneous structure, and that both blame the dielectric loss upon this heterogeneity. The two theories differ in that in one, moisture particles are held to be the culprits, whereas in the other, the impregnating compound is blamed.

There is no doubt about the fact that moisture was to blame for the high dielectric loss of many of the cables of years ago. These cables were not thoroughly dried, both the paper and the oil containing moisture in considerable quantities. The power factors of such cables, when plotted against oil resistivities, do not lie anywhere near the theoretical curve in Fig. 3 of our paper. For example, an oil resistivity of 0.5×10^{12} ohm-cm. corresponds to a theoretical power factor of 5 per cent at 85 deg. cent. A cable with about 2 per cent moisture, as derived by vacuum dessication at 130 deg. will have a power factor of about 18 per cent. The water, in such a case, is the principal factor determining dielectric loss. In our paper we expressly state that in applying the theory it is assumed that practically no moisture is present, as a very small proportion will have a greater effect than even a fairly large reduction in the resistivity of the oil or cellulose. Our theory is intended to explain that element of the dielectric loss which occurs in a well-dried cable, and it has been found to be so reliable, as a working guide, that we can confidently state the power factor of every length of cable made in the factory merely by making resistivity tests of the oil. Since the wr ting of the paper, an experimental point has been obtained for Fig. 3 corresponding to a resistivity of 6×10^{12} ohm-cm. The theoretical value of the corresponding power factor was 2.04 per cent; the experimental value was 2.1 per cent. We are pleased to note that Mr. Shanklin's views support our own.

We may thus claim to be able to scientifically design cables for power factors. Having accomplished this, our next step was to try to design for dielectric strength. The first obstacle to be encountered was the lack of formulas to express a relation between the dielectric strength of the insulation and the breakdown voltage of a cable. A fundamental difficulty stood in the way; the apparent dielectric strength of flat samples varied with their area and thickness. Dr. Wagner came to the rescue with his mosaic electrodes, which enabled true dielectric strength to be measured. Knowing the true dielectric strength of the insulation how can the breakdown voltage of a cable be calculated? Mr. Peek has given a working solution in the case of single-conductor cables which may be expressed by the formula

$$E = 2.3\, S\,(r + 1.1\sqrt{r})\log_{10}\frac{R}{r}$$

Where E = breakdown tension, kv.
S = dielectric strength, kv./cm.
R = outer radius of insulation, cm.
r = inner radius of insulation, cm.

In the case of triplex sector cables which we have tested

$$E = 0.9\ St$$

Where E = breakdown voltage between conductors, kv.
S = dielectric strength, kv./cm.
t = thickness of insulation between conductors, cm.

With the same kind of insulation, these two formulas give about the same value of S. Our own experiments confirm Mr. Peek's formula far more strikingly than the experiments cited by him. For example, twelve single-conductor cables having $r = 1.04$ cm. and $R = 2.67$ cm. broke down at an average of 200 kv. the same value being attained at 25 deg. and 85 deg. cent. Mr. Peek's formula also gave 200 kv.

Some experimental data published by Dr. Klein in the E. T. Z. and abstracted in the *London Electrician* of Dec. 26, 1913, show a much more uniform stress at the energy distance suggested by Mr. Peek than either at the conductor surface or the sheath surface.

Equipped with these formulas the next step was to find the factors upon which the value of the dielectric strength S depends.

The ion-baffle theory was applied in the following way. The dielectric strength of impregnated paper insulation in a cable may be expressed by the following formula:

$$S = S_o\, B F$$

Where S = dielectric strength of impregnated paper in cable,
S_o = dielectric strength of oil,
B = factor expressing baffling effect of paper,
F = factor expressing variations other than those affecting the factor B. (Principally factors affecting the formation of vapor pockets.)

The range of variation of the above quantities with ordinary commercial materials and processes is about as follows:

S_o	20 — 33
B	2.0 — 5.0
F	0.5 — 1.0

Hence, the maximum and minimum values of S would be 165 and 20 respectively, but the combination required to produce so low a dielectric strength as 20 kv./cm. would be rare. Most commercial cables run between 50 and 100 kv./cm. The stress, in this case, is assumed to be calculated by the formulas given above.

By analyzing the causes of the variation in each of these factors, it has been found possible to raise their values and so greatly increase the dielectric strength of the insulation.

I am pleased to note Mr. Shanklin's general concurrence with our theory of dielectric loss and with our conception of ionic migration in oil. While he agrees that this conception serves to explain both ordinary conduction and dielectric failure under long applications of tension, he takes exception to applying it to explain failures under short applications of tension. He cites two reasons for this point of view. The first is that cables of low dielectric loss and therefore of low ion mobility, often breakdown at low voltages on short period tests, and the second is that impregnating compound of high resistivity and therefore also of low ion mobility, often has very low dielectric strength. He argues from this that as low ion mobility does not result in high dielectric strength, the failure of insulation cannot be due to the mobilization of ions.

There is a general answer to both of these reasons, namely, that the kind of ionic mobility that constitutes the conductivity of the insulation is obviously the average mobility, whereas, that which would lead to sudden dielectric failure would be a local maximum mobility. Such a local maximum is not necessarily proportional to the average, especially in dielectrics of such complex nature as either impregnated paper or impregnating compound. There is also a special answer to Mr. Shanklin's first objection, namely, that the ionic mobility of the impregnating compound only affects the factor S_o in the above formula, whereas, the low breakdown voltage of the cables may have been due to low values of the factor B or F.

Mr. Shanklin has called our attention to a very important element in cable failure, namely, the establishment of local

high-frequency surges at vapor pockets. I am inclined to believe that practically every cable that fails on five-minute test, fails from this cause, but I do not believe that a failure will start at either the conductor or the sheath because these large masses of metal would prevent any sudden local temperature rise in the insulation adjacent to them. It is generally the heating due to these surges which creates the local maxima of ion mobility referred to above.

A curious fallacy has obsessed cable makers for many years, namely, that the thickness (*i. e.* viscosity) of the compound should be so great that it will not flow in the cable. In the attempt to follow this theory, compounds have been made of heavy mineral oils thickened with resin. This theory would have been satisfactory if cables were stationary apparatus, but it neglected the fact that cables have to be bent in manufacturing, testing, installing and splicing. When a cable is bent, it is contracted on the inside of the bend and expanded on the outside. If the oil is too viscous, it will not flow from the inside to the outside of the bend, and therefore, the cable will be dielectrically weak due to vapor pockets on the outside of the bends. Cables made with oil of a viscosity properly adjusted to the paper tightness, break down at the same voltage hot or cold.

K. W. Wagner's interesting paper delivered at a Chicago meeting of the Institute this year should be read in connection with Mr. Roper's paper, as both arrive at similar conclusions from entirely different avenues of approach. In this paper, the theory is advanced that solid dielectrics fail due to their negative temperature coefficients of resistivity. If heat is generated in a filament of insulation more rapidly than it can be dissipated, the resistivity will fall off cumulatively until it is so low that the current becomes high enough to burn the filament. According to this theory, it is the slope of the resistivity-temperature curve and not the actual value of the resistivity which determines dielectric strength.

Prof. Scott has told us that a successful 25,000-volt cable was installed some twenty years ago and that we are still practically at the same stage. The cable he was thinking about was installed twenty-two years ago, and practically no important progress in cable making occurred in twenty of those twenty-two years. The advances recorded at this meeting are the product of the last two or three years and are due entirely to the progressive spirit of a few manufacturers and to the untiring efforts of a few cable users.

D. M. Simons: I believe that possibly one of the most important developments of the discussion is the emphasis laid on the negative temperature coefficient of insulation resistance by Dr. Steinmetz, Mr. Peaslee and Mr. Del Mar's quotation from Mr. K. W. Wagner. Mr. Peaslee's application of this idea to the case of concentric electrodes in terms of insulation resistance and the current density, instead of the more usual method of voltage and stress, is most interesting. I believe that even if the negative temperature coefficient is not the complete answer, it will undoubtedly have to be included in any future theory of cable breakdowns.

While my paper is not really a criticism of Mr. Fernie's article, but merely an attempt to explain one section of his data by a different theory and to emphasize the lack of true constancy of his experimentally determined minimum stresses, I was especially glad in reading the final proof of the discussion to find that he had had an opportunity to comment in writing. His remarks have been read with pleasure. Mr. Fernie's formula for the breakdown strength of a multi-conductor cable is interesting. During the preparation of this paper, the writer also developed a formula for the breakdown voltage of a three-conductor cable on the same theory as that outlined for a single-conductor cable, based on the ratio of diameter under lead sheath to conductor diameter giving the minimum value of maximum stress as calculated for triplex cables in the paper of which he was co-author in the January 1921 JOURNAL. This, however, was not included in the present paper, since the theory did not seem to be vindicated sufficiently for the case of single-conductor cables.

Many theories have been proposed. The true solution must exist, but it undoubtedly cannot be determined until the amount of available experimental data is vastly greater than at present.

J. E. Shrader: I wish to say just one word in regard to the potential gradient and the formation of corona, which, as Prof. Whitehead has said, is rather a difficult one to calculate. I do not know with our present state of knowledge, that we could calculate the potential gradient through the range which is used.

Dr. Whitehead also spoke of the abruptness with which the power factor changes in some cases and not in others. That there is a very abrupt change in some cases, I attribute to the fact that there are more uniform layers of gas. With the thinner layers it is almost impossible to have a uniform thickness of gas layer, in which case there is a gradual variation of the power factor.

I think, as Prof. Karapetoff has said, that we ought not to be afraid to tackle these problems on the ionization theory, and modern theories which are being produced. I think it is going to be a matter of getting at the fundamental data and coordinating it with modern theory which will solve all of our engineering problems.

C. F. Hanson: Referring to the Del Mar-Hanson paper, the imperfection angle is the angle by which the current falls short of leading the applied voltage by 90 deg. In a perfect dielectric the current would lead the applied voltage by 90 deg.

Other data on the relation of the power factor of impregnated paper and the resistivity of the impregnating compound have been obtained since Fig. 3 in the paper was produced. In Fig. 3 the points shown from actual measurements were obtained at 85 deg. cent. We have now obtained additional points at 70, 80 and 90 deg. cent. These points, in addition to the 85 degree points, are shown in Fig. 4 of this discussion. The points all lie very close to one curve.

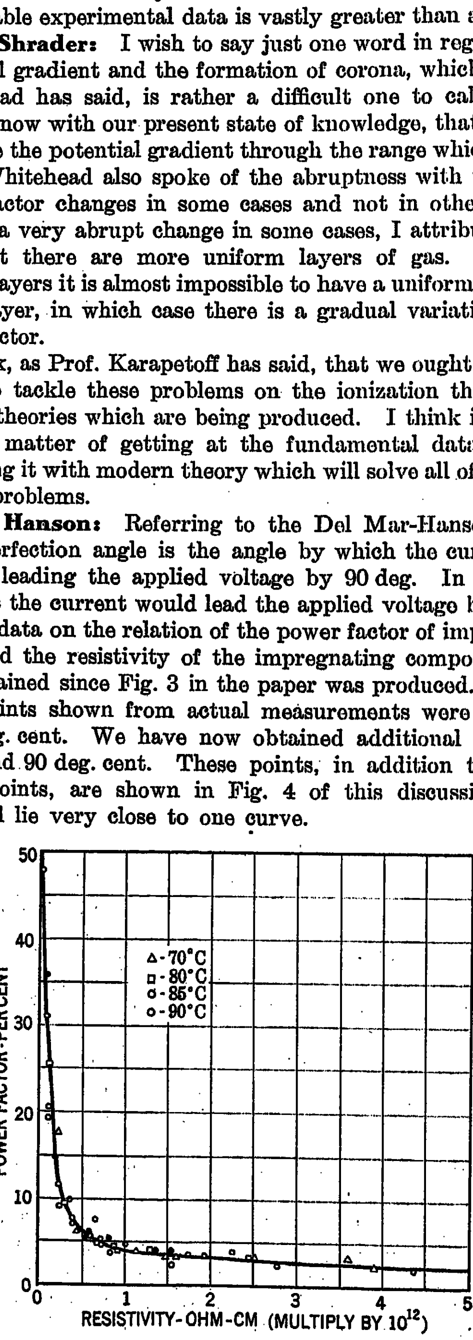

FIG. 4—RELATION OF POWER FACTOR OF IMPREGNATED PAPER AND RESISTIVITY OF IMPREGNATING COMPOUND AT TEMPERATURES 70 TO 90 DEG. CENT.

The use of the curve may be illustrated best by an example. Suppose the resistivity of a compound at the various temperatures is as follows:

Temp. deg. cent.	70	80	85	90
Resistivity (ohm-cm.)	2.5	1.3	1.0	0.80×10^{12}

From the curve we obtain the power factor of paper impregnated with the above compound for the given temperatures. Of course the paper has to be thoroughly dried and impregnated. The power factors obtained are as follows:

Temp. deg. cent.	70	80	85	90
Power Factor (per cent)	3.0	3.7	4.0	4.5

The curve does not hold good for 60 deg. cent. or less.

Mr. Shrader has contributed some valuable information in his paper. His curves marked "1" in his Figs. 3 and 12 are very interesting. They show that manila paper saturated with petroleum jelly has a smaller imperfection angle than white India mica at stresses up to 60 kv. per cm. Ordinarily we do not think of an impregnated paper having any electric qualities superior to mica.

Referring to his Fig. 14, Mr. Shrader discusses the difficulty encountered in obtaining consistent values of power factor and potential gradient in the ionization region. We have found that one reason for this difficulty is that when ionization is reached the deflection of the wattmeter is a function of time of the application of voltage. Perhaps a part of the difficulty could be

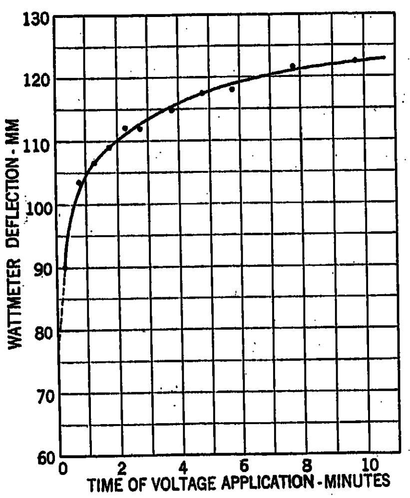

Fig. 5—The Effect of Time of Voltage Application on the Measurement of Dielectric Loss when Ionization is Present.

overcome by taking readings after a definite period of application of voltage. The length of the period would have to be determined by experiment. It is impossible to obtain readings at the moment the voltage is applied because, even though a wattmeter is aperiodic, there is a time lag in the deflection. I submit a curve, Fig. 5, showing variations of deflections with the time of application of voltage. The readings were taken on impregnated paper at 30 kv. Ionization started at about 24 kv.

The first point on the curve was taken 15 seconds after the full potential of 30 kv. was applied to the dielectric. We could not obtain a reading sooner because it took 15 seconds for the wattmeter to come to a steady deflection. The reading was 90 mm. If we could have read the wattmeter the moment full potential was applied we would, perhaps, have obtained a reading of about 75 mm. as indicated by the curve. The time for building up the voltage was about 15 seconds. The curve shows the importance of allowing a definite fixed period for building up the voltage and a fixed period between the time when full voltage is obtained and the time when the wattmeter is read.

Mr. Shrader has calculated the effective a-c. resistance both from the point of view of a fictitious resistance in series with a perfect condenser and also in multiple with the condenser. If the resistance in series with the condenser be designated as r and the resistance in multiple as R, the power factor may then be expressed as follows:

$$\cos \theta = \sqrt{r/R} \tag{1}$$

or

$$\sin \psi = \sqrt{r/R} \tag{2}$$

where ψ is the imperfection angle and is equal to $(\pi/2 - \theta)$.

The above equation is useful in checking the calculations of r and R which have been obtained from

$$r = W/I^2 \tag{3}$$

and

$$R = E^2/W \tag{4}$$

The power factor is ordinarily obtained from the equation

$$\cos \theta \frac{W}{E\,I} \tag{5}$$

Values obtained from equations (3), (4) and (5) should satisfy equation (1).

D. W. Roper: Mr. Fisher has apparently misread or misinterpreted the statements in my paper regarding the relative merits of foreign and American cables. It is my impression, based upon the results of a great many dielectric loss measurements, made for the company with which I am connected, and comparing these with the dielectric loss figures which have been furnished me by foreign engineers and manufacturers, and also by the figures quoted by Mr. Welbourn this morning, that on the question of dielectric loss the American manufacturers are not at any disadvantage as compared with the foreign manufacturers.

The figures obtained appear to indicate that the dielectric losses of the foreign cables are about on a par with the best American practise, and in fact some of the figures obtained from a few samples of American manufacture are lower than any I have been able to obtain on foreign cables, the only exception to that statement being one very special case of a foreign cable made with a hollow conductor and impregnated with a thin liquid insulation of the nature of transformer oil rather than a grease, of the nature of petrolatum, and even in that case, the loss was not materially below the best records of tests published in this country.

Mr. Atkinson made some comments on the bending test called for in the English specifications, and in the National Electric Light Association specifications. He did not mention, however, that the English specifications, although they are more severe, call for three cycles instead of two, as is the case with the American specification, but they do not permit of any tearing of the insulation, whereas the National Electric Light Association's specifications permit a maximum of two layers being torn at any one point.

As a matter of practical experience, we know that with this limitation of two torn papers at any one point, there can be scattered throughout the cable a great many other tears of the insulation, following the bending test, without there being two at any one point, and this is a radical point of difference between the two specifications.

We have found, although we have made several hundred bending tests in the last four years, that only in cases where the insulation is very poor in quality, do we find that the bending test shows any difference whatever between the test at room temperature and the test at minus 10 deg. cent. The curves shown in the paper, on bending tests, quality of paper, etc., shows that in most cases no tearing whatever results, even at the minus 10 deg. cent. test.

There is one point, however, in which the English have an advantage over the American manufacturers, and which is not brought out in this paper, and which was contributed as a part of the report of the Committee on Transmission and Distribution.

The American cable manufacturers were all given an opportunity to present their ideas regarding the thickness of insulation they would recommend for various voltages, and we also had the thicknesses published by the British Engineering Standards Association. The thicknesses recommended by the British are in general below the thicknesses recommended by the American manufacturers, and some of the latter recommend up to 25 per cent more. The English practise, however, appears, as

near as we can discover from correspondence with their engineers, and from some of our engineers, who have been to England,—to use somewhat less insulation than is specified by the British Engineering Standards Association. The thicknesses which the Commonwealth Edison Company have been using in the last year or two are about the same as the British Engineering Standards Association, although we have been accused of being somewhat radical on that point. It was, therefore, of great interest to learn recently, that one of the English companies, that has been operating 20,000-volt cables for a number of years, and has had considerable experience, has, upon the basis of their own experience, and on the advice of their consulting engineers, reduced the thickness of insulation by 25 per cent on these 20,000-volt cables, so that the thickness of insulation which will be used on 20,000-volt cables, is only a trifle more than the Commonwealth Edison Company is using for 12,000-volt cables.

It is to be hoped that the investigations which the American cable manufacturers have started, as evidenced by the series of papers this morning, will continue until they are at least on a parity with the foreign manufacturers in this respect.

It is also of interest to note that apparently some of the data which have been presented this morning have resulted primarily in further investigations into the properties of cables and into the properties and desirable features to be incorporated in condensers for insulation with 60-cycle systems for improving the power factor. Private information indicates that more than one manufacturing company has a larger engineering staff investigating this subject, which is not yet in serious commercial production, than they have investigating the properties of paper insulated cables.

We are perfectly willing that the manufacturers should get information in that way or any other way, which will help them in the design of their cables.

It is also interesting to note the serious advances made in this country in the direction of dielectric losses. In looking over the guarantees received in the last few years, from the American manufacturers,—and we give them all a chance when we ask for bids—it was noticed that the maximum dielectric losses on a certain size of cable last year at a temperature of 80 deg. cent., was double the maximum figures we received this year at the same temperature and same size of cable.

It would have been interesting if Mr. Welbourn has given his dielectric loss data in power factor rather than watts, as, without knowing the size of the cable, it is difficult to compare it exactly with the other data that are available.

The calculations to determine the maximum permissible current on various sizes and voltages of cables were based on the average duct radiation as given in the Clark and Shanklin paper of 1919, and now Mr. Shanklin in a measure discredits these data, or at least casts a doubt on its accuracy for this purpose. This serves to emphasize the importance of securing more fundamental data. To obtain the data from cables in commercial operation appears to be a very difficult task due to the variations in load on the cable, but it would be of great value if some investigator could surmount the difficulties and devise a method which the operating companies could use for measuring the radiation constant of their conduits. In spite of the inaccuracies of the fundamental data as pointed out by Mr. Shanklin, we do find that for the conditions in Chicago, the figures obtained from these calculations are a sufficient guide to enable us to determine within less than ten per cent the amount of load that can be safely carried on our cables without being subject to dielectric loss failures.

W. I. Middleton, C. L. Dawes, E. W. Davis: In view of the present day tendency to operate cables at higher voltages without increasing the walls of insulation, it is of vital importance to engineers to know the actual rather than the theoretical stresses within a cable. A mathematical formula which cannot be checked experimentally should not be accepted as standard for calculating such stresses. If the formula published by Mr. Atkinson in the PROCEEDINGS of the A. I. E. E. in 1919 has been "thoroughly substantiated" as Mr. Simons says, it would be of inestimable value to engineers to have the figures published.

The design of three-conductor cables depends largely upon insulation constants obtained from tests on single-conductor cables. The relation between breakdown stresses in single and three-conductor cables is necessary to assure the proper design of the three-conductor cable.

We do not believe that the rupturing stresses in three-conductor cables are materially lower than for single-conductor cables, especially if such cables be well made. From the data of breakdown tests made by us, the stresses calculated by the old method are much more in accordance with our belief than stresses calculated by the new method.

In the discussion, Mr. N. L. Morgan has remarked that he does not understand how insulation can be overstressed and at the same time not destroyed.

The stressing of insulation is analogous to stresses and strains in the testing of mechanical materials. In the latter case, if the test is not carried beyond the elastic limit, the material recovers immediately after the test load is removed. If the elastic limit has been passed, the material never completely recovers, even though the material is not destroyed.

In a paper "Voltage Testing of Cables" by Middleton and Dawes read before the Institute in June 1914, the matter of overstressing cable insulation was discussed. It was shown that it is possible to apply such severe voltage tests to cables that they do not recover their original insulating properties. The following table shows the results of stress on some rubber insulated cables:

MEGOHMS PER 1000 FEET

Test No.	Length tested feet	Initial M. O. before voltage	Immediately after 2500 V 1 min.	Immediately after 5000 V 1 min.	2 Hours after 5000 V 1 min.	Immediately after 5000 V 5 min.	2 Hours after 5000 V 5 min.
1	1562	14,500	14,500	7,500	11,500		
2	1547	22,000	22,000	16,000	18,000		
3	3150	7,500	7,500	6,000	7,000	5000	5000
4	1740	15,000	15,000	6,500	10,000	750	2500
5	2402	15,000	15,000	7,500	10,000	2500	3500

The insulation resistance in tests 1 and 2 were considerably affected by the 5000-volt, one-minute test, but practically recovered after 2 hours. Test 3 showed the least effect of the 5000-volt, one minute test, while 4 and 5 showed rather slow recovery. An additional 5000-volt, 5-minute test apparently caused permanent injury to 3, 4 and 5, as they showed very little recovery after 2 hours.

In no case was the insulation ruptured but in 3, 4 and 5 it was most certainly overstressed.

We quite agree with Professor Karapetoff that the effects on the dielectric strength of the various elements entering into the composition of a dielectric should each be analyzed separately, in order to understand more thoroughly the nature of voltage breakdown. The papers of Messrs. Del Mar & Hanson, Du Bois and Schrader are analytical in this sense and their data and conclusions give in a degree, quantitative effects of moisture, air spaces, etc., on the ultimate properties of the dielectrics.

On the other hand whether or not the results of such investigation are correct can only be ascertained by data obtained from the finished cable, both in the factory and under operating conditions as are given in Mr. Roper's paper. Therefore even though data do not involve the individual effect of each element of the dielectric, they are nevertheless valuable.

fessor Karapetoff mentions the fact that the stresses in tries, which are stressed beyond the elastic limit should e calculated with constants derived for the material when s stressed. Our investigations on the special cable, the of which are shown in Fig. 5, was undertaken to deter- such effects. The average effect for insulation in the or of the cable which was overstressed was only of the of 5 per cent at the instant of break down, a negligible as compared with deviations ordinarily obtained with tric tests. This cable was purposely made with an inferior of rubber compound in order to exaggerate the effect of tressing. A high-grade compound would have shown a smaller change in permittivity. This combined with other irements that we have made, leads us to believe that the ge of permittivity of the ordinary rubber compounds under can be neglected when calculating potential gradients. vould expect greater changes in paper cables, as the low sity of the filler permits the components having the greater ittivities to seek positions in those portions of the electro- field which have the greater intensities. We have as nade no attempt to measure this change with paper cables.

e pyro-electric theory of dielectric destruction presented r. Steinmetz and Mr. Peaslee offers a very plausible ex- tion of dielectric rupture. The phenomenon of the volt- re characteristic of the dielectric attaining a negative , and the current running away must occur in a very short val of time as otherwise the comparatively small amount of y involved would be unable to raise the temperature to alues necessary for this phenomenon to occur, for the heat l be conducted away too rapidly.

will be interesting to see if further investigations sub- iate this theory.

are very interested in Mr. Peek's energy-distance theory e breakdown of gaseous dielectrics as applied to solid di- ics. Accordingly we have attempted to evaluate constants for the series of tests given in our Tables I, II and III inclusive.

In Table I, we find that equation $g_v = M\left(1 + \frac{K}{\sqrt{r}}\right)$ gives consistent results as shown in the following tabulation.

M was found to be 116 and $K = 0.345$.

Size cond. A.W.G.	r Cm.	$0.345\sqrt{r}$	R_1 Radius to point of constant stress. cm	R Outside radius cm.	R_1/R	Stress from curve for Table I similar to curves for Table II shown in Fig. 10. Values of R_1/R same as in preceding column
24 Sol	0.0255	0.0550	0.080	0.476	0.168	300 Volts per mil
20	0.0407	0.0696	0.1103	0.476	0.232	270
14	0.0826	0.0992	0.1818	0.476	0.382	270
..	0.1140	0.1165	0.2305	0.476	0.485	270
8	0.1625	0.1390	0.3015	0.476	0.634	300
6	0.206	0.1435	0.3495	0.476	0.734	290
5	0.236	0.1535	0.3895	0.476	0.818	295
2	0.328	0.1975	0.5255	0.476	1.104	340
2 strd.	0.330	0.1980	0.528	0.476	1.11	410

It will be noted that except in the case of the two solid and two stranded conductors, the stress was practically constant at a radius R_1 from the center of the conductor.

We were unable to find any values of M and K that would satisfy Tables II and III. In fact in some instances the constant K became negative. Therefore, it would seem to us it has not yet been proved that this theory is applicable to all breakdown of solid dielectrics. Perhaps if the time of test were made very long, hence give the ions greater time to bombard the dielectric, the breakdown voltages might more nearly agree with these energy-distance equations.

Some Suggestions for Possible Improvements in Methods of Engineering Education

BY B. G. LAMME

Member, A. I. E. E.

Chief Engineer, Westinghouse Electric & Manufacturing Co.

Attention is call d to the fact that very few of those who take engineering courses in the colleges are fitted by previous mathematical training to take up the work properly. Suggestion, therefore, is made that all engineering courses drop back into the more elementary mathematics during the first year, in order to give a thorough drilling in the practical use of such mathematics, with a view better to fitting the students for more advanced work. It is believed that with this elementary training the students can make much more rapid progress in their advanced work, not only in engineering work, but in physics, mechanics and various other related lines.

Moreover such a course would assist the schools in eliminating those who are totally unfit for engineering work, and thus overcome one of the most serious defects of the present technical courses. The application of mathematics to practical work should be taught much more thoroughly than at present, but that appears to be impossible under the present circumstances where the students have a very incomplete elementary training.

IT may be that all real engineers are born engineers, or, on the other hand, it may be that the necessary fundamental traits are acquired *in very early childhood.* The personal experience of the writer, based upon intimate knowledge of hundreds of variously trained engineers, indicates that the real engineering traits are not acquired, to any great extent, in later childhood. But it is possible, in some few instances, that the necessary traits are present in early childhood but do not come to the front until later. However, in practically all cases of successful engineers, within the writer's experience, these traits were easily recognizable in the very early years. In fact, of the majority of the cases it might be said that the successful ones were about as good engineers at six years of age as at twenty-six, taking into account their relative knowledge and training at those respective ages. As to these traits being acquired in very early childhood, a leading engineer and educator once remarked—"The child may get some kind of a fatal twist or kink which starts him in a certain direction, and he keeps on growing that way." This is not at all unreasonable. The small boy who can "do" things or can "fix" things, naturally is called upon by his associates to do much of the fixing and mending that is required for their playthings, etc. In consequence, he gets all of the practise and becomes relatively more experienced than his playmates. The same thing may be said of mathematics. The small boy who becomes "handy at figures" is very often called upon for assistance by his schoolmates and playmates, and, in consequence, he does the helping while the others are helped and he thus gets ahead of them. Once in the lead he finds such things are easier for him and he more or less follows the path of least resistance. Thus whether the necessary traits were born in him, or are acquired in very early childhood, the natural tendency is toward cultivation, or exaggeration, of these traits through the normal activities of the child.

A symposium presented at the Annual Convention of the A. I. E. E., Niagara Falls, Ontario, June 26-30, 1922.

Two of the most valuable traits that a small child can have is the ability (1) to use his head, and (2) to use it in a more or less quantitative way. By the latter is meant that a child with a quantitative sense has a great advantage over others. Apparently this sense can be cultivated and quite highly developed in early childhood by proper direction, and here is probably where the real training of the engineer should begin. From the writer's own observations, and from discussion of the subject with many others, he is firmly convinced that one of the best trainings that the child could have is the old-fashioned kind of "mental arithmetic." This seems to have been largely abandoned in recent years, due doubtless to the inability of the teachers to handle it properly. Mental arithmetic, if properly taught, develops quickness in thinking, and also a quantitative or numerical sense which is of utmost value in later years. In fact, a numerical, or dimensional, or quantitative sense, whatever you want to call it, if highly developed, is one of the greatest assets that an engineer can have, and it is doubtful whether this sense can be acquired properly except in comparatively early years. The man with a quantitative or numerical sense can see relationships and can reason from cause to effect to a degree, in some cases, which seems uncanny to one not possessing this trait.

Obviously, therefore, one of the first great errors in our engineering education is the improper or insufficient training in the earlier years, and it is impossible to estimate what an enormous handicap this puts upon the colleges. The earlier training too often tends to suppress imagination and independent methods of thinking. The child is taught to do things by rule, and if he happens to develop, through his own originality, a new method of solving a problem, for instance, in his school work, far too often he is criticised instead of being commended. The arbitrary methods of teaching by fixed rules, by some incapables in our public schools, is one of the curses of the country. The old-fashioned country schools with a single teacher who handled the entire work, quite often developed

stronger mentalities than the modern supposedly much higher class schools.

It must be, and probably is, well recognized that the colleges can only cultivate existing traits, but cannot create new ones. As a prominent educator once said, "You can hatch only a gosling from a goose egg." The colleges, therefore, are handicapped in attempting to create traits and characteristics, in many cases, where such do not already exist. They are asked to build engineers out of non-engineering material,—an impossible task. Even with the modern supposed improvements in the public schools and high schools, the requirements of good engineering material, as far as the colleges are concerned are worse than they were some years ago, simply because of the enormous growth of the college population within the past few years has brought in many men of less suitable characteristics and traits than in former years. It has seemed to the writer that, many years ago when engineering education was less popular than at present, a fairly large percentage of those who sought an engineering education were men who had the "urge" or "call" for such work. Very often these were men who recognized that engineering was their life work, and who realized quite fully that an engineering training would be of great assistance to them. Such men very often were the outstanding younger men of their generation. Such men are also to be found at present, but it is questionable whether they have grown in numbers proportionally any faster than the total population of the country, whereas the technical school population has grown probably ten times as fast. If such assumption is reasonably correct, then the technical schools are being very greatly diluted, or adulterated, by those who may be classed as the unfit, in the true engineering sense. If such is the case, engineering education is bound to be on the down-grade sooner or later, unless steps are taken to correct the evil. The insolubles, so to speak, must be precipitated. Here is a truly big problem. The unfit in engineering may be the fit in something else and naturally we do not wish to prevent any one from getting a college education when he really desires it. At the same time those who "belong" in a given technical course should not be handicapped by those who do not belong. Otherwise, as the writer has stated repeatedly in the past, the training tends naturally toward mediocrity, for the poorer men are a drag upon the better ones. In fact, if the course is laid out for the average man, the less able students will have to work much harder than the better ones, whereas the more capable students, or those of stronger mentalities, should be the ones who receive the most drastic training, for our future engineering development depends very largely upon them. These should be trained to the utmost, and this is not possible, with many of the technical courses, as now constituted. This condition is well recognized in many of the schools and various attempts are being made to rectify it. As one prominent professor stated recently,—he has arranged his courses in two sections, one of which embodies the "slow freights" and the other the "fast expresses." In the former are included those with insufficient ground-work, or who are not capable of keeping up with the latter division. If any student in the "slow freights" is able to speed up sufficiently to keep pace with the "fast expresses" he can be transferred. This arrangement is an incentive to the better class of men, and, to a certain extent, removes the handicap previously described. Other schools have proposed so called "professional" and "non-professional" courses. The professional courses would take in those who have real aptitudes for engineering, while the other would include young men who desire a technical education for general purposes, but who have no strong call for true engineering.

As stated at the beginning of this article, the necessary traits of the real engineer are usually to be noted in early childhood. This should really form one of the deciding points in selecting those who should take the better engineering training, or who should be given the preference in such work. Such traits, along with a certain amount of mathematical skill and ability are necessary in real engineering, and, therefore, these should be given preference in the decision as to whether the young man is to take up an engineering course or not. This brings up the subject of mathematics, upon which something pertinent can always be said.

As has often been said in the past, one of the principal weaknesses of the engineering students lies in their inability to *use* ordinary every-day mathematics. Here and there one or two can really use their mathematics in a common sense way, but such cases are quite rare, based upon personal experience with large numbers of especially selected college men. Such criticism has often been made, but, in itself, does not help materially except to call further attention to what is already fairly well known. The writer is now going to suggest a partial remedy, which many educators may consider as unduly radical and a big step backwards, but which, in the end, should mean greater progress in the right direction. A step backward is all right at times, especially in those cases where one is going in the wrong direction; and, apparently, at present, many of the college courses are going in the wrong direction in their mathematical training.

The suggestion is embodied in the following: A great majority of the college men, in the technical courses, have had their preliminary training in algebra, geometry and trigonometry in the high schools, and such training as experience shows, is totally inadequate as a basis for the future work of the engineer. It is inadequate largely from the fact that only one student in possibly twenty-five ever sees or is shown

any real use for algebra and trigonometry. It is a study with him purely, and real practise does not enter. This condition is more or less inherent in the high school training, and such training, therefore, should not be accepted as a basis or foundation for future solid technical training. The suggestion is this,—that the engineering courses in college, especially the mechanical and electrical engineering courses, *should drop back one year in their mathematics*. This suggestion may raise a cry of protest, but nevertheless, it will appear that in the long run this dropping back is more imaginary than real. What is meant is that the first year in college should take up again the purely elementary algebra and trigonometry, as now covered by the high schools, but with the difference that this first year's work should largely consist in *the application to practical problems*. If the student cannot learn to *use* algebra and trigonometry practically and skillfully, in their elementary forms, he cannot expect to use them intelligently in their more advanced forms, such as in the calculus and other work. Therefore, as said before, this first year in mathematics should be expended largely in purely elementary algebra and algebraical trigonometry, involving the necessary small amount of theory and a great deal of practise in the form of various problems. These problems should be of such a nature, in many cases, that the elementary algebraical and trigonometrical expressions are not already formulated, but the problem should be of a descriptive nature, requiring the student to develop or formulate his own equations. Herein lies a great weakness of the students. Many of them can handle equations already set down for them, by following certain fixed rules which they have learned, (this is the mechanical part of mathematics) but many of these same men cannot possibly formulate the problem in the first place.

The result of this teaching would be far reaching. In the latter half of the freshman year, for instance, the class could be led gradually into more difficult problems, involving more advanced algebra and trigonometry of a practical nature, and by trigonometry is meant analytical or algebraical rather than simple plane trigonometry. In this way the student can gradually be led into the more difficult work by easy stages and he will acquire, if he is at all capable of it, a broader understanding of the general principles of elementary mathematics. He will build up a foundation for his future mathematics especially from the practical standpoint,—and engineering primarily is built upon practical mathematics.

In the teaching of practical mathematics, however, a distinction should be made between what one of the writer's old-time professors used to designate as "mathematical gymnastics" and "horse sense mathematics." By the former he meant the kind of mathematics where everything was carried into mathematical formulas, ofttimes of more or less complex nature, when the use of a little "horse sense" would have allowed the result to be obtained directly with no equations whatever. Such spectacular exhibitions of mathematical symbols are too often considered as the primary object in view. Too often also, the actual result which is striven for, is entirely hidden by the mathematical machinery used in producing the result. The students should become imbued with the fact that their mathematics are simply attacking tools or weapons and that an exhibition of the tools themselves is not of first importance. They should also be taught to understand that really good mathematicians very often can, and do, reach the desired results with but little or no evidence of the merely mechanical part of their work, and that mathematics really must be considered, in general, as simply a very effective mechanical aid to our methods of reasoning. For instance, one can take a physical fact and express it in mathematical symbols and then by rigid mathematical operations may transform the formula into some different one which expresses another physical fact. The mathematics here represent simply accurate or rigid methods of reasoning from one fact to another related one.

Returning to the subject, an important result of this first year's training would be that it would assist the teachers to separate the capable from the incapable, in the engineering sense. Those who prove totally unable to grasp the practical application in the early and easy stages of the work could then be weeded out, so to speak,—that is, they could be transferred to other courses where practical mathematics are less needed. Those who are mentally capable in practical mathematics but who have had a very poor foundation in their previous training, would have an opportunity to catch up and thus would suffer no handicap in their later work. This would be a great step in the right direction, and one of the great advantages which would accrue from such training would lie in the weeding out of the unfit from the engineering courses proper, as stated before. This would be a very great step in advance, as it would remove the present great handicap which the lagging classmen impose on their more advanced fellows.

It was suggested, as a first step, that the engineering schools drop back a year in mathematics. However, upon reaching the second year in the engineering classes, it is the writer's opinion that the survivors of the above first year of training could handle their mathematical subjects, as well as physics and other subjects, in so much better manner that, by the end of the second year they would actually be farther along mathematically than with the present course of training, due to the fact that the fundamental training is so much better. Unquestionably with a training of this sort, those who take up studies requiring analytical work of a mathematical nature, for instance, would obtain a far better grasp of the subject, and in many other engineering subjects they would tend to get

at the fundamentals far better than is possible under the present training. With such a course of training, the average engineering student, by the end of his senior year, should have a far greater practical sense than he has at present, due to the fact that his knowledge of physics, mathematics, mechanics and electrical phenomena, would have a foundation of practical mathematics. In the writer's experience with large numbers of the higher grade college students, he has found that nothing tends to develop their active thinking powers like practical or applied mathematics. This teaches them to think accurately and rigidly; it teaches them how to formulate general statements in concise form; it teaches them how to pass more directly from cause to effect; and it shows them how to pick out defects in their own reasoning and analysis, whether it be of a mathematical nature or otherwise. In other words, a good practical mathematician does not appear to be able to "fool himself" into thinking certain things are so or not so, as easily as is the case with other kinds of people. Again a mathematical mind, of a practical nature, has the ability for bridging across between apparently disconnected points and for obtaining short cuts to results, such as are not possible with other types of minds. This is why the writer argues so strongly for practical mathematics as a basis for true engineering. Men so trained possess tools which enable them to obtain quickly and accurately, results which others can only reach by roundabout methods as already said in other words.

In the proper engineering education, other lines of endeavor than mathematics are also needed, in order to broaden a man, but one essential ingredient is a broad fundamental training in practical mathematics, and without this it is hard to see how a high grade technical education is possible. Without this, schools may turn out *engineers in name*, as is so often the case, but *engineers in fact* cannot be turned out without a working knowledge of mathematics, which, as already said, is to a great extent the basis of all engineering. Therefore, let us put more work on this part of the foundation in order that the whole structure may be more substantial.

Discussion

Education

BY S. E. DOANE
Fellow, A. I. E. E.
Chief Engineer, National Lamp Works, Cleveland, O.

The author points out that a college course should turn out men who have acquired habits of clear thinking, concentration, perception, observation, and decision. These men should have some knowledge of the details of the subject on which they plan to specialize in later life, but this knowledge is purely incidental and is acquired in illustrating the broad principles which are useful in all phases of engineering education. It doesn't really matter much on what a young man thinks he will specialize when he leaves school, if he has clearly in mind that the purpose of education is to train his mind to enable him to acquire as much fundamental knowledge as possible, and also to acquire an incidental knowledge of the specific applications of such fundamental knowledge.

The obvious point to the paper is that mental training is the principal thing, assuming, as a matter of course that physical and moral training are sufficient to physically support an active mind.

The man has well begun his education who has acquired the inclination and the ability for self study and development, and who graduates with the thought that he has merely begun a lifetime of self education. His college education has served its purpose if it has given him a good start.

The author suggests that the instructors in our colleges should be given an opportunity thoroughly to acquaint themselves with the industry for which they are training men by spending one year out of three in industry, the other two years to be spent in teaching.

THE chairman of the Educational Committee of this Institute, Professor Magnusson, has invited me to define my views on Engineering Education. He has suggested that, "if engineers would * * * frankly state their views on the training or lack of training given engineering students, and offer constructive suggestions for improving the college trained engineer, much of value might be gained."

During my thirty-five years in the electrical industry, it has been my privilege to know several hundred college men. Many of these came to work in my department directly upon their graduation. Practically every engineering school in the country contributed its quota. My long association with these men has led me to form certain opinions regarding the training they received, and the training which I think they should have received, which I shall attempt to outline in this paper.

The purpose of education is to cause the person who is being educated to acquire experience of others.

Generalities of the character which must be considered in a paper of this sort can only apply to men who are normal physically, morally and mentally. It is my observation that those who stand high in all these qualities will do best as engineers.

I would, therefore, if I had charge of the destinies of the average college, aim to so sift out my applicants that the majority of my students would be men above the average in these three fundamentals.

I would eliminate those who are weak in any one of

the three fundamental requirements without regard to their strength in other qualities. Mind you, I am talking now about the general engineering training. There are many men who are weak in body who can qualify for brilliancy of effort and become highly trained specialists. In my judgment, these men find no place in a standardized program. If I were considering how best to educate a particular individual who was weak in any one of the three, I would never advise him to take a general course of engineering. He might, however, become a great success in life in some highly specialized effort because of very superior mental attainment. Let us assume that we are training the average engineer and that he is well balanced physically, mentally and morally.

The college should perform six functions. It should offer directly:

1. Instruction in engineering knowledge. This might be subdivided into the teaching of
   a. Fundamentals
   b. Specific applications.
2. Instruction in non-engineering subjects, such as English, Economics, Law, etc.
3. Instruction and training in hygiene.

It should also make adequate provision for:

4. Inculcation of habits of clear thinking, concentration, persistence, observation, decision, imagination, etc.
5. Infusion of principles of fairness, unselfishness, tolerance, refinement, courtesy, etc.
6. Formation of friendships.

Obviously, no special courses to teach clear thinking, concentration, persistence, observation, decision, etc., can, or need, be given. It nevertheless appears to me that these qualities should be taught. This may seem paradoxical, but what I mean is this. Every instructor, in teaching a subject, knows that he is teaching more than just that one subject. He knows that he is also conveying lessons in perception, efficiency, decision, and so on, as a part of the more specific study. For example, in teaching drawing he emphasizes accuracy, neatness, observation, etc.

The point I want to make is that emphasis, during the regular course of study, should be placed upon the characteristics which contribute so largely to the future success or failure of an engineer. If the instructor will always bear in mind that he is teaching more than the facts or principles involved in a particular subject, he will do much to mould his students into efficient and productive contributors to the common good.

In addition to the "concurrent courses" in the class room, it would seem that a great opportunity exists to develop these qualities during physical training. It is apparent that many of the sports which are so popular in this country (and which I believe have contributed toward making the American what he is) are capable of developing these habits. Take tennis, for example. Tennis will develop promptness of decision, quickness of thought and concentration. Indeed, the game cannot be well played unless the player possesses these qualities to a marked degree.

Many of these things which have just been said also apply to the infusion of principles of fairness, unselfishness, tolerance, refinement, courtesy, etc. The instructor must stress these qualities at all times, but the greatest training will come, not from the instructor, but from contact with one's fellow students. It will also come indirectly from better developed minds and better developed bodies. It will come from the exercise of the qualities which were previously mentioned—observation, decision, concentration, etc. It is obvious that a man with a well developed sense of observation and perception will very easily learn what is proper in the way of courtesy, refinement, tolerance, etc. A man who can think clearly is not likely to be bigoted, or unfair.

The sixth value of a college education lies in the opportunity it offers for the formation of friendships. This needs no special reservation of time in the college curriculum. The constant association with fellow students, the common purpose, the similarlity of ideals and ambitions, a school spirit—all these go far toward making college friendships lasting and sincere.

We are now left with the problem of dividing the student's time and effort among engineering instruction, non-engineering instruction, and physical training.

My experience has led me to believe that a person's physical characteristics play a great part in what he can, and will, do. If they are good they serve as accelerators; if they are bad, they are handicaps.

It would seem to me that such time should be devoted to physical training, hygiene, etc., as would best meet the needs and requirements of the normal or average college man. This is a rather vague statement but I hesitate to make it more specific.

I do believe this, however, that more physical exercise, by a great many who are now in college, would result in great benefit. There are many students who are so intense in their desire to acquire knowledge that they cram their minds at the expense of developing their bodies.

Having allowed time for exercise and recreation, how much time should be allotted to non-engineering instruction and how much to engineering? How much of the latter should be devoted to fundamentals and how much to special applications?

Broadly speaking, I would say that the college man should have sufficient non-engineering training to enable him to express himself clearly (both orally and in writing); to give him a fair knowledge of economics—of the principles which govern our daily life; to offer him at least a speaking acquaintance with the laws by which we are governed in our relations with our fellows. He should be taught the principles of ordinary business, such as the rudiments of accounting, methods of computing costs, etc.

This may seem to be a large assignment, but such a program of non-engineering education should not be

allowed to consume very much time. It is not necessary to go into any of these subjects very deeply. It is sufficient to touch upon their more important features.

Some of this non-engineering education may be obtained in connection with the engineering courses. Clear expression and good composition should be as definitely required in written work on any engineering subject as knowledge of the subject itself.

The greatest problem in allotting time and effort among the various aims of the college engineering education arises in considering whether fundamentals, or specific applications, should be emphasized.

Some claim that a good knowledge of the fundamentals of a subject (though not necessarily the most thorough kind of knowledge), followed by a thorough training in typical applications of these fundamentals, will be of greatest benefit to the student. They claim that the knowledge of certain specific applications of the fundamentals in practise will enable the student, by analogy, to best meet his needs in later life.

Others, and I believe they are now in the majority, believe that a very thorough knowledge of the fundamentals involved in engineering practise, and less acquaintance with the applications which have been made thereof, would be preferable. This is my belief.

The stressing of application leads to specialization. No student really knows exactly what he will do after he leaves school. Those who specialize while in school may find themselves doing something entirely different within a short time of their graduation. As the result of specialization many discover that studies which they had neglected, because they did not consider them of practical value in the field they intended to enter, were really of the utmost importance and value in the field they really entered.

In reading over the suggestions summarized by the chairman of your committee, Professor Magnusson, it seems to me that many of us expect too much from the immature youths from our colleges.

In all of this summary the reply of Mr. Lamme is most directly parallel with my own judgment. It seems to me that there is only one of the three fundamental assets that we can hope to find fairly well rounded out. A man reaches physical maturity at an earlier age than he will reach either his moral or mental maturity.

He should be physically fit and should know how to keep himself fit when he graduates.

He should be well advanced toward his moral maturity and should be well grounded in his habits to the end that he will maintain a high moral standard.

His mental equipment will be the farthest from development. When he graduates I think he should have the following mental qualities:

He must know how to study and should face the fact that he must be a student, throughout the remainder of his life,

a. Of knowledge

b. Of mental technique.

Under "a" he must know the fundamental laws and statements of fact of physics and chemistry. The so-called laws which an engineer must learn are, many of them, beyond explanation and must be accepted as statements of fact. Quantitative ratios must be understood. For illustration, a man should know broadly the qualities of materials, ratios of speeds, and the values of time in the quantitative sense.

My feeling is that while specialization in college avails little and that to attempt to teach a man in college anything specific, such as to design generators or motors, is almost useless, at the same time the principles of design can be taught as illustrations of the use of fundamental laws. At the time the man is acquiring his acquaintance with a law he also is obtaining a useful and sufficient illustration of its application.

I believe all specialization should come after graduation.

It is my belief that it will be found to be impossible to so define courses of study that we shall feel that our problem has been solved without approaching it from quite another angle.

I think that we will ultimately agree that these courses must be laid out understandingly by the educators themselves. How can these men do this without some experiences similar to our own?

How can these instructors, these teachers who have had no practical experience, plan to teach their students the things which those students will most need after they leave college, the knowledge which will be of greatest value, the details which will be of most use? How can they train their students best to meet the problems they will encounter, and the obstacles they will have to overcome, after they leave school, if they do not have clear ideas as to the form and character which these problems and obstacles will assume?

Thoughts of this kind have led me to suggest to several of my friends, who are directing educational work in colleges, that we should take these college instructors into industry for a period of time.

There are laboratories—excellent laboratories—in many of our large industries throughout the country, and upon the staffs of these laboratories are to be found some of the most eminent scientists and engineers in their respective lines. They are constantly at work seeking to add to existing knowledge. They are making important discoveries.

The plan which I have in mind—which is in an unfinished form, and which I know can bear much development—is roughly this. I suggest that the instructors in our engineering schools spend one of every three years in industry. Place these men in the laboratories of our great industries, in their research departments, in their engineering departments, in their manufacturing departments, perhaps in their commerical departments.

Allow them to acquire an intimate knowledge of the application of fundamentals in every field. Acquaint them with the latest methods and means by

which these fundamentals are utilized in actual practise. Permit them to breathe the atmosphere in which their students will later have to work. Give them an opportunity to acquaint themselves with the actual requirements which will be expected of the college man. Introduce them to the general nature of the problems with which their students will have to deal.

If the instructor can learn all these things, I am quite sure that the men who are sent out from the engineering colleges will be benefited beyond measure.

As I think of this proposal, I can conceive that the National Lamp Works might be able to use one college instructor every year, who would obtain a thorough acquaintance with modern practise in electric lighting and allied fields while earning his salary at productive work.

At the end of three years the instructor, who has spent a year in the electric lighting industry, followed by two years of teaching, would be released to devote a year to some other industry related to the subject he teaches. Three years later he would go to still another industry, or branch of industry, and so on.

During all this time, the instructors will learn to view the subjects they teach from new angles. They will become better able to emphasize the importance of any particular phase that their industrial experience has shown them to be important. They will be able to observe their own work in more accurate perspective, and their results will be of correspondingly greater value.

It may be argued that an acquaintance with one particular industry once in three years will not enable all, or even most, instructors to keep up with modern practise in that industry. It is my thought, however, that the men who return from a year's experience in industry will convey their impressions, and will impart their new knoweldge to their colleagues.

The acquaintances which these instructors obtain during a year in business will continue throughout a life time. Through these they will maintain a very desirable contact with the field.

A procedure, such as the one I have so roughly outlined would probably have to be worked out over a period of years. As I have said, it requires consideration by those who are in intimate touch with the deficiencies which it is desired to remedy. Perhaps I am too optimistic of the results which it may accomplish. Possibly the same results may be obtained by other, and more desirable means.

In any event, my suggestion is offered for whatever it may be worth.

Discussion

Principles of Engineering Education

BY PHILIP TORCHIO

Fellow, A. I. E. E.

Chief Electrical Engineer, New York Edison Company

The college training should be directed to imparting to the students the fundamentals of all physical sciences. Elementary calculus and analytical geometry should form the ground work to equip the pupil with the tools for analytical study of the problems of engineering applications. Laboratory work and drawing serve to solidify the theoretical ideas. The sound study of a foreign language is of vital importance to broaden the education of an embryo engineer. Any course of study that disciplines the mind is beneficial to the student. Anything that is easy does not discipline.

IN the greatest task of educating the youths of the nation, elementary and preparatory schools labor under extreme difficulties in securing moderates success in disciplining the pupils' minds for concentrated work and independent investigation. The college is thereby handicapped but, in an engineering college, this deficiency should be easily made up if the technical subjects are properly taught, remembering that "Any course of study that disciplines the mind is beneficial to the student. Anything that is easy does not discipline."

The college cannot make engineers; it can only build the foundation on which the graduates will erect the structure of their careers. For a solid foundation, the young man should be thoroughly trained in the fundamental laws of physical sciences and the units of measurements and their equivalent relations. He should also be made familiar and conversant with the use of elementary calculus and analytical geometry as later applied in the study of mechanical, electrical, and other subjects in the curriculum of engineering courses. These should include the physical and mathematical analysis of elements of mechanical structures, thermo-dynamics, flow of water, air and steam, laws of motion of bodies, radiation, transmission and transformation of energy, electrical and magnetic phenomena, et cetera. "It is better to see one thing than to look at a hundred. It is better to conduct a student to the inner chamber of one fact than to take him on a trip seeing greater knowledge." The only fitting time for mastering these fundamentals is during the college years, when the mind is receptive and reposeful, and the aid of the teacher is at hand.

The laboratory work should be planned to give the pupil an insight of the theoretical facts applied to practise. For the same object, it may be beneficial that, in the drafting room, each student or group of graduating students should make to scale detail drawings of a different machine, with accompanying calculations of the important elements affecting its construction. Besides this machine drawing, each group

should make a detail project layout of an industrial installation for an assumed definite production or service, like a cotton mill with electric drive, a coal skip hoist, a mine mechanical equipment, an ice plant, a shoe factory, a power plant, a transmission line and substation, et cetera. The benefits accruing to the whole class from these different projects are great, not only for what each student absorbs and makes intimately his own from the close study of the details of his project, but also for what he learns by the interchange of thoughts and ideas with the other students who naturally fall into discussing with each other the features of their respective problems. Such discussions open their minds to widely different engineering problems and broaden their views in correlating the importance of these factors.

In addition to these studies, the pupil should pursue the study of a foreign language, like French, Italian or German, so that he can read and write it fluently, and possibly speak it with facility. I cannot emphasize these advantages too strongly. I do not know of a more broadening, instructive and inspiring education.

My conclusions are that "it is not so much knowing a whole lot as knowing a little and how to use it that counts." The greater the concentration and thoroughness with which the embryo engineers are trained in the fundamentals and their applications, the more self-reliant they will be made for practical life. I wish it to be understood that I do not aim to make engineers theorists, but I wish to instill in them broad and sound theory at the time and place when it can be done most efficiently. My idea is that a broad knowledge of the fundamentals of all physical sciences is the most liberal education with which a future engineer may be endowed.

Discussion

Better Preparation of Students for Railway Work

With Special Reference to the Telegraph and Telephone Department

BY I. C. FORSHEE

Associate, A. I. E. E.

Electrical Engineer, Telegraph, Pennsylvania Railroad

The more complicated communication systems, their use and importance on railroads, the extension of power transmission lines and electrification of railroads with the resultant effects upon the communication systems require that technical men, who preferably have been given special training that will qualify them to handle such problems, be employed in railroad telegraph and telephone departments. Many problems are in common with the large wire-using commercial companies but others are peculiar to communication systems on railroads.

ON account of the great development of the methods and means of electrical communication in railroad work, the extensive and varied uses of such means, and the importance of having the service always available under widely varying conditions, it is becoming increasingly important that electrical engineers adequately trained in communication service be available in the telegraph and telephone departments of the railroads.

On many railroads the telegraph and telephone plant, which is very much larger than is realized by those not intimately informed, compares favorably with some of the large commercial wire-using companies. In such a system, extending as it does over hundreds and in many cases thousands of miles, there are problems that must be solved that are not encountered in the smaller plants. These problems involve an intimate technical knowledge of a specialized nature and many times require careful and extensive investigation and study to obtain the best solution.

While many of the graduates from the technical schools may be well informed in mathematics and fundamentals of physics, chemistry and applied electricity, all of which are essential, yet it is felt that if such institutions and the students contemplating such employment, were more familiar with the railroad communication problems there might be some advantages gained and time saved both by the technical graduates and railroads if there were included in the curricula more practicable applications of abstract theories and principles to concrete cases as met in this department. Many of our problems are common with the large wire-using commercial companies, but others are peculiar to the railroad systems.

It is believed that opportunities for men technically trained and who have specialized on communication work will be greater on the railroads in the future than they have been in the past, as the communication systems are rapidly becoming more complex, the problems of transmission more complicated, troubles from power interference and their solution more involved, and the possible applications of the recent developments more varied and important.

Among the various problems with which the department has to deal might be mentioned:

1. Construction of pole lines carrying open wires or cables or both.
2. Construction of conduit and cable systems.
3. Installation of telegraph and telephone equipment.

4. Telegraph and telephone transmission.
5. Design of circuits.
6. Specifications and tests for construction and maintenance material.
7. Electrolysis of underground structures.
8. Inductive interference.
9. Telegraph and telephone traffic.
10. Accounting and estimating.
11. Preservative treatment of woods and metals.
12. Radio and wire carrier systems.
13. Contracts and patents.
14. Electrical protection.
15. Wire testing, maintenance and service restoration.
16. Engineering research.

There are details associated with each of these items which are peculiar to the application on the railroads. Only general subjects are given and could be amplified appreciably, as will be obvious to one familiar with telegraph and telephone problems.

If more specific information is desired on any of the above subjects it can be obtained from the Secretary of the Telegraph and Telephone Section of the American Railway Association.

Discussion

For discussion of this paper see note, page 639.

Training for Character

BY A. M. DUDLEY
Fellow, A. I. E. E.
Automotive Engineering Department, Westinghouse Electrical and Manufacturing Company

Some fundamental requirements in the character of a successful engineer as a man and as an engineer are outlined, together with considerations of the school and the instructor to produce and train such a character. Some ideal accomplishments to be attained are pointed out.

THE requirements for character in an engineer are two-fold, first as a man and second as an engineer. The motto which should hang before every worker in every line of work is this; "*First*, be a *man*", with the accent on the first and last words. The fundamental requirements for manhood in engineering are the same as for all professions and may briefly be touched upon as follows; absolute honesty, first with one's self and then with others; sincerity in one's work, remembering that whatever is worth doing is worth doing well; courage to put one's ideas across in the face of influential opposition and courage to accept the results of one's errors and build anew, courage to "keep your head when all about you are losing theirs and blaming it on you"; self control in all things, especially one's temper; self control of the ego, thereby keeping a sense of proportion as to one's real place in the world and preventing selfishness, tactlessness, discourtesy to others and a long train of ills; charity in judging men, recognizing that the heart and real intent are what count and not accidental circumstance; respect for the highest ideal of manhood and man's work in the world, based first, last and all the time on *service*—service to God, man and country.

The special requirements for character as an engineer might be sketched in this way; a fundamental sense of fairness, never letting one's judgment be warped by one's feelings; never distorting physical facts as shown by tests, to fit a theory instead of making the theory fit the facts; generosity in recognizing the good work of others and giving full credit to them and sharing their pleasure in it; recognition at all times of the commercial side of engineering, remembering that "an engineer is one who adapts the forces of nature to the uses of man" and that of two engineers who do the same job equally well from the viewpoint of physical results, he is the greatest who accomplishes it at the least outlay of money or physical resources; character to cooperate to the fullest extent with one's fellow workmen when joined with them to do a job, regardless of temperamental incompatibility or personal likes and dislikes; tenacity of purpose—never to be a "quitter" but to stick to it always and put the job across—*quickly* if possible but *surely* in any event; open mindedness to acknowledge personal error when plainly proved and to start anew without prejudice on the right basis.

To anyone considering this matter there will appear other and perhaps more essential qualities, but these are sufficient to show the necessity for a strong character in an engineer. The next question is how shall this character be trained. The two fundamental requirements are the right institution and the right instructor. No time will be taken here to discuss the relative merits of the exclusively technical school as against the college or university. Men of character graduate from both, and the humblest schools can claim alumni who shine as bright stars in the engineering firmament. But the ideals of the institution must be right. It must regard engineering as one of the learned professions, and as such must not be satisfied with any less degree of scholarly attainment in its engineering faculty than in its divinity or law or medical school. At the same time, since engineering is intensely practical, it should have on its faculty men who have made good themselves in the practise of the engineering profession, who, by their attainments as well as their ability can command doubly the respect of students. Since these specifications for instructors are high, the institution must be prepared and ready to pay a com-

mensurate salary. It should not make the mistake now so regrettably common of employing a high grade man as instructor at a salary below his commercial value and expecting him to carry on a lucrative private practise as a side issue so that he can afford the sacrifice of teaching.

One more thing that the institution should not do if it would preserve the respect necessary to inculcate character in the youth is to carry on commercial research or similar work where the facilities of the school become the source of private profit to outside individuals or to the investigator inside the school. Particularly is this true of institutions supported directly by the state. Wide open publicity as to the result of all investigations and payment made by the client to the school and by the school to the investigator is the only safe course to keep the atmosphere clear and conducive to the best ethical ideals which make for character.

As to the instructor, it is realized his personality and his attitude to his work are the greatest single element in the training of his students in all ways. One of our great men has said that his idea of a university was a log with a student sitting on one end and Mark Hopkins sitting on the other. To be a great success the instructor must be many things which are achieved only after a struggle with human nature. He must be unselfish and self sacrificing. He must be so sure that the building of men is the greatest profession in the world that he will be willing to accept his salary as a teacher and bend his entire energies toward becoming the best possible teacher of engineering. While he has himself practised engineering, he must limit his outside consulting work to an amount necessary to keep his hand in and to serve as texts for his lectures and laboratory work and not use it as a primary means of subsistence. He must be vitally interested in young men and interested in all their phases and problems, capable of advising on human questions of all sorts. He must establish a personal contact that exists beyond the class room and he must use that contact to instill the fundamentals of character while he instills the fundamentals of mathematics and other subjects in the curriculum.

If the school is right and the instructor is right and the student does his part, we shall have an outstanding race of engineers whose word is good as their bond, who bring to their work an enthusiasm that glorifies both the work and the worker, who accept praise and blame with a level head and a steady hand, who take suggestions and ideas from the humblest sources and develop them into real engineering, who give credit where credit is due, who carry their message to Garcia and hang on to the job till it's done, who worry more about the work they are doing than the pay they are getting, who know that a "man's a man for a' that and a' that," and whose personal conception of character blooms into two great requisites for human happiness—good health and the spirit of service.

Discussion

Some Suggestions Concerning the College Education of an Engineer

BY CARL HERING
Fellow, A. I. E. E.
Consulting Electrical Engineer, Philadelphia, Pa.

The author considers the first requisite of college training to be a thorough drilling in the fundamentals in physics. A student who is well grounded in the fundamentals is in the best position subsequently to acquire a knowledge of details.

The student's most useful tool to work with is mathematics, but this should be taught to engineers by one who considers it an engineer's tool, and not a source of amusement. All the mathematical results should convey as clear a quantitative meaning to the engineer as numbers do when they represent an amount of money.

A third requisite is the use of mental exercises to develop mental strength. The student should be disciplined by mental exercises in the form of problems which should have some practical significance, so as to show the utility of the mental process, thereby developing interest.

Today is the era of specialists; even electrical engineering, as one subdivision of engineering, is again subdivided into so many branches that a student should either make a choice between them, at least in his last college year, or take a special post-graduate course. Different colleges would do well to specialize on different subjects, especially in their post-graduate courses. The writer has urged that at a time when a student must choose his vocation he has little knowledge of what his choice involves, and it is suggested that the regular college courses should include lectures describing the different vocations, the nature of the work involved in each of them, and the prospects of advancement, salaries, etc. Success in teaching can be measured by the interest that the teaching can develop in the minds of the students.

It is a mistake to keep the able students back to the level of the poorest in the class. The brightest students should be given every possible opportunity to advance.

THE college education of an engineer should be considered to be analogous to the foundations of a building on which a superstructure is subsequently to be erected, rather than to the superstructure. When a foundation is bed rock, it will support any superstructure that may later be decided upon.

The foundations of an engineering education are the fundamentals in physics, that is, the laws of nature

concerning matter and energy in their various forms, just as the addition and multiplication tables are the foundations of arithmetic. A profound and thorough drilling in these fundamentals and how to use them should, therefore, be the first and most important requisite; they should be so thoroughly grounded in the mind of the student that they become almost an intuition, involving little effort of mind to deal with them, and an almost instinctive revulsion against their violations. An intuition is well defined as "instinctive knowledge of the relations or consequences of ideas, facts, or actions." As in a building, the foundation is the least conspicuous part in the final product, but it is the part on which the stability of the whole superstructure depends. In a choice between the two, a student well grounded in the fundamentals but with less instruction in the superstructures like specialities, professor's hobbies, details and refinements, will unquestionably become a greater engineer than when the amounts of these two kinds of instruction are reversed. To one who is well grounded in the fundamentals the subsequent acquirement of the knowledge of details and refinements, even if after leaving college, will be a far easier matter than under the reverse conditions.

While these fundamentals are the most useful materials for his work, his most useful tool to work with is mathematics, not pure mathematics but applied mathematics. As a reliable means to arrive at a useful end quickly and directly, it is a most wonderful tool, generally a far better one than arithmetic, but its use as a mere means of entertainment should be left to the mathematicians. It should be taught to engineers by one who considers it an engineer's tool, a utility, and not a mere source of amusement. All numbers and their decimal points obtained mathematically should convey as clear a quantitative meaning to the engineer as they surely do when they represent an amount of money.

Another important factor in the education of an engineer is mental exercise to develop mental strength. When we lift a weight in the gymnasium it is not because there is any useful result in that weight being put on a higher level, but it is to strengthen our muscles. Similarly the mental strength of a student should be developed and disciplined by plenty of mental exercises, say in the form of problems, which should by all means have some practical significance so as to show the utility of the mental process, thereby developing interest; he should be taught to think and reason correctly and not merely have his memory crammed with words and facts as in the teaching of a monkey or parrot. A strong, well trained mind can subsequently absorb details with great ease, with the additional advantages that it can distinguish between the wheat and the chaff, and is not so easily misled. The great mass of engineering facts and data are better preserved in books of reference than in ones brain, which can be made better use of for correct reasoning. Generally a brain is not entirely a vacant space to be filled by college professors, but is rather like a muscle which is to be trained by them to do skilful work.

Knowledge has made such vast strides that in a four years' course it is today physically impossible to teach and mentally impossible to learn, all that it would be of benefit to know. The present is the era of specialists; a Jack of all trades is a master of none; better let a trained financier do the financing, a trained engineer the constructing and a trained salesman the selling. It is imperative, therefore, to make a choice; in general the first choice in an education is that between utility and what might be called polish or ornamental education. Formerly, and in some colleges of today, particularly those for girls, the latter is the main goal. Having chosen utility the next choice is between science and the other learned and useful professions; science and financiering do not always mix well, their standards of morals sometimes differ. In science there are many further subdivisions one of which is engineering, which again is subdivided into branches. Even electrical engineering, as one of these, has so many subdivisions which have little more than the fundamentals in common, that a student ought to make a choice between them, at least in the last year, or take a special post-graduate course. Different colleges would do well to specialize on different subjects, especially in their post-graduate courses, which should then be directed by specialists.

Having decided on any one particular vocational training, the choice of the particular subjects to study should be decided solely and only on the ground of utility. In an electrical engineering course for instance there is so much more to learn than could possibly be crammed into four years, especially when there is an excessive and time robbing indulgence in athletics, that the student is deprived of much useful instruction and training if he has to devote a lot of this valuable time to such things as the dead languages, bible history, literature, etc. The proper use of the English language should have been taught in the preparatory schools.

The subsequent failures of college trained men have frequently been due to a mistake in the selection of their course in college. Other conditions being equal, the best choice is unquestionably the subject in which he is most interested. But in most cases at the time he has to make the choice he has no proper knowledge of what a particular career involves; the fact that as a little boy he enjoyed playing with toy electric railways does not, as some fond parents think, mean that he will make a good electric railway engineer. The writer has, therefore, often urged that at the time when the student must make a choice, a part of the regular course should be a few lectures describing what the various vocations involve, what subjects he will have to agree to study in each one, what the nature of the work will be and what the prospects are of employment,

advancement and salaries. Such lectures would unquestionably greatly reduce the deplorable number of misfits and the great loss of time in later changing from one course to another.

The province of a physicist is to discover and formulate the laws of nature regarding matter and energy while the province of the engineer is then to apply these laws for the benefit of mankind. Another definition of an engineer in popular terms is that he is one who can show how a thing can be done for one dollar that any fool can do for two dollars; a complementary definition of an administrator, or organizer, at least of some of them, then is that he is one who can get two dollars for something worth only one. In recent times, so many engineers have abandoned the true profession of engineering, that of designers and constructors, and have become administrators, organizers, financiers, or salesmen, for which positions their engineering training has undoubtedly helped them greatly, that these and many others, like the handling of labor, have recently often been included under engineering, a noble name to conjure with. Larger salaries and less interest in engineering, are generally the incentives for the change; some adminstrators can vote themselves their own salaries. But whether this modern use of the term engineering is desirable or not, it is true that an engineering training is of great value in such positions, and that, therefore, students should be told about these vocational possibilities and if they choose them they should be given a somewhat different course omitting certain studies and substituting others.

In the writer's opinion, success in teaching can be properly measured by the interest that the teacher can develop in the mind of the student. There are, of course, some very necessary studies that are without any interest, and, therefore, pure drudgery, like learning the multiplication tables, rules, terms, relations, formulas, etc, but aside from such cases of mere memorizing of some necessities, when a teacher cannot awaken the student's interest either the student is hopeless and should leave college, or else that teacher has not mastered the real art of teaching. Often have students told the writer how greatly they were interested in a certain subject, adding the significant clause that they liked that particular teacher, as he made it so clear; in the reverse case it may be the fault of either or both.

A serious error in many colleges, which might even be called an educational crime, is to keep the bright and able students back to the level of the poorest in a class. It should be the duty of every teacher to give the brighter students every possible opportunity to advance. The deficient ones should either be helped to catch up or made to repeat the previous year's work.

Students naturally take a delight in pointing out errors in what their teacher has taught them; finding such errors also tends to shake their confidence in other things he taught them, which is fatal; they also lose interest and respect when they find there is a simple, easily understood way of explaining something which they had been taught in a complicated, confusing way which was difficult to understand and hard to retain. It is therefore of the greatest importance for the teachers to be absolutely sure of the correctness of what they teach and to keep abreast with the times in their interpretations and explanations. It is, for instance, an intellectual crime, which might do much harm, to teach that a law is universal after it has been shown that it is not. The writer has been surprised to see the strong opposition of some teachers to modify their teachings of a year before in accordance with developments during that time.

What constitutes success in a career is variously defined and is a matter of opinion. Some measure it by the ratio of the money received to the time and effort spent, that is, the present labor union idea of doing the least work for the most money. According to that scale one who loots a bank is at the head of the list of the successful; there is a wide difference of opinion as to what is and what is not honorable; when the looting is done by a teller, he is a criminal, but when done by the president he is an expert financier. Others think that success is measured by the kind of service rendered or by doing something that is of some lasting benefit to mankind and to the world, such as the products of the researches of scientists, the discovery or development or invention of something useful, or erecting great and useful structures. Students have their choice, some look only for the dollar, others for something higher; the choice of their college course depends somewhat on this; many persons have made much money without having had a college course, but today the so-called self-made engineer who has not had a higher education and has not made up for it later, is hopelessly handicapped as an engineer in competition with those who have.

The engineer deals with the laws of nature, which govern him; nature is mercilessly strict in insisting on their enforcement to the letter; such a training therefor, tends to develop a respect for laws, an instinctive effort to do only what is right and to abhor what is wrong. He cannot cover up his faults or ignorance as doctors, lawyers, financiers and ministers can, and he must therefore be better trained. An engineering training is therefore also ethical in its effect.

Discussion

(Owing to the large volume of discussions on the educational papers presented at the Annual and the Pacific Coast Conventions it has been found advisable to omit them from this volume of TRANSACTIONS. They have, however, been published in full in pamphlet form and copies of the same may be procured by anyone interested on request to Institute Headquarters.)

Baltimore Oil Circuit Breaker Tests

BY H. C. LOUIS
Associate, A. I. E. E.
Consolidated Gas Electric Light and Power Company, Baltimore, Md.

and

A. F. BANG
Associate, A. I. E. E.
Pennsylvania Water and Power Company, Baltimore, Md.

Review of the Subject.—*In view of the tremendous growth of electric power systems it has been realized for sometime by many of the larger operating companies that many of the old circuit breakers were not adequate for the increased duty. There seemed also to be considerable uncertainty as to the actual ratings of many of the more modern types. It was realized that this condition was largely due to the fact that the manufacturer was handicapped in making tests due to lack of power. These circumstances led the Consolidated Gas, Electric Light and Power Company of Baltimore and the Pennsylvania Water and Power Co. to make a series of oil switch tests on their interconnected 13,200-volt, 25-cycle power system, cooperating with the Westinghouse Electric and Manufacturing Company and the General Electric Company.*

The largest generating capacity used on these tests was 170,000 kw. Currents obtained vary from 750 to 23,700 ruptured r. m. s. arc amperes.

All of the tests were made by throwing three-phase metallic short circuits directly on the system which the breaker under test was called upon to clear immediately. Proper protection of the system was provided in case of failure of test breaker.

Three oscillographs were utilized to record the sequence of events.

A total of about 200 short circuits was made directly on the Baltimore system without any breakdown whatever of the major equipment of the two operating companies, and in practically all cases without causing more than a momentary voltage disturbance to the system.

The results as described in the papers submitted by Messrs. Hilliard and MacNeill indicate that it is possible with proper design to build oil circuit breakers which can be relied upon to satisfactorily interrupt large currents on high-capacity systems many times in succession without damage to the breakers, without oil throw, and without change of oil or adjustments.

CONTENTS

THE tremendous growth of electric power systems with corresponding increase in size and number of generators, feeders, transformers and other station apparatus, has thrown an ever increasing duty on the switching equipment. Likewise, the modern tendency to secure higher efficiency, economy and flexibility by interconnection of older systems and running all the generating stations in parallel, has still further augmented the burden of oil circuit breakers. The high degree of reliability and continuity of service generally expected, also necessitates high standards of oil circuit breaker performance. That not all of the oil breakers at present in service were able to meet these new demands, has been realized for some time by many of the larger operating companies. Older breakers were proving themselves inadequate for heavy duty, while breakers of later design were not entirely satisfactory. Some breakers failed to clear short circuits, were badly injured or completely wrecked, throwing oil and parts around by explosive action, with consequent danger to other apparatus and station attendants. Occasionally even serious oil fires would result from the failure of a breaker forcing the operators to abandon the station for a time. Even when breakers cleared they were frequently damaged, requiring the breakers to be carefully gone over, repaired, and adjusted and refilled with oil, before being put back in service. That is, many breakers could not be relied upon to handle more than one heavy short circuit without repairs or adjustments of some kind, making them virtually "one short" breakers. This limitation of the number of times a breaker could satisfactorily open heavy currents was indeed a serious drawback.

There has also been considerable uncertainty as to the individual performance and rating of the various sizes and types of oil circuit breakers. This placed the selection of the proper type and size of breakers for new services, and design of new stations on a very uncertain basis, with little exact information upon which to base designs and selection of sizes. With the large investments involved, this lack of exact knowledge made a most undesirable condition.

That this situation has existed for some time has largely been due to the fact that the manufacturers were handicapped in making tests to obtain the desired information, by the lack of sufficient power which would approximate conditions on actual power systems. Tests have been made before, but these were generally few in number or involved relatively small capacity, as most operating companies were averse to risking their equipment in any extended set of tests. Still this was necessary as a very important consideration is that small generator capacity not only limits the short circuit currents to low values, but causes the voltage to fall off so rapidly that a breaker opens a very low voltage, thus destroying the value of tests made under these conditions.

These circumstances and conditions caused the Consolidated Gas Electric Light and Power Company of Baltimore and the Pennsylvania Water and Power Company to make an elaborate set of oil circuit

Presented at the A. I. E. E. Annual Convention, Niagara Falls, Ontario, June 26-30, 1922.

breaker tests on their interconnected 13,200-volt, 25-cycle power system, in cooperation with the Westinghouse Electric and Manufacturing Company and the General Electric Company, which furnished the switches tested. Generator, transmission line and cable capacity were furnished equalling or even exceeding normal operating conditions. The fact is the currents obtained in the tests exceeded those usually met with in short circuits on this system. All the tests were made by throwing "dead" metallic short circuits on the entire connected system, which the breaker under test was called upon to open.

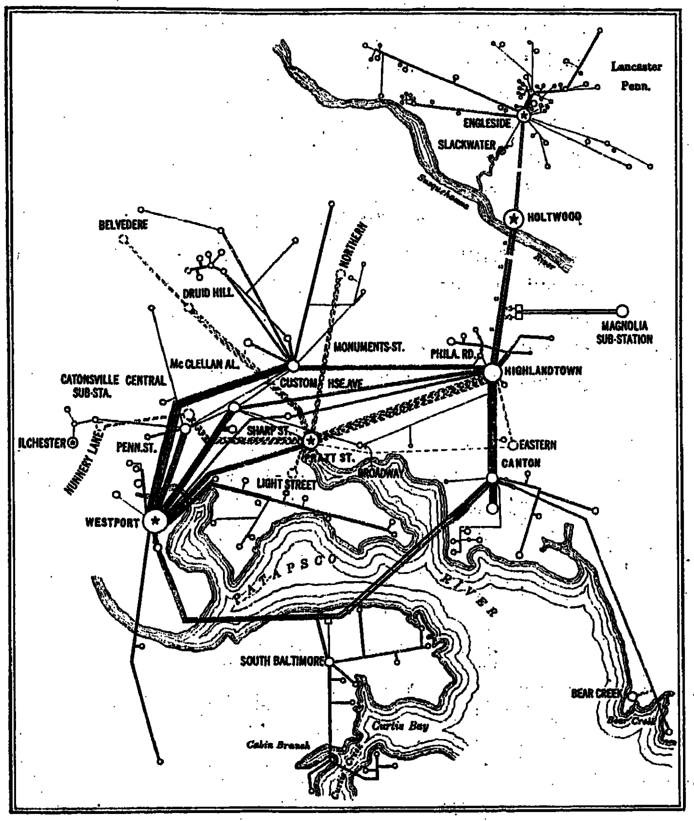

Fig. 1—System Diagram
Baltimore Gas, Electric Light and Power and Pennsylvania Water and Power Companies.

The Canton substation in Baltimore was selected as the best location for these tests for several reasons:

It is situated about seven miles from Westport, the main steam generating station of the Consolidated Company, and about forty-one miles from the hydraulic power plant at Holtwood of the Pennsylvania Water and Power Co. and current can thus readily be supplied from both of these generating stations over a large number of cables and transmission lines, as shown in Fig. 1. The current in this way becomes well distributed on the generators, transformers and feeders, without excessive overloading of any individual units.

Some other locations such as Westport might have given higher initial currents, but these would have caused the voltage to fall off more rapidly due to greater demagnetizing action, thereby making it questionable whether the breakers actually would be subjected to a more severe duty than at Canton. Actual test results showed the great effect of sustained voltage. The voltage at Canton, *i. e.*, the re-established voltage, appearing right after the short circuit was cleared was never less than 77 per cent normal voltage, even after the heaviest short circuits obtained, and on lighter short circuits was practically normal.

Furthermore available space at Canton permitted of convenient arrangement of sheds sheltering oil breakers under test outside of the station. These also could be located so as to be of little or no hazard to either the company's or other people's property in case of failure of the switch. It was, also possible for observers carefully to watch the tests at a safe distance with little danger to themselves.

Capacity of System

The main steam generating station of the Consolidated Gas Electric Light and Power Company, which is located at Westport, has a generating capacity of 127,500 kw. in steam driven turbo-generators, of which 87,500 kw. was usually available for tests. The generating station of the Pennsylvania Water and Power Co., at Holtwood, Pa., has a generating capacity of 83,500 kw. in water-driven units. There is also one 20,000-kw. steam-driven unit at the Pratt St. Station in Baltimore. These three generating stations are interconnected through a number of substations, giving the system a combined generating capacity of 231,000 kw. The maximum generating capacity used in these tests was 170,000 kw. Canton substation is directly connected with the Westport steam station by four 26,000-volt submarine cables, banks of transformers being provided at either end, and is also tied to the city network by eight 13,200-volt cables through the Pennsylvania Water and Power Co. Highlandtown substation.

As breakers of various rupturing capacities were tested, it was necessary to get various values of short-circuit current. Also, some tests were made by starting in at low values of current.

To obtain these short-circuit currents of different magnitudes the number of generating units was varied to some extent, but the main variation in current was obtained by changing the cable connection between the generating stations and the test bus at Canton substation so that even in the case of the minimum current used a very large capacity was behind the short circuit. From the constants of the system the short-circuit current of a large number of possible combinations of generators, transformers, and transmission arrangements were thus calculated and these figures used as guides for our set-ups in the tests. A typical arrangement used is shown on Fig. 2. It is perhaps remarkable to note that these calculations came within 5 to 15 per cent of the currents actually obtained in the tests at the time of rupture.

Currents Obtained

All the tests were made at 13,200 volts, 25 cycles. Short circuits ranging from 950 to 30,800 initial r. m. s. amperes and from 750 to 23,700 ruptured r. m. s. amperes were obtained. The water-power station being far removed from the test bus supplied about 30 per cent of the initial short-circuit current, 70 per cent being supplied either by Westport alone or by Westport and Pratt St. stations. The maximum

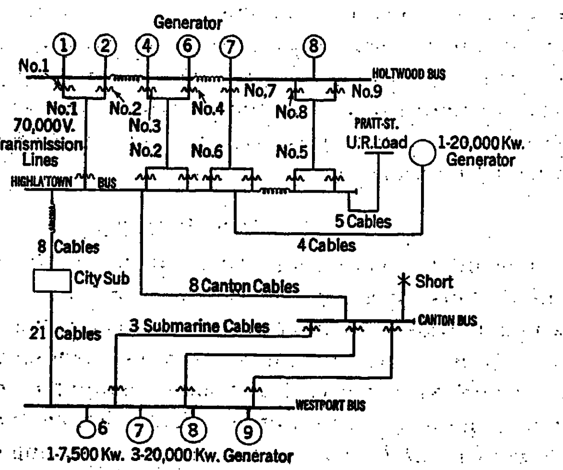

Fig. 2—Typical Test Arrangement of System

Calculated short-circuit current:
Initial = 29,400 r. m. s. amperes at 42.2 per cent power factor.
After 5 cycles = 24,850 amperes at 39.3 per cent power factor.

instantaneous loads on any of the generators did not exceed five times the normal load. Under the heavy short circuits, some cables (4/0) carried from 2000 to 2500 amperes.

Most of the short circuits were made across all three phases and ground. A few were across two phases and ground, and several on one phase and ground only. After finding that two-phase and single-phase short circuits produced severe vibration of turbo-generators, they were subsequently avoided. In this connection it should be pointed out that in the Baltimore system the neutral of all generators and transformers is "dead" grounded without any resistance, so that in each three-phase test it was necessary for each individual phase of the oil circuit breaker to clear its own part of the short circuit without any help from the other phases, as might have been the case in any ungrounded or partially grounded system.

Test Breaker Arrangement

The general method of testing was to throw a dead short circuit on the breaker under test, which was set to open instantaneously. Two other oil circuit breakers were in series with the test breaker serving as protective breakers in case of failure of the test breaker, being set for later opening. A separate switch was used to act as closing-in breaker exclusively. There were thus four breakers in all used in the test circuit, which was connected to the system set up to give the desired currents.

Fig. 3 shows the arrangement of the four breakers in detail. The breaker under test was next to the short-circuit connection, which provided a metallic short circuit between all three phases and ground. It was arranged to trip automatically by means of a plunger type relay with "instantaneous" time setting, the only delay being that due to the inherent characteristics of the mechanism and relay. This varied from three to nine cycles (0.12-0.36 sec.) The closing in breaker was non-automatic and was closed by means of a switch under the control of the oscillograph operator. The protective breakers were operated by Westinghouse type CO time element relays. In the earlier tests both of these breakers were operated by the same relays so that they would open simultaneously. In the later tests one of them located in the test shed, was set to open in about 10 cycles (0.4 sec.) after closing of the short circuit, so as to be the first to operate in case of failure of the test switch or other damage. The other protective breaker was in the bus structure of the station itself, being part of the station equipment, thus acting as the connecting link between the test circuit and station bus. It was set so as to open in about twelve cycles (0.48 sec.), or a few cycles later than the other protective breakers. This combination afforded protec-

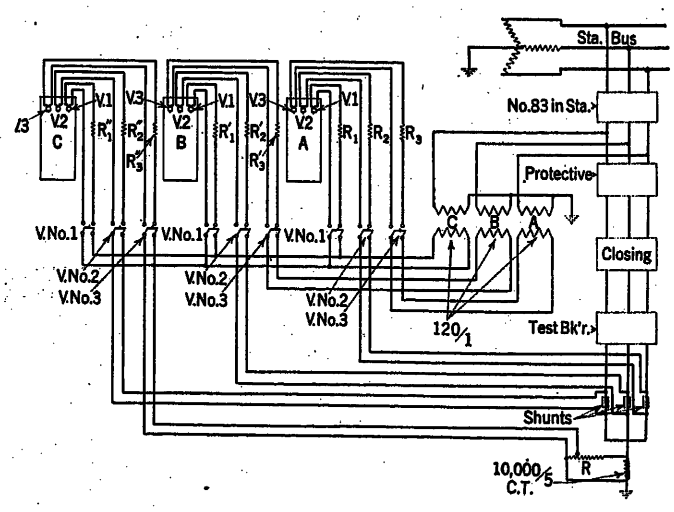

Fig. 3—Diagram of Test Breaker Arrangement and Connection of Oscillograph Elements

tion not only against failure of test breaker, but against failure of closing-in breaker, or one protective breaker, also breakdown or short circuit of leads. Some of these different troubles were experienced during the tests. Both of these schemes of protection proved to be absolutely adequate throughout the many tests, as in no case did the protective breakers fail to clear the test equipment from the bus in the station.

Test Sheds

The test breakers were placed in temporary sheds about ten feet from the station. Three breakers were originally placed in one shed, but as injury to the test breaker in early tests was communicated to the others

a second shed was built and the test breaker placed in it. The general arrangement is shown in Fig. 4. Doors were put in the ends of each shack, providing accessibility and ease of observation.

Sheds were built of wooden framework, covered on the inside with galvanized corrugated iron as a protection against the weather and fires. The floor of the first shed was dirt at first, but this was replaced later by a wooden floor to which the switches could be bolted to keep them from rocking. The floor of the second shed only was made of concrete.

Leads

Leads to sheds from the station consisted of lead-covered varnished cambric single-conductor cables, size 4/0. These were brought to the sheds in tile ducts. Leads in the sheds to switches were flameproof varnished-cambric, rubber-insulated wire.

It was learned by experience that the leads had to be carefully and securely braced. Magnetic stresses

Fig. 4—Test Sheds

produced by heavy short-circuit currents caused a great tendency of leads to shift and whip, sometimes resulting in breakdowns. It was also found that very careful attention had to be given to soldered joints and connections, as repeated heavy currents by heating and pulling action caused defective joints to open up with consequent arcs, which sometimes spoiled the tests and often damaged other parts. Not only did this pertain to the connections in the test sheds but it was also of special importance in the leads in the station connected with the test, in order to prevent trouble being communicated to the rest of the station, as occurred in one case with considerable damage. Therefore, in the station proper, all buses were carefully gone over and specially braced. Disconnects were also given special attention, in fact, some of these were eliminated in any cables which carried excessive currents.

Fig. 5—Oscillographs and Control Apparatus for Tests

Measurement of Time, Currents and Voltage

Three oscillographs containing three elements each were used, thus making a total of nine elements, and three films. Each of these generally recorded the current in one phase and corresponding voltage to ground. In order to provide a common timing curve two of the films in addition to their own voltage (to ground) also recorded the voltage corresponding to the third phase. The third film in addition to its phase current and voltage also recorded the ground current.

Potential transformers were connected from each phase to ground at a point between the two protective breakers, thus providing a measure of voltage across each phase of the test breaker, showing in succession

Fig. 6—Laminated Shunts, 10,000-Ampere, Placed in a Triangular Frame

full voltage before the short circuit, zero voltage and arcing voltage during the short circuit, and the re-established voltage after the short circuit was cleared, thus indicating the action of the various breakers. Fig. 5 shows a typical arrangement of these oscillographs.

In some cases it was desired to accentuate the scale of the arcing voltage, in which case one potential transformer was connected directly across one phase of the switch, and oscillograph resistances adjusted to give heavy deflection even at low voltage. This put excessive currents in the vibrator circuits, so a gold-leaf fuse was inserted in this circuit, which blew at high voltage which occurred due to complete restoration of voltage across breaker contacts on opening up. This scheme could not well have been used on all phases as it cut out other useful and necessary information obtained with the regular connection. A study of the voltage at the arc was also obtained by making photographic enlargements of parts of the oscillograms of voltage waves taken in the regular way.

For current measurements, slip-over type current transformers were used by one manufacturer. These were put on the line between the two protective breakers. The other company used shunts to measure current. As the use of these brought the oscillograph elements to the same potential as the shunts, these shunts were put in the leads at the short-circuited and grounded end of the test breaker. To further insure keeping this grounded end at ground potential and prevent the burning open of this ground, the size of this ground wire was doubled, two 4/0 wires being used. The scheme worked out generally satisfactorily, as no markedly bad effects were experienced, although shunt leads were charred in the conduit several times.

In the first tests the shunts were located in the same plane. In later tests they were located in the corners of a triangular wooden frame with axes parallel to incoming current leads, see Fig. 6. Care was taken to bring the instrument leads out from the center line of the shunts. These instrument leads consisted of twisted pairs; an important consideration, as failure to twist these leads in early tests had caused errors due to inductance effects. The latest arrangements of leads and shunts were made so as to reduce the effects of inductance to a minimum; in fact results indicated these to be practically negligible.

Current transformers and shunts each have their particular advantages as well as faults. There is some question as to how accurately current transformers record transient phenomena. Furthermore the partial saturation of the iron produced by heavy overloads during short circuit introduces other errors. However, current transformers can carry surprisingly heavy overloads with a fair degree of accuracy. It should be remembered that the oscillograph itself has but limited accuracy. On the other hand shunts record accurately transient phenomena. They are, however, subject to inductive effects, which can introduce considerable error. The uneven distribution of current in these may also introduce other, though probably slight errors. The ever present danger of putting line voltage on the oscillograph is of course a serious objection.

Oscillograph Layout

In the Westinghouse tests three oscillographs as developed by J. W. Legg were used. The special features of these oscillographs are described in detail in the July, 1920, Journal of the A. I. E. E. and will not be dwelt on here, except to point out such outstanding features as the use of incandescent lamps instead of arc lamps as a source of light, and the automatic arrangements which make it possible to secure the start of the short circuit at the beginning of the film, thereby making it possible to use satisfactorily short films only 12 in. long. In the G. E. tests, three standard G. E. oscillographs were used, all driven from the same jack shaft. 24-in. films were used, and the general method adopted was to start the oscillograph a moment before the short circuit was applied, and then close in the oil switch which applied the short circuit to the system independent of the oscillograph, both the switches controlling the oscillograph and the closing-in breaker, however, being under the immediate control of the oscillograph operator.

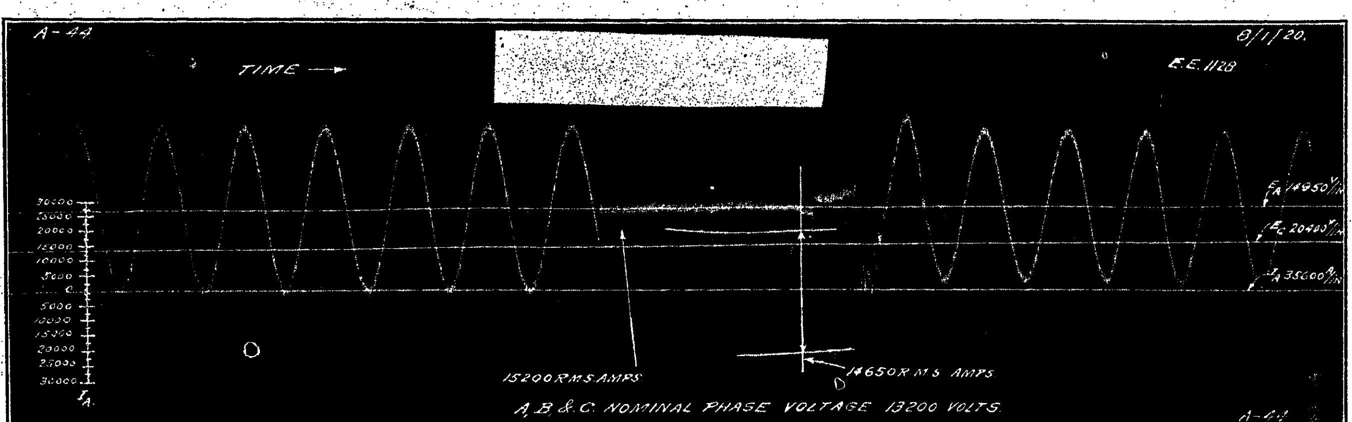

Fig. 7—Typical Oscillogram

Analysis of Oscillograms

Fig. 7 shows a typical oscillogram. The bottom curve represents the current in A phase and the top curve the corresponding voltage measured to ground. The middle curve represents the above mentioned reference voltage (C phase). It will be noticed that A-phase voltage becomes zero the moment the short circuit current appears, but later on reappears as a typical "arcing voltage", with the well known flat arc characteristic, corresponding to the instant the arcing contacts separate. After a little over one-half cycle of arcing the current in this case is ruptured and tion of this method in detail in one particular case. As indicated, the current is divided into an a-c. and a d-c. component whenever unsymmetrical and the true r. m. s. value of current at any moment is obtained by combining the effective a-c. component ($I_{a.c.}$) and the d-c. component ($I_{d.c.}$) in the usual way, *i. e.*,

$$I_{r.m.s.} = \sqrt{I^2_{a.c.} + I^2_{d.c.}}$$

To determine the true r. m. s. value which the breaker interrupted, the component parts are taken from the films at the moment the arc voltage first appeared, *i. e.*, at the instant the arcing tips parted. At this time in most cases, however, the d-c. component of

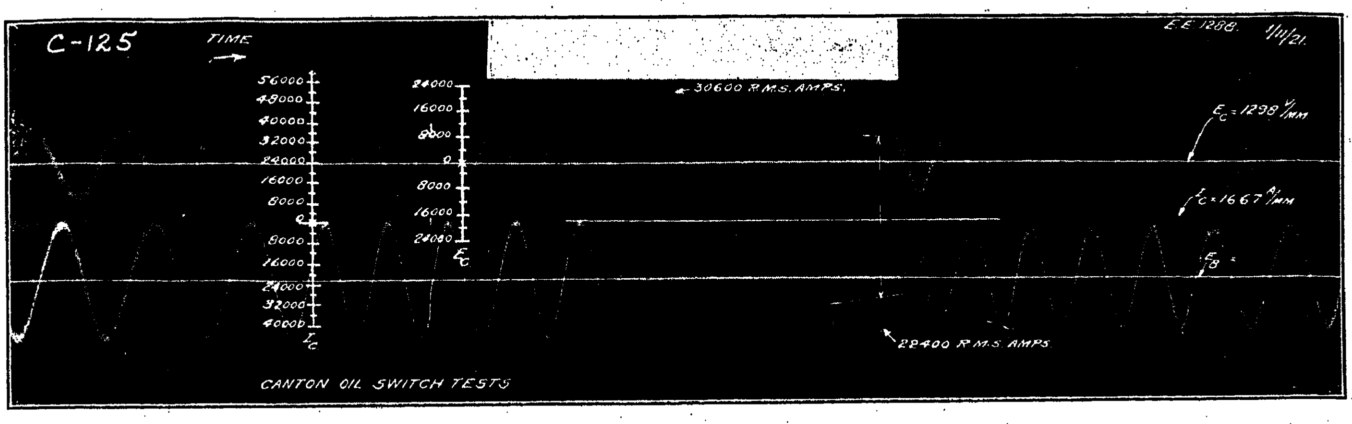

Fig. 8—Oscillogram showing Current Ruptured Past the Zero Point

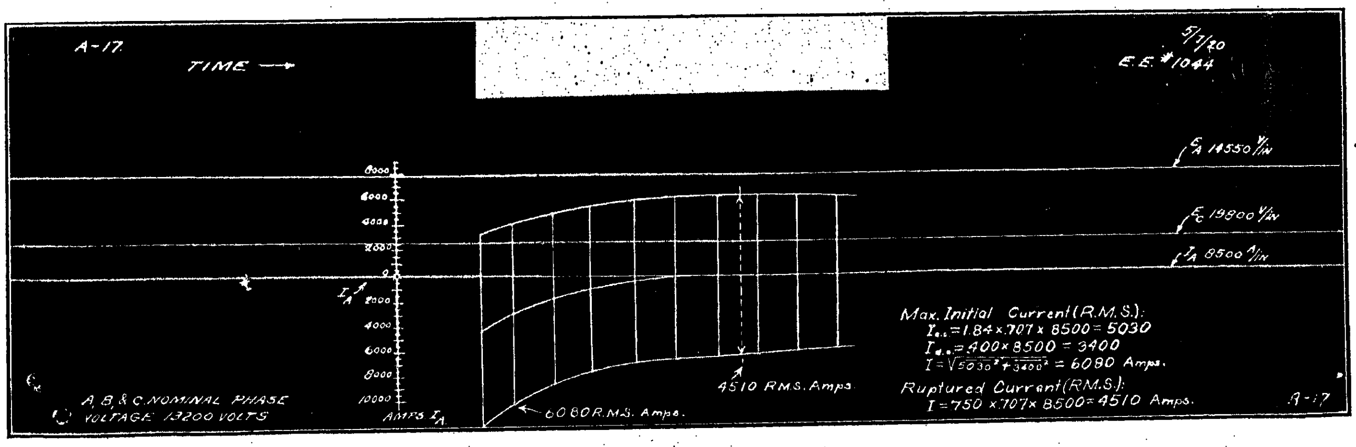

Fig. 9—Oscillogram showing Method Used in Calculating the R. M. S. Values

practically normal phase voltage reappears. By far the larger percentage of short circuits seem to break the arc at the zero point of the current wave corresponding to the time at which the magnetically stored energy of the system is a minimum. Occasionally exceptions are found to this rule. Oscillogram Fig. 8 shows such a case where the arc broke about 1/10 cycle after passing through its zero point. The method adopted in determining the r. m. s. current value from the oscillograms was the one described in the A. I. E. E. paper of February 19, 1918, by Messrs. Hewlett, Mahoney and Burnham on the rating and selection of oil circuit breakers. Illustration Fig. 9 shows the application the current wave was usually negligible. To determine the maximum r. m. s. obtained on the short circuit, the components parts were taken at the peak of either of the first two half waves, depending on which was the largest. Unless specifically stated otherwise, all the current values quoted in this and subsequent papers refer however to the actually ruptured arc amperes and not to the initial amperes.

Effect on the System

It may be interesting to note that it has been possible to make a total of about 200 short circuits directly on the Baltimore system at Canton, many of which

involve the largest short circuit obtainable at this place without any breakdown whatever of the major equipment of the two operating companies, and with no more than two serious disturbances resulting to the system, one being due to the opening of a disconnector in the station, and the other being caused by the burning open of one of the leads in the station at its terminal. All of the tests naturally meant momentary voltage disturbances to the system, and for this reason most of the tests were made after midnight or on Sunday morning when such momentary disturbances could best be tolerated. In some of the later tests the load of a number of the more important customers was also carried on separate generators apart from the tests. In no case did the two power companies generators fall out of step, and in only a few cases was any of the customers' synchronous load lost momentarily. The most sensitive equipment on the system seemed to be the rectifiers used for street lighting which frequently would drop out, but as these could always be re-started immediately, this was not considered of serious consequence. The chief reason for the fact that it was possible to make so many short circuits with so little serious interference with the system lies undoubtedly in the short duration the short circuit was permitted to hang on to the system, usually not more than ¼ second and never more than ½ second. Additional reasons may be the fact that short circuits were not made directly at the generating stations so that there would always be some voltage left on the generators to maintain synchronism, and the fact that the system in question is equipped with a carefully designed and adjusted selective relay system.

Conclusions

In the papers presented by Messrs. Hilliard and MacNeill the individual performance of a number of breakers are described in detail and will therefore not be dwelt on here. A study of these papers will show that the tests have resulted in marked improvements in the design and performance of oil circuit breakers for moderate voltage and high interrupting capacity. The results unquestionably indicate that it is possible, with proper design, to build oil circuit breakers which can be relied upon to satisfactorily interrupt large currents on high-capacity systems many times in succession without damage to the breaker, without any oil throw and without change of oil or adjustments.

The tests have also proved that it is possible to conduct a series of tests directly on a modern system without damage to equipment and without serious interference to its normal operation. It is hoped that this fact will encourage other operating companies to cooperate with the manufacturers in further improvements of oil switches of other designs and ratings to the benefit of the whole industry.

Tests on General Electric Oil Circuit Breakers at Baltimore

BY J. D. HILLIARD
General Electric Company, Schenectady, N. Y.

DURING the year 1920 an invitation was received by the General Electric Company from the Consolidated Gas Electric Light and Power Company of Baltimore, Maryland and the Pennsylvania Water and Power Company to submit oil circuit breakers for test on their system in Baltimore. The object of the test was to develop a breaker which would satisfactorily handle a short circuit on the 13,200-volt, 25-cycle system as it then existed, and show an apparent factor of safety at that load (20,000 to 25,000 r. m. s. amperes) which would be fairly conclusive to them that the breaker would also handle a short circuit on the system of at least 40,000 amperes. r. m. s. when the generating capacity had been increased by a proposed new generating station.

The tests proposed offered greater advantage than any heretofore made because the power available for testing at this voltage was much greater than any previously employed, because the breakers were to interrupt short circuits at the working busbars of the system, instead of utilizing an isolated bus section as had heretofore usually been the case at tests, and because the tests were to be made by the two companies above mentioned who were to make the report of tests and draw their own conclusions as to operations.

It is obvious that without an exact knowledge of the facts and conditions governing the tests the engineers of power companies might draw wrong conclusions, and if these conclusions were applied to their own system they might be unduly concerned with their equipment, which as a matter of fact might be perfectly safe under their conditions of operation. For that reason it was stipulated that no report of operations were to be made public without the consent of all parties concerned.

It is important to emphasize that the tests on General Electric apparatus herein reported are not to be taken as *applying universally* to all 13,200-volt, 25-cycle *systems and circuit connections* but are conclusive *only upon this particular system under the particular connections used during the tests* with the *special* circuit breakers tested. Conclusions drawn from these tests and applied to systems where different conditions exist and where standard breakers are installed may lead to unfortunate results. It is believed that the wisdom of the company's conservative policy in the rating of current-interrupting apparatus is conclusively proved by these tests.

After it had been decided that the company would accept the invitation and submit breakers for test, consideration was given to the selection of the type of breaker best suited to meet the severe conditions. The Type *F H* breaker was decided upon for the following reasons: Its satisfactory operation in the past; the small quantity of oil these breakers contain relative to their interrupting capacity, with a corresponding small fire risk; the great strength of the oil-vessel; the ease of making inspections and contact repairs on the spot, or of substituting spare vessels and inspecting those removed at leisure; the impossibility of the arc going to ground by burning through the insulating lining of the oil tank; the fact that since each arc is drawn in its own tank there is no possibility of the arcs whipping together causing a sustained short circuit; the possibility of greatly increasing the interrupting capacity of this type of breaker in a cell of the standard floor space and the fact that so many stations were already equipped with this type of breaker.

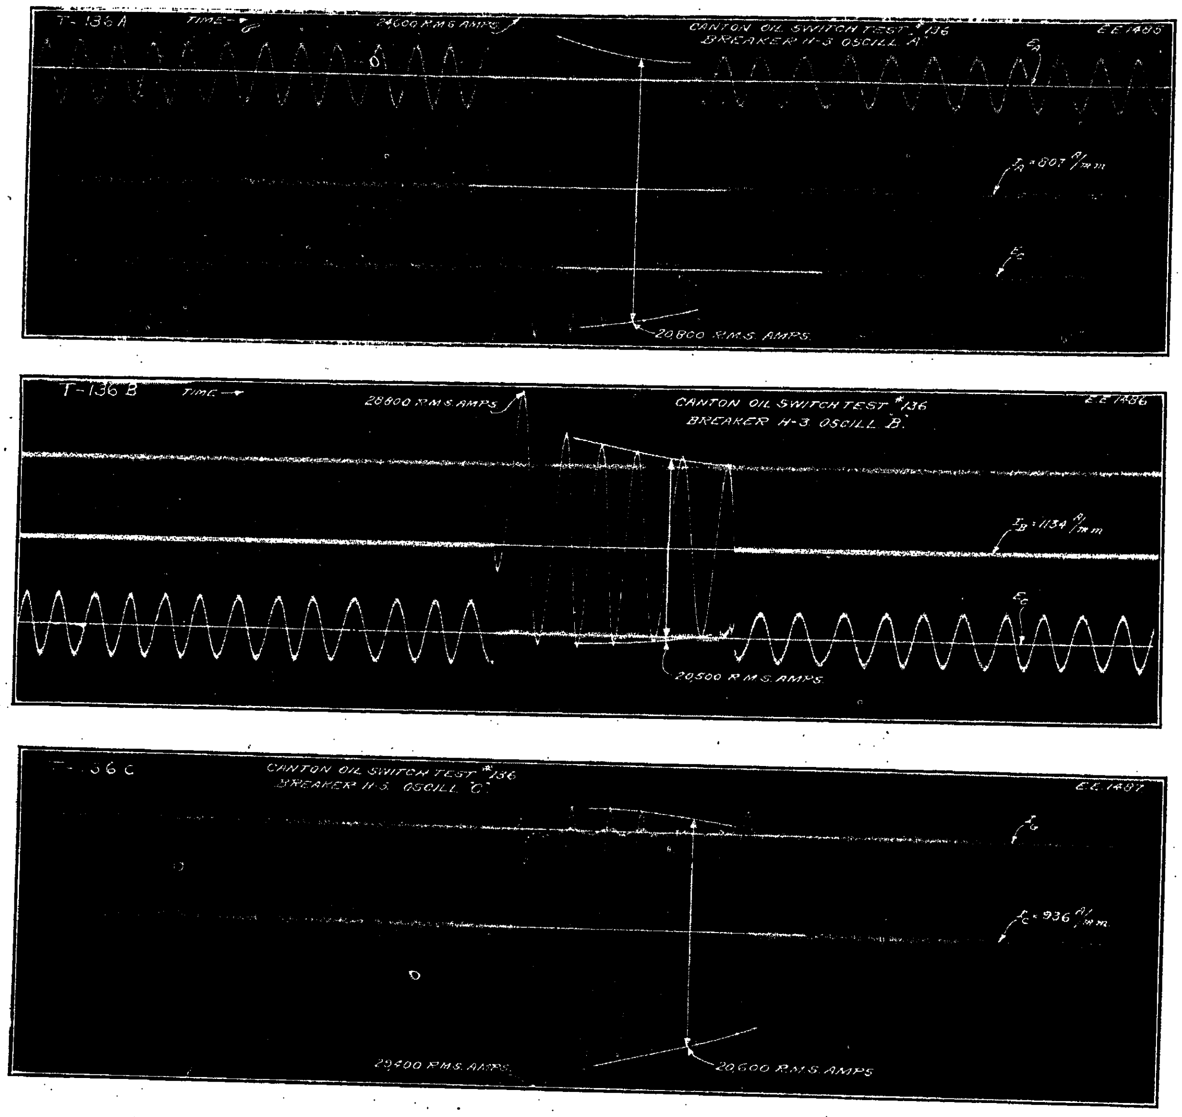
After some preliminary testing the Consolidated Gas, Light and Power Company changes the specifications as to the number of short circuits the breaker was to open, from two to five successive short circuits at two-minute intervals. The tests as reported in this paper, which were to determine the suitability of the breaker to handle five successive short circuits with all the power the operating companies could deliver were not begun until after the changes indicated as a result of the preliminary tests had been made. The remodeled breakers consisted of one *F H*-3 *Y*, one *F H*-6 *Y* and one *F H*-9 *Y*, and a single pole of the experimental *F H D*-17 *Y* the so-called dead pot *F H* breaker. The remodeled type *F H Y* breakers differed from the standard type *F H* breakers in having heavier tops, contact rods, bolts and bolting members, also heavier internal baffle construction, and an external separating chamber of insulating material, leading from the top of each oil tank, through which the gas is ejected and in which chamber any atomized oil vapor is retained by the condensing material contained in the tube, and returned to the oil tank. Various lengths of oil tanks were also provided and tested as well as various separating arrangements in order to determine the one most satisfactory to prevent oil throw.

This external separator was so designed that it could be placed on the present type *F H* breaker in the standard size cells after suitable modifications have been made to the breaker elements.

THE TESTS

Type *F H*-3 *Y* breaker interrupted an average current of 20,600 r. m. s. amperes once without oil throw.

Presented at the A. I. E. E. Annual Convention, Niagara Falls, Ontario, June 26-30, 1922.



Oscillograms Nos. 136-*A*-*B*-*C*

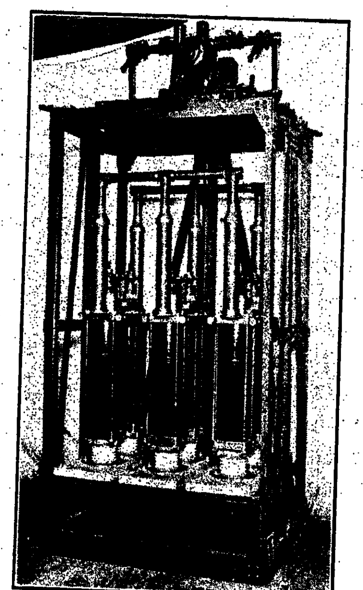


Fig. 1—Front View of Test Breaker Frame With Type *F H*-3 *Y* Tanks in Place

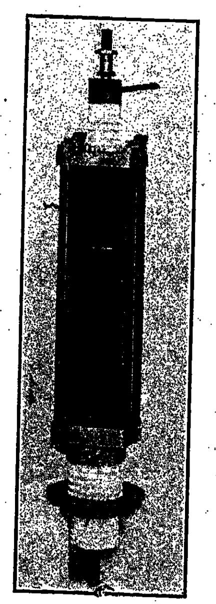

Fig. 2—Type *F H*-3 *Y* Tank Completely Assembled

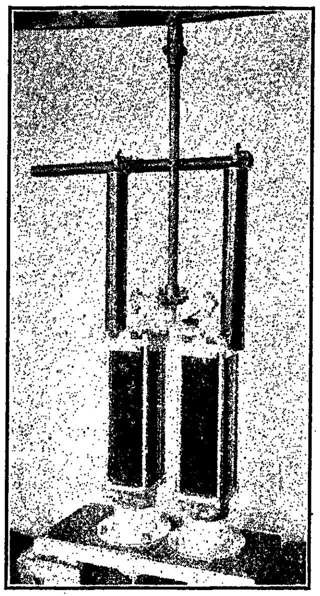

Fig. 3—Type *F H*-3 *Y* Single-Pole Element—15,000-Volt Breaker

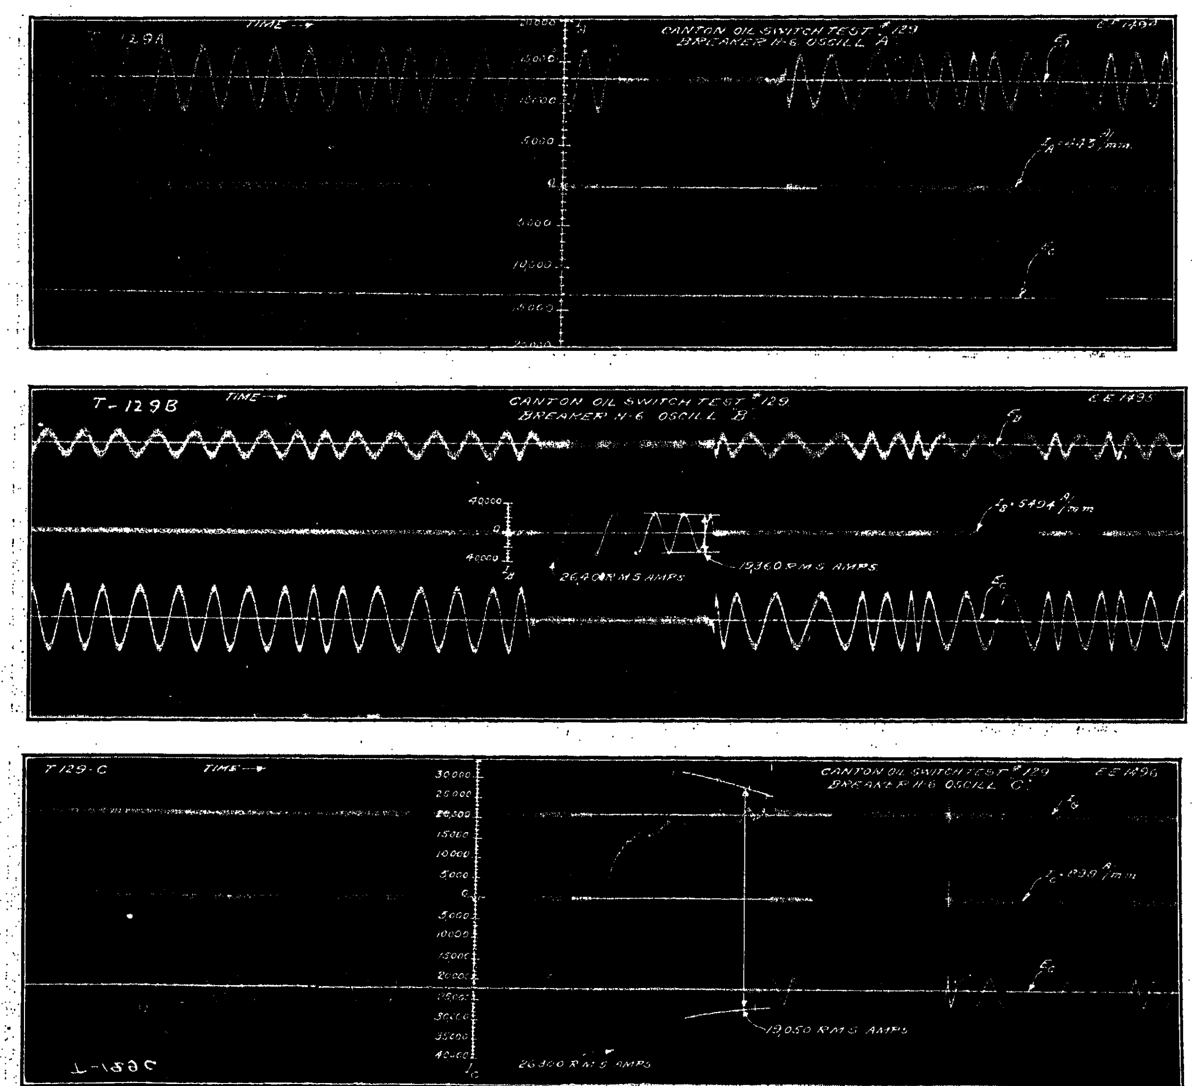
The same breaker interrupted an average current a second time at 20,200 r. m.s. amperes at the arc without oil throw. At this second shot a defective lever arm on the mechanism broke and the breaker was not tested further. The generator capacity connected was 147,000 kw., oscillograms 136 *A, B, C* show the circuit phenomena during the interruption. Fig. 1 and Fig. 2 show the triple-pole breaker and a single-pole element as tested, and Fig. 3 shows a standard single-pole element of the breaker as furnished for standard production orders.

The type *F H*-6 *Y* breaker interrupted five successive short circuits averaging 20,200 r. m. s. arc amperes. A few drops of oil was the extent of the oil throw in any of the tests. Some smoke was emitted from the separating pipes but no distress was shown by the breaker and it was evident that the load interrupted was much below its interrupting capacity. The generator capacity connected was 147,500 kw. oscillograms 129, *A, B, C* show the circuit phenomena during



Oscillograms Nos. 129-*A*-*B*-*C*

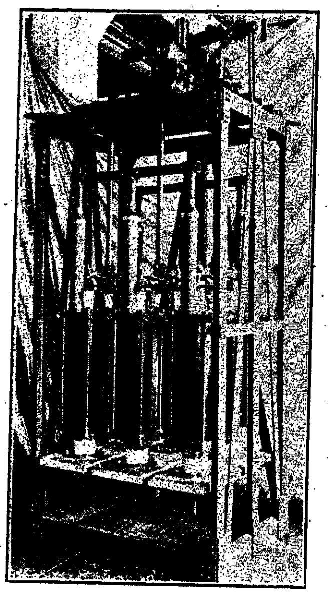


FIG. 4—TYPE *F H*-6 *Y* OIL CIRCUIT BREAKER COMPLETELY ASSEMBLED

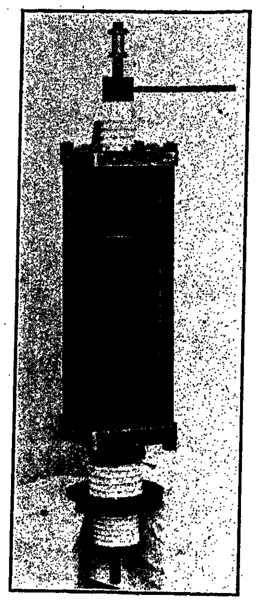

FIG. 5—TYPE *F H*-6 *Y* OIL TANK ASSEMBLED WITH BUSHINGS AND REENFORCING RODS

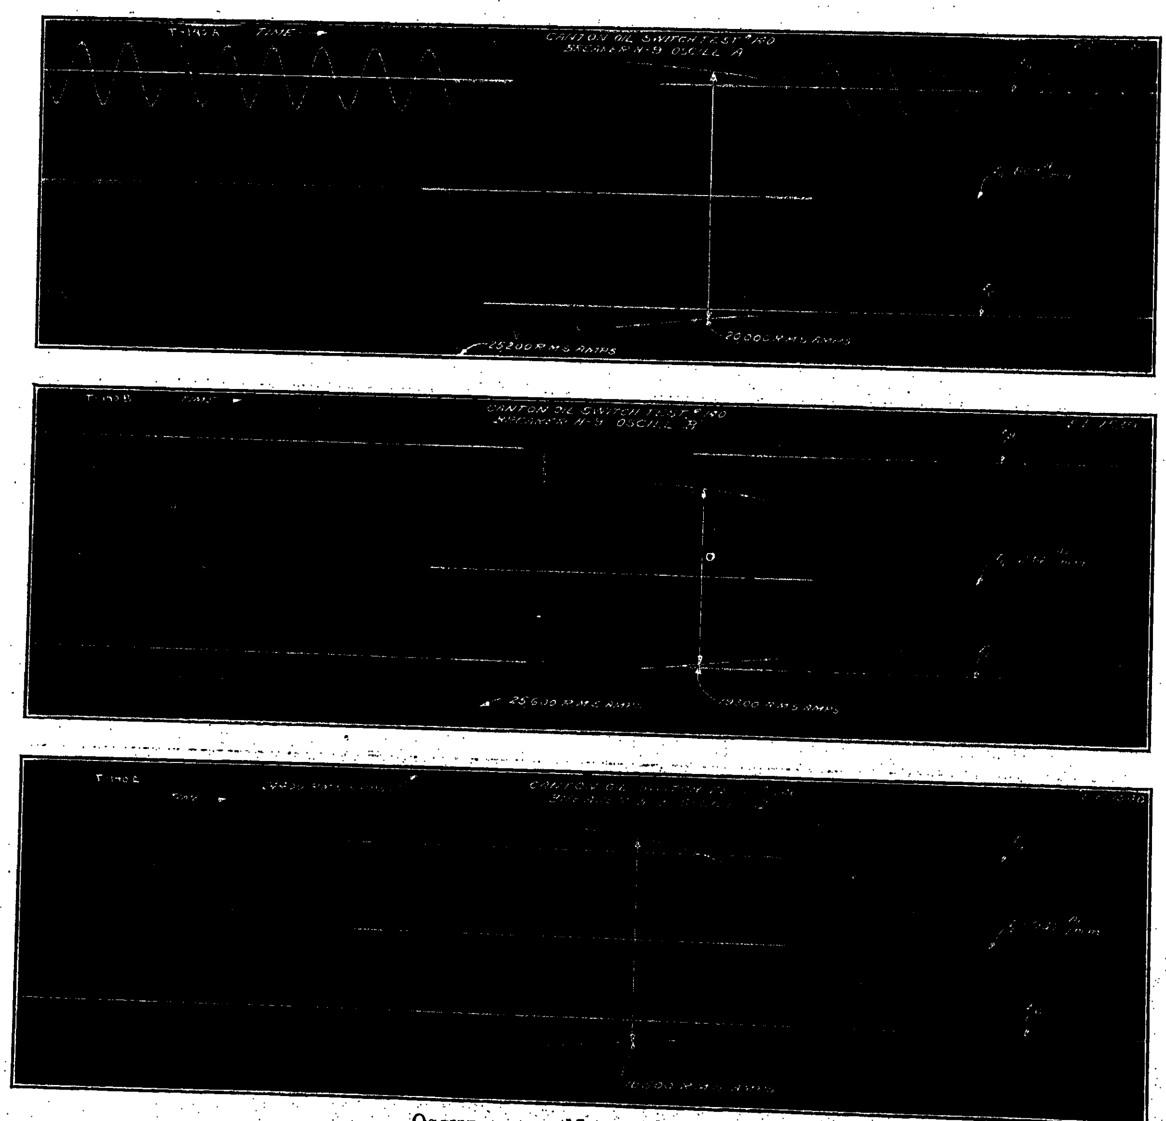
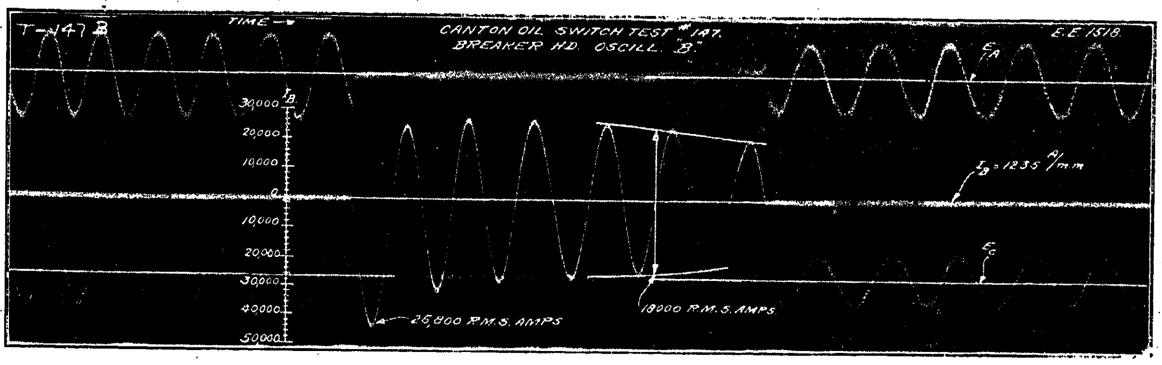


OSCILLOGRAMS NOS. 140-*A*-*B*-*C*

the interruption. Fig. 4 and Fig. 5 show the triple-pole breaker and a single pole element as tested.

The type *F H*-9 *Y* breaker interrupted five successive short circuits with an average current of 19,160 r. m. s. arc amperes. The oil throw was limited to a few drops during any test except from a leaky gasket on phase *C*. The breaker evidently has a large reserve interrupting capacity above any load which could be thrown on it during the tests. The generator capacity connected was 147,500 kw. oscillograms 140 *A*, *B*, *C* show the circuit phenomena during the interruption.

The type *F H D*-17 *Y* breaker—single pole element—interrupted five successive short circuits averaging 17,670 r. m. s. arc amperes. During this series of tests the oil throw was very small and it was evident that the interrupting capacity of the breaker was much greater than the available load which could be thrown upon it from the system. The generator capacity connected was 147,500 kw. Oscillogram 147 shows the phase phenomena during the test. Fig. 6 shows the single-pole element as tested. This test of the type *F H D*-17 *Y* breaker was a single-pole test; the other two poles at the time of the test were the type *F H*-9 *Y* breaker elements.



Oscillogram No. 147

This type *F H D*-17 *Y* breaker was not tested with its regular operating mechanism but with the standard type *F H*-9 *Y* mechanism, the single-pole element therefore did not show the exact characteristics it would have shown if its own operating mechanism had been used. The burning of the contacts and contact rods for the five short circuits was small on all of the breakers tested and was substantially the same for all breakers (about ¼ inch was burned from the end of each contact rod.) This is what would be expected because the size of all contact rods was the same.

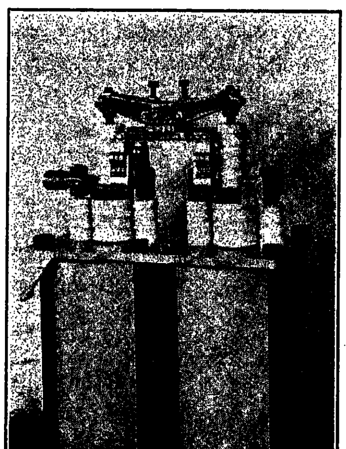


Fig. 6—Type *F H D*-17 *Y* Oil Circuit Breaker, Single-Pole Unit, 15,000 Volts, 1200 Amperes

The quantity of oil lost was negligible and was as to be expected less in the larger oil tanks than in the small tanks. The interrupting property of the oil was not seriously affected by the five interruptions and it is evident that oil deterioration is not the factor which will determine the number of interruptions which can be made by any of these breakers.

The interrupting capacity of any of the *F H Y* type breakers can be increased to almost any desired current by making a small modification of the oil vessels, but the number of interruptions which can be safely made at any current and voltage will, of course, decrease with the increase of current, unless the arcing contacts are increased in size at the same time the current to be interrupted is increased.

The Baltimore tests, as well as other tests where large currents have been interrupted, have demonstrated the necessity of maintaining the arcing contacts in good condition, because the safety of the main contacts are determined by the condition of the arcing contacts. These remarks, apply to oil circuit breakers of any type.

The breaker may be designed for instance to stand four interruptions, but if it has handled two interruptions without examination there are but two left at the guaranteed rating, and at the next case of trouble the breaker may have to open so many times that the

main brushes will be seriously burned before the trouble is remedied, and if so, the carrying capacity of the breaker will be seriously affected. The necessity of keeping the arcing contacts in first class condition at all times on breakers of any type interrupting large currents cannot be overemphasized, the continuous operation of the system and the safety of the breaker both require it.

In the recording by the oscillograph of the currents interrupted, shunts were used instead of current transformers, as the company's engineers feel that they more correctly record the transient phenomena.

In taking the records, two foot films were used as their use enabled us to spread out the wave and thus secure a better record and at the same time assured a record of any delayed phenomena, such as the re-establishment of the arc, should it occur, which could not be had with the short film. With the long film it is also possible to obtain a good record without adjustment of the drive of the oscillograph on breakers having widely different speed characteristics.

Conclusions

The test proved that the *F H* type of breakers could be constructed to interrupt the heaviest short circuit on a large power system within its voltage rating and without oil throw; that the present line of type *F H* breakers could be changed so as to be free from oil throw at their present rating.

We wish to here express our appreciation of the many favors shown us by the power companies during the tests. The manufacturing and operating companies both are deeply indebted to them for supplying the facilities and labor with which to make the tests which made possible the realizing of results not otherwise obtainable at that time. It took a great deal of courage to throw repeated short circuits on the combined systems and the results showed that their belief in their engineering practise and substantial construction were merited, as not a single serious accident to personnel or apparatus occurred during the series of tests.

Discussion

Tests on Westinghouse Oil Circuit Breakers at Baltimore

BY J. B. MacNEILL
Associate, A. I. E. E.
Westinghouse Electric and Manufacturing Company, E. Pittsburgh, Pa.

This paper deals with short-circuit tests made recently at Baltimore on dead tank oil circuit breakers of Westinghouse manufacture. Tests were made against the combined capacities of the Consolidated Gas, Electric Light & Power Company and the Pennsylvania Water & Power Company systems, and currents as high as 24,000 amperes at 13,200 volts were interrupted repeatedly. Tests on breakers of different sizes are described, the rupturing capacity ratings of the breakers referred to, ranging from 10,000 amperes at 15,000 volts up to 40,000 amperes at 15,000 volts.

Improvements of design and construction have greatly increased the ability of this type and make of breaker to handle heavy short-circuit currents and severe duty cycles. The demonstration connected with the opening of heavy short circuits, including oil throwing and gas ejection, has been controlled and the fire hazard greatly reduced. A positive means for preventing oil throw, while at the same time relieving gas pressures in breaker tanks, has been developed.

Data are given regarding tripping speed, length of arc duration, and condition of the oil and circuit-breaker structure after the tests.

THE electrical industry as a whole owes a debt of gratitude to the Consolidated Gas, Electric Light and Power Company and the Pennsylvania Water and Power Company for the broadminded and capable manner with which they have attacked the difficult problem of determining the capacities of heavy power house oil circuit breakers. While considerable testing of a similar nature had been done from time to time in the past, nothing approaching in scope the tests recently completed at Baltimore had been undertaken previously. These operating companies have in this work assumed large expenses and operating risks which could only be compensated for by the far-reaching results achieved.

The time was ripe for such a series of tests. Power concentrations have grown to a point where the capacity and price of switching equipment are serious considerations. Operating requirements also have become more diversified and actual test data under field conditions were needed to meet them. There has grown a strict demand for circuit breakers that will function satisfactorily under maximum operating conditions as the results of inadequate performance become more hazardous with the growth of switching equipment.

The breakers tested by the Westinghouse company were all of the dead tank form (see Figs. 5, 7, 9, 11) this being the general form of oil breaker built by this company for many years. The general features of all these breakers are the same, and the more significant of these are as follows:

All tank structures and mechanism parts are dead and can be solidly grounded.

All contacts, that is the main current-carrying contacts and the arcing tip contacts, are made and broken inside the oil tanks.

The breaker closes against gravity and opens with gravity, accelerated by spring action, both in normal operation and also in event of failure of closing power, failure of mechanical linkage, or failure of latch.

Presented at the Annual Convention of the A. I. E. E., Niagara Falls, Ontario, June 26-30, 1922.

The purpose of this paper is to give the results which are of most general interest with some of the more important details. Briefly, the more marked improvements in this type of breaker, as a result of these tests, consist in:

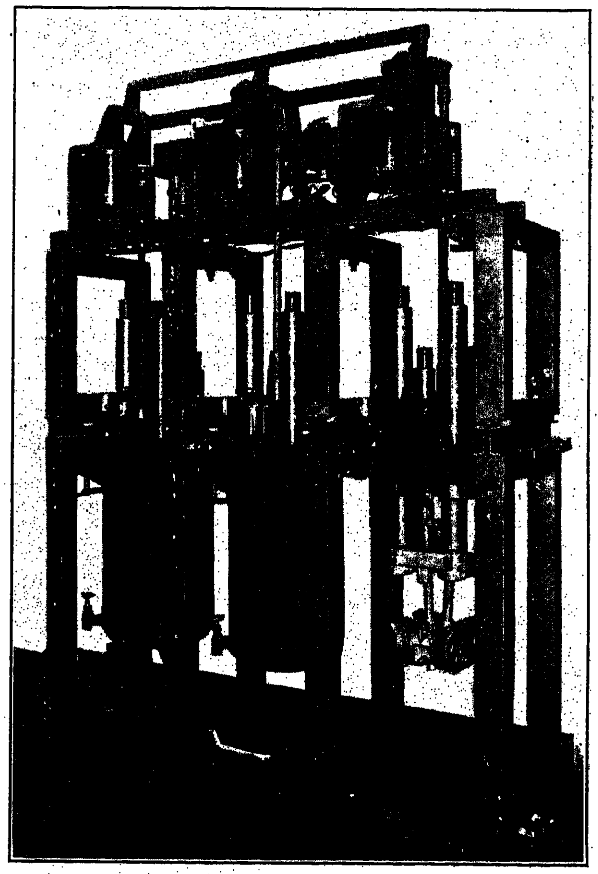

FIG. 1—ELECTRICALLY OPERATED OIL BREAKER SHOWING GENERAL FEATURES OF DEAD TANK BREAKERS
Westinghouse type O-2, 4000-ampere, 15,000-volt.

(1) Decrease in energy losses within the tanks, with improved control of arcs and gases formed.

(2) Scientific relief of pressures generated combined with reinforcement of mechanical construction where necessary.

(3) Elimination of oil throwing.

The result of these improvements has been increased rupturing capacity and ability to handle more severe duty cycles.

It was realized at the start that a knowledge of pressures developed in the tank structure at the time of rupturing short circuits was necessary. The small pressure gage shown in Fig. 2 was devised so that it could be placed in any location in a tank without interfering with the operation of the breaker as would be the case if the device were large enough to cause grounds or short circuits within the tank. This type of gage consists of a piston *a*, which is free to slide in a cylinder *b*, but the chamber *c* of which is sealed from the surrounding medium. The pressure in the breaker tank, acting on the piston, causes the ball *d* to make an impression on the lead washer *e* and the corresponding pressure can be read from the calibration curve shown in Fig. 3.

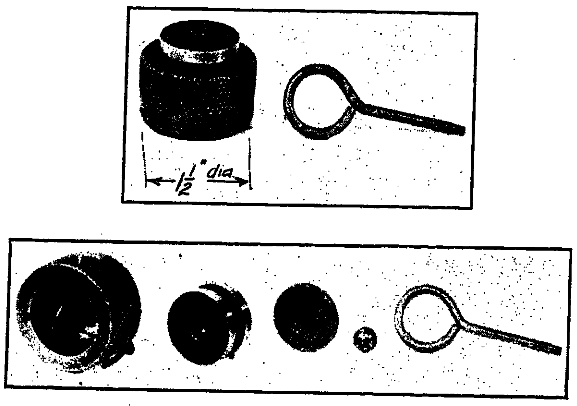

Fig. 2—Pressure Gage
Used in tests on Westinghouse Oil Breakers.

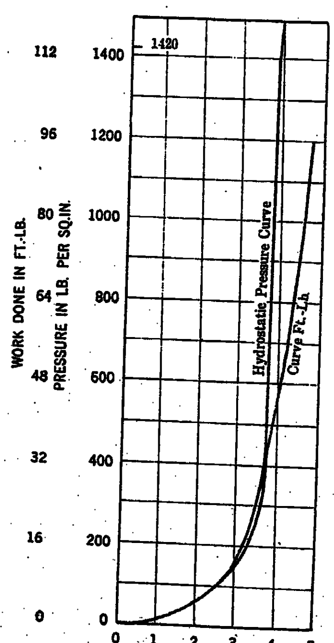

Fig. 3—Calibration Curve of Pressure Indicator

While the results secured from such a device are probably not accurate and have to be used with care, still they are very useful in determining the distribution of pressure over a breaker structure, and in determining relative pressures in breakers of different sizes and different types of design.

Quite early in the series of tests, it was found extremely desirable to provide ventilating and cushioning means for taking care of the pressures generated at the time of opening the circuit. It is realized that a considerable pressure in the tank is necessary to help quench the arc, but the more violent pressures due to gas explosions are not necessary for this purpose, and the ability of a given structure especially on repeated short circuits, can be increased by minimizing such pressures. The oil separator shown in Fig. 4 was developed for this purpose.

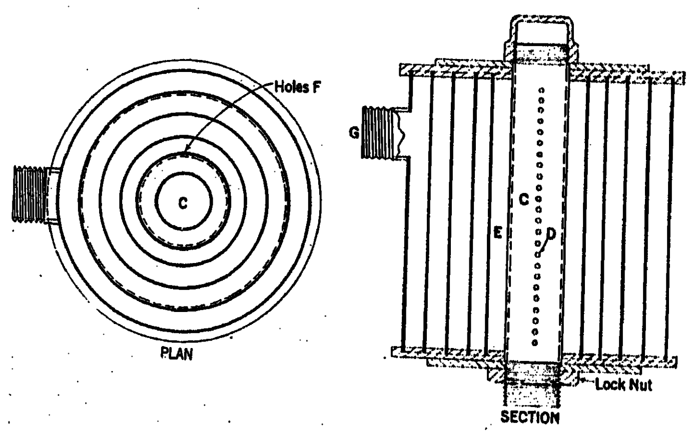

Fig. 4—Oil Separator

The oil separator was designed with the idea of ventilating gas mixtures, relieving pressures due to gas formation, and still preventing the throwing of oil from the structure. This separator consists of several concentric cylinders, the inside one being connected directly to the tank and the outside ones to the atmosphere. The mixtures of oil and gas entering the first chamber from the tank passes at high velocity out of the first chamber *c* through the row of holes *d*, and must then change its direction of flow in order to pass out of the second chamber *e* through the holes *f*, which are 180 degrees away from the holes *d* in the first path. In this way, going from the inner to the outer chamber at constantly decreasing velocity, the oil being acted upon by gravity drops into the bottom of the outer chamber and the gas flows through the vent *g*. With a properly designed oil separator, only a mist of highly vaporized oil escapes on the heaviest short circuits from the breaker structure with the gas, and the rest returns to the tank automatically by gravity as soon as the pressure is relieved.

The largest breaker tested was the Type "O-3" shown in Fig. 5. This is a three-pole electrically opera-

ted round tank breaker with condenser type terminals, parallel path contacts, and noninflammable insulating tank lining. The inside diameter of the tank is 24 inches. This breaker was subjected to eight short circuits on a system set-up calculated at 29,400 initial r. m. s. amperes. The current actually ruptured by the breaker varied all the way from 16,000 r. m. s. amperes to 24,000 r. m. s. amperes. The last seven short circuits were made in succession without inspection of the breaker, and the time elements between short circuits varied from 1½ minutes up to 35 minutes. Probably a small wine glass full of oil was ejected from the three poles during the whole eight tests, mostly in highly atomized form through the mufflers.

As the rupturing capacity rating of this breaker is 40,000 r. m. s. amperes at 15,000 volts, the pressure generated inside the tanks on these tests was small, amounting momentarily to about 5 per cent of the value of hydrostatic pressure for which the structure is good.

The arcing tips of this breaker opened three cycles after the short circuit was placed on the system, and the arc in all cases was completely ruptured within four cycles from the time the short circuit was placed on the system, the average being 3½ cycles (0.14 sec.). The average time of arcing was 0.5 of a cycle (0.02 sec.) with a maximum of one cycle (0.04 sec.). Samples of the oil used, taken from the three tanks after the completion of the test, broke down when stirred before testing at values varying from 14,000 to 24,000 volts on a 0.15-inch gap. Inspection of the breaker showed that deterioration consisted of burning on the arcing tips, singeing of the tank liners, and some pitting of the corners of the main brush. Later tests will show how pitting of the main contact was reduced. Fig. 6 gives a typical set of three-phase oscillograms showing line current, line voltages and ground current.

The ground current I_g is interesting as at times it rises to considerable values and is due to the arcs in the different phases being extinguished at different times as they reach the zero point of their respective current waves. In order to dispose of a question on which there has been some discussion in years past, we point out that in all these tests we have not found a case where the arc was not ruptured at the zero point of the current wave.

B

FIG. 7—WESTINGHOUSE TYPE *C O*-2 OIL BREAKER
Three-pole, 1200-ampere, 25,000-volt, electrically operated.

The oscillogram of restored voltage is interesting, showing that the system held up remarkably well considering the size of the short circuit, thus imposing the most severe kind of duty on the breaker for a given current. This was because the short circuit at Canton Substation caused relatively small demagnetization of the machines connected to the system. It is important to note that a large percentage of restored voltage may cause the reestablishment of arcing and consequently more severe duty on the breaker than if the restored voltage is small due to killing of the machine fields.

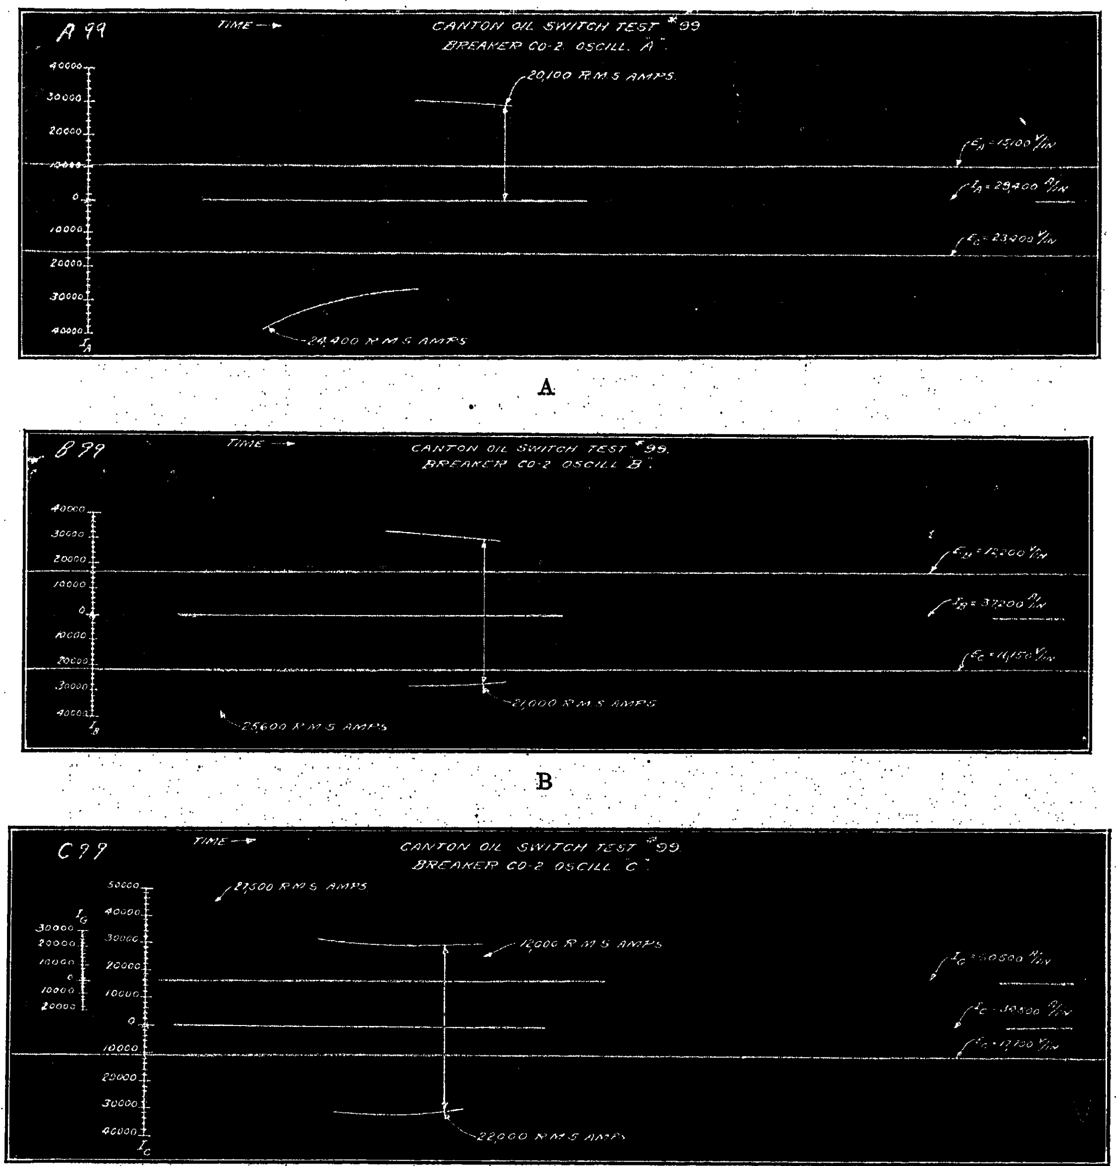
The type "*C O*-2" breaker shown in Fig. 7 has a cylindrical tank per pole 20 inches in diameter, and the three-pole breaker is built into a compact self-

contained unit with tanks, terminals and mechanisms mounted on one steel base. It has parallel path contacts and condenser terminals. This breaker is a modification of the "*C O-2*" breakers now in general use.

This breaker was tested seven times in succession without inspection or alteration on a system set-up calculated at approximately 20,000 r. m. s. amperes. The current actually ruptured varied from 18,000 r. m. s. to 22,000 r. m. s. amperes. The arcing tips opened approximately 3.75 cycles (0.15 sec.) after the short circuit was thrown on, and the circuit was completely ruptured on the average of 4.25 cycles (0.17 sec.) from the time of short circuit. The time of arcing averaged ½ cycle (0.02 sec.).

Five of the seven short circuits were made in a total time of nineteen minutes to determine what effect operations in quick succession might have on the structure. The breaker threw probably a half gallon of oil from each tank during the set of seven tests, this oil coming through the oil separators. This particular oil separator was superseded by a superior design shown in Fig. 4, on subsequent breaker tests.

Deterioration of parts was limited to burning of arcing tips, pitting of corners of the main contacts, and a slight scorching of the fireproof insulating tank lining. Samples of oil when stirred broke down at values from 12,000 to 18,000 volts on a 0.15-in. gap. As closely as could be determined, the maximum instantaneous tank pressure was about 12 per cent of the value of hydrostatic pressure for which the structure was good. Fig. 8 shows a typical oscillogram of this series of tests.



A

B

C

FIG. 8—OSCILLOGRAMS OF SHORT-CIRCUIT TEST
Westinghouse type *C O-2* oil breaker.

The Type "*O-1*" breaker shown in Fig. 9 is a modi-

fication of the line now in general use, and was tested against a system set-up calling for 19,400 r. m. s. amperes, twelve times in succession. The first five short circuits were made in a period of eighteen minutes, and the last four were made in a period of four minutes without waiting for oscillograms. The other short circuits were made at varying intervals. Aside from readjusting a tank gasket after the fifth short circuit, the breaker was not altered during this period of tests. the twelve tests was approximately two quarts which came through the oil separators in highly atomized form. Samples of the oil when stirred broke down from 6000 to 7000 volts on a 0.15-in. gap.

Deterioration of the contact parts was limited to burning of the arcing tips and slight pitting on some corners of the main contacts. There was no scorching of the tank lining. Momentary tank pressures in some cases had run as high as 1/3 of the hydrostatic

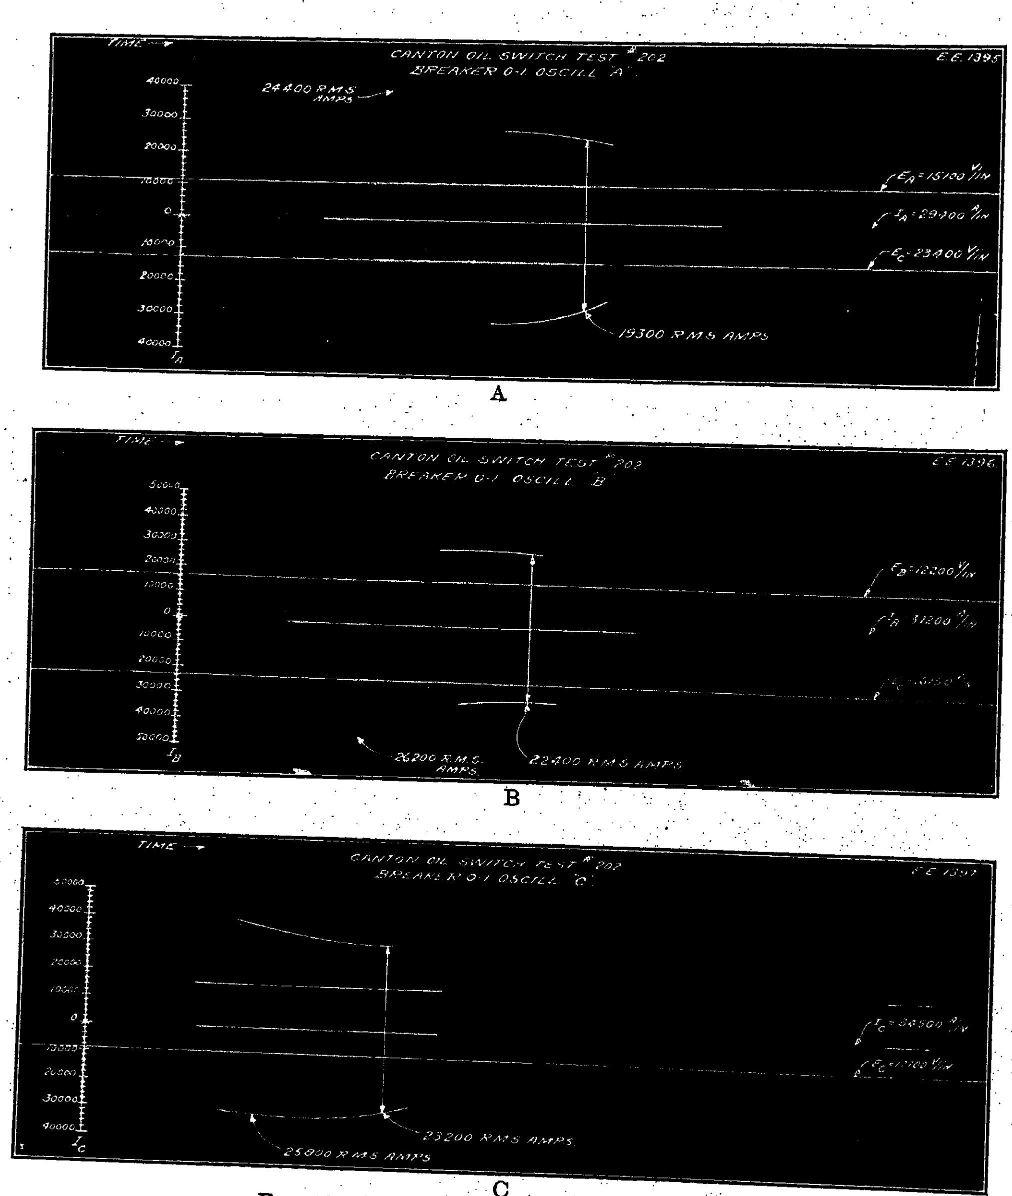


FIG. 10—OSCILLOGRAMS OF SHORT-CIRCUIT TEST
Westinghouse type O-1 oil breaker.

The current actually ruptured ranged from 19,000 r. m. s. amperes to 23,900 r. m. s. amperes. The arcing tips parted on an average of approximately 3 cycles (0.12 sec.) from the time of short circuit, and the circuit was completely ruptured on an average of 3.6 cycles (0.144 sec.) from time of short circuit, making an average time of arcing of approximately 0.6 cycle (0.024 sec.).

The total amount of oil thrown from all phases on pressure for which the structure is good. Fig. 10 shows typical oscillograms of this series of tests.

The Type "*O E-6*" breaker shown in Fig. 11 has cylindrical tanks 14½ inches in diameter, and is built in single-phase units with a common mechanism and intermediate cell walls. This breaker was subjected to a final series of nine short circuits against a system set-up calculated at 19,400 r. m. s. amperes. The first five short circuits were made in a period of eighteen

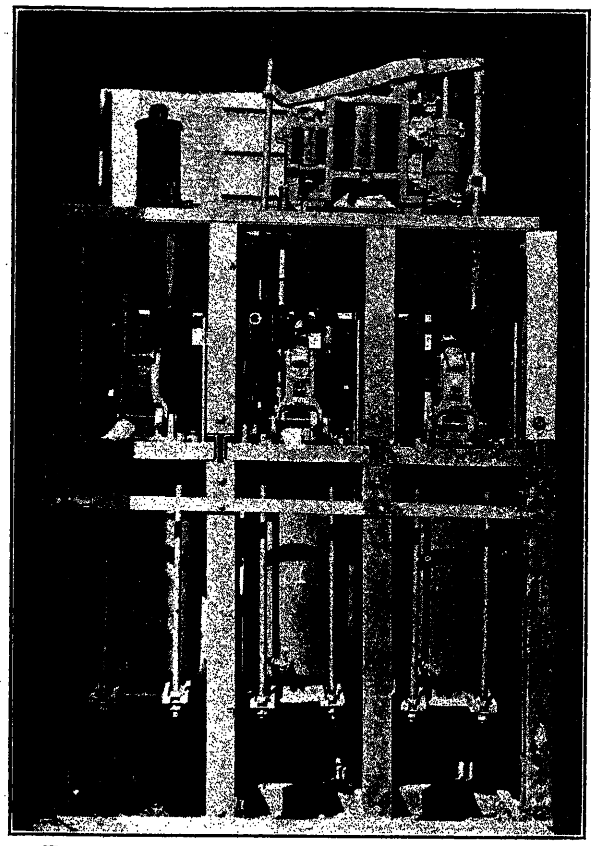

Fig. 9—Westinghouse Type *O*-1 Oil Breaker
1200-ampere, 25,000-volt, electrically operated.
Arranged for test.

minutes and others at varying intervals. The current actually opened ranged from 16,300 r. m. s. amperes to 21,000 r. m. s. amperes. The average time from the point of short circuit until the arcing tips parted was approximately 3.25 cycles (0.13 sec.), until the circuit was completely ruptured the time averaged 3.75 cycles (0.15 sec.) and the period of arcing averaged 0.5 cycle (0.02 sec.). The amount of oil thrown was practically negligible, being limited to a few drops that leaked through gaskets from time to time, and a slight amount in highly atomized form through the mufflers amounting to half a cup full for the whole series of tests for three vessels.

The oil was extremely black and muddy at the end of the test, and while not tested for breakdown probably was not good when stirred up for more than 25 per cent of its original test value of 35,000 volts on 0.15-in. gap.

The deterioration of contact parts was limited to slight scars on the tank lining, and a rather slight amount of burning on the arcing tips considering the severity of the service. There was absolutely no sign of pitting or burning on the main contact members, as previous test had indicated methods for eliminating this pitting. Fig. 12 shows typical oscillograms of this series of tests.

The modified Type "*E*-6" breaker shown in Fig. 13 is an elliptical tank breaker with the ordinary semi-

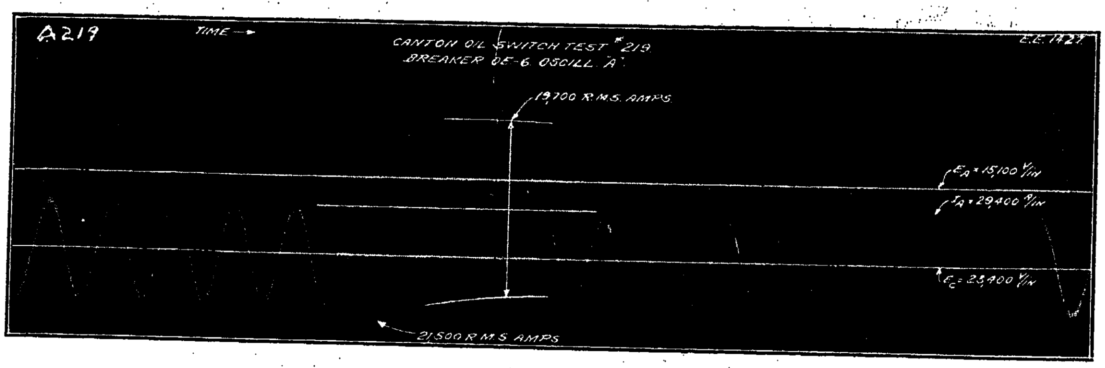
Three-pole, 1200-ampere, 15,000-volt, electrically operated.

elliptical form of main contacts and combined porcelain and micarta terminal insulation. It is built in single-phase units operated from a common mechanism, and with intermediate barrier walls. The tests on this breaker are exceedingly interesting, as they indicate the possibility of elliptical tank breakers for heavy power house service where for lack of space, their use may be desirable.

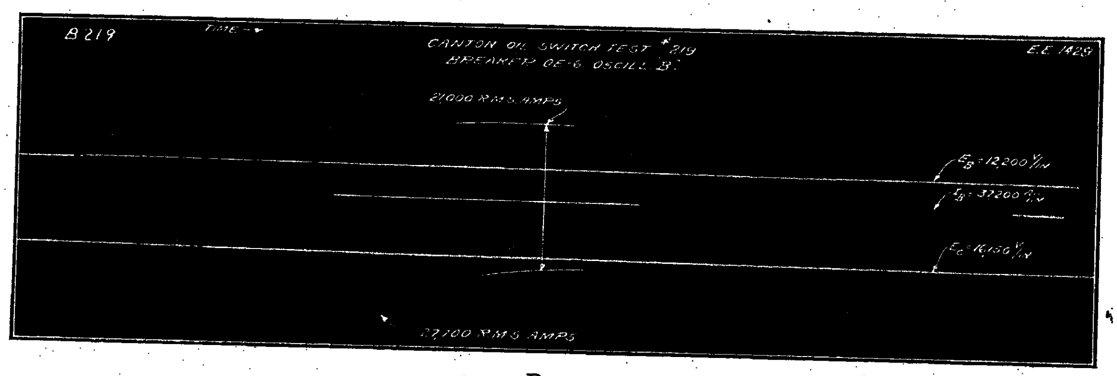
This breaker was subjected to a final test of ten short circuits on which the current actually ruptured varied from 10,000 r. m. s. amperes to 11,800 r. m. s. amperes. The average time from moment of short circuit until the arcing tips opened was approximately 3 cycles (0.12 sec.), the average time until circuit was completely ruptured was 3.75 cycles (0.15 sec.) and the average time of arcing was 0.75 cycle (0.03 sec.). The last five short circuits were made in a period of four minutes or an average of less than one minute between short circuits.

Approximately one-half gallon of oil was thrown from each tank through the oil separators on the ten short circuits, this breaker having been equipped with oil separators giving less back pressure in order to relieve the tank pressure. Some little oil leaked out around the tank gaskets.

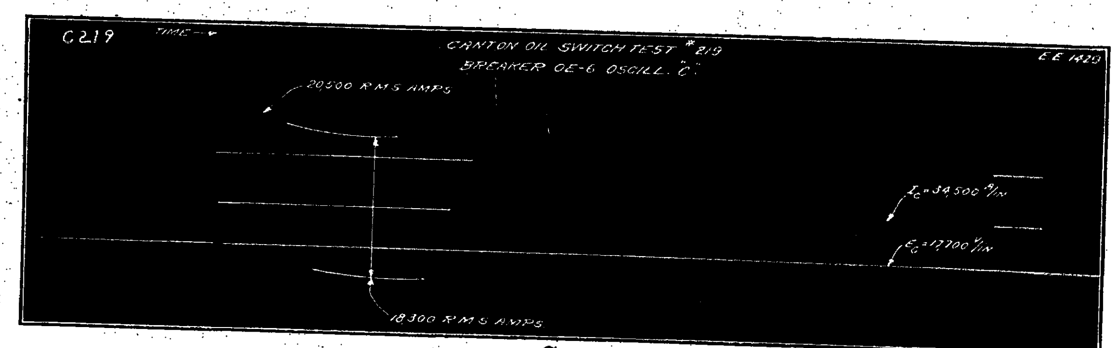
Depreciation was limited to burning of the arcing contacts, slight pitting of the main contacts, and slight charring of the tank liners. Fig. 14 shows typical oscillograms of these tests.



A



B



C

Fig. 12—Oscillograms of Short-Circuit Test
Westinghouse type O E-6 oil breaker.

The results of the tests detailed above increase greatly our knowledge of the action of higher-power moderate-voltage circuit breakers of this make and type. We can not hastily draw conclusions regarding the action of breakers having different constructions

and operating under different conditions from those actually tested. However, it seems these tests have been comprehensive enough to warrant drawing some conclusions.

It seems desirable from the point of view of securing maximum rupturing capacity in a given space that heavy power house breakers be equipped with means for freely venting large amounts of gases without at the same time throwing oil.

It is evident that designs can be produced which will be capable of opening heavy short circuits several times in succession with intervals either short or long between succeeding openings. In other words, the life of the breaker between periods of inspection and repair is principally a function of the amount of copper in the arcing tips.

With proper design, the condition of the oil does not seem as important as heretofore had been thought. This applies only to moderate voltage, heavy capacity breakers, such as those tested, and we wish to emphasize that regular inspection and good maintenance of oil is a desirable thing in connection with circuit breakers in general.

It seems that designs can be made in which the distress on the breaker on repeated short circuits is no greater than that on the first or second short circuit. This, of course, requires a construction which does not depreciate in any way with succeeding short circuits, outside of the depreciation of contact details and oil.

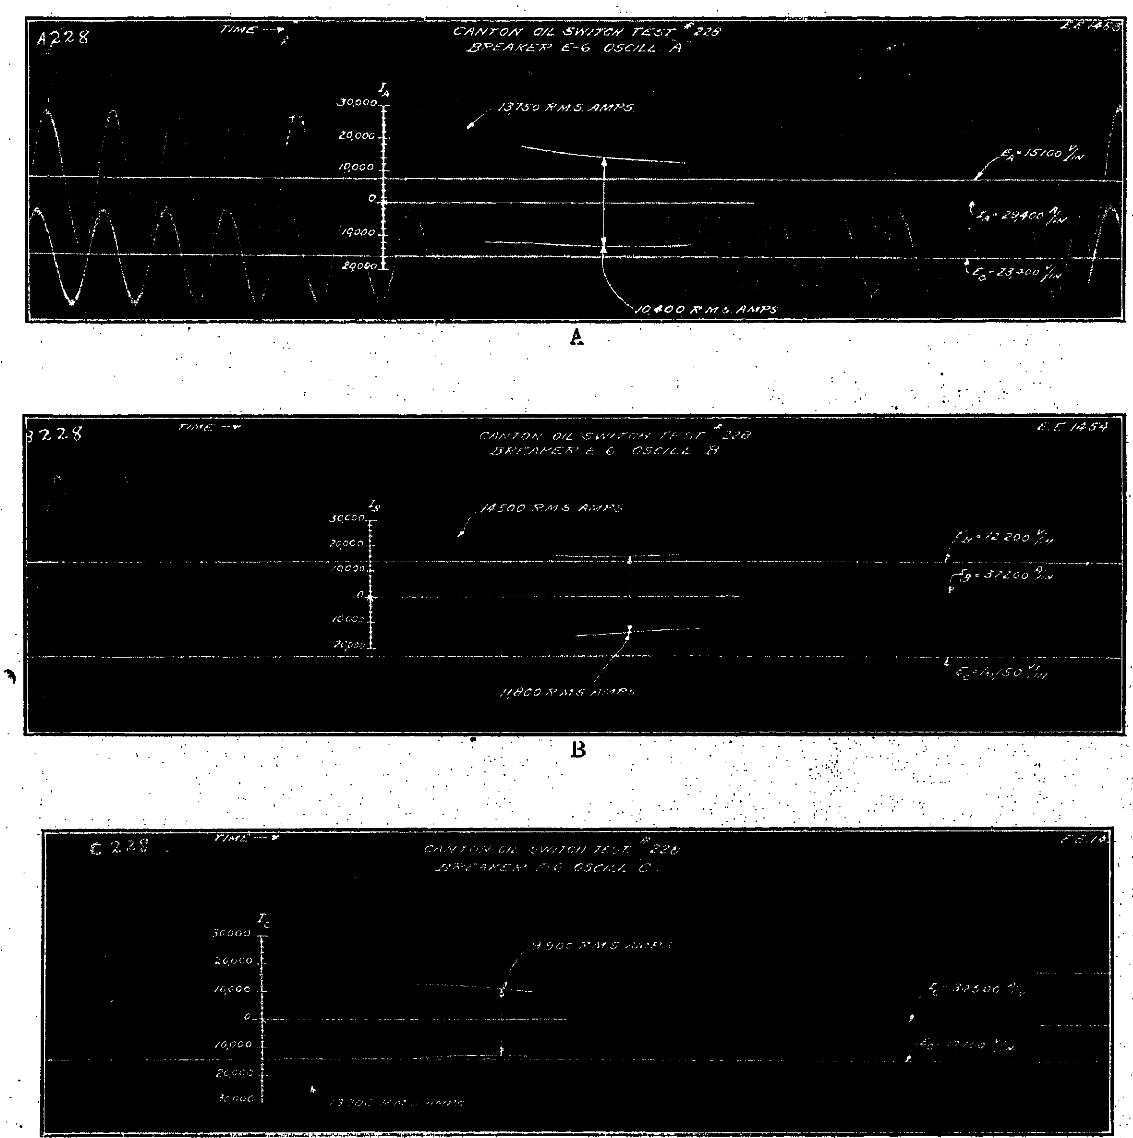


FIG. 14—OSCILLOGRAMS OF SHORT-CIRCUIT TEST
Westinghouse type E-6 (modified) oil breaker.

All the tests detailed above were made on 25-cycle circuits, and it seems probable that the rupturing capacity of a given breaker on 60 cycles is more than it would be on 25 cycles. The data show that on 25 cycles with heavy currents of the order of 15,000 to 20,000 amperes, the arc can be expected to go out in less than one cycle after the arcing tips part. On 60 cycles, the energy liberated in the tanks per half cycle is only two-fifths as much as on 25 cycles, and the opportunity for putting out the arc occurs more frequently on 60 cycles.

Circuit breakers can be made in which the oil content presents practically no fire hazard beyond that found in an oil-immersed transformer or feeder regulator.

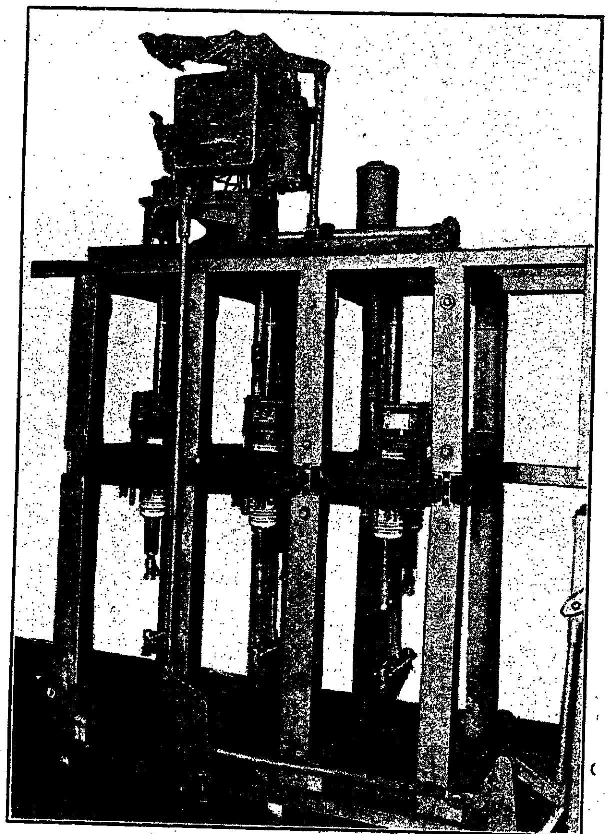

FIG. 13—MODIFIED TYPE *E*-6 BREAKER
Showing application of "oil separators."

It is well to call attention to the fact that sustained circuit voltage and high reestablished voltage are necessary to secure the maximum tests on a given breaker with a given service voltage. A truer criterion of the capacity of the breaker is the product of the current it opens and the voltage at the instant the contacts part. The severity of service also depends in many cases on the value of reestablished voltage. Very misleading results are likely to be obtained where these items are not taken into consideration.

In connection with the above test results it is desired to emphasize the effective and speedy arc rupture in all cases and the control of oil and gas throw by means of positive separating devices.

Discussion

DISCUSSION ON BALTIMORE OIL CIRCUIT BREAKER TESTS (LOUIS AND BANG), TESTS ON GENERAL ELECTRIC OIL CIRCUIT BREAKERS AT BALTIMORE (HILLIARD), TESTS ON WESTINGHOUSE OIL CIRCUIT BREAKERS AT BALTIMORE (MACNEILL),

Niagara Falls, Ontario, June 30, 1922

B. G. Jamieson: I would like to make an announcement which I was commissioned to make by the Subcommittee of the A. I. E. E. on oil circuit breakers. We have as a heritage a definition of duty cycle, which is fundamental in determining the rating of oil circuit breakers. That duty cycle, as defined by Hewlett, Burnham, Mahoney in a paper written about four years ago, represents the sumtotal of available literature on the subject. The adoption by the American Institute of Electrical Engineers of a standard definition is based on that paper.

Unless we know what the duty cycle is, we do not know much about what the breaker will do, because we cannot purchase and install breakers on an equitable basis.

One of the authors who presented a paper has emphasized the point that as the result of the Baltimore test it is a fair assumption that the closing of the breaker on the short circuit is something of rather slight importance. A representative of another company, equally interested, has stated that it is a matter of paramount importance. Whatever the facts may be, you will notice that in all circuit breaker tests conducted in this country, at least, the manufacturers have always been very careful to close in the "first" and use the second breaker.

I think we ought to know the facts on that point, and that brings me to a point I want to refer to specifically in connection with the announcement just made. The A. I. E. E. subcommittee on oil breakers has had a great deal of difficulty in defining specifically where the duty cycle should begin, and where it should end. It had some difficulty in putting into words in which there was no ambiguity, just what the condition of the breaker should be at the end of the test. That matter has been disposed of. It has also been agreed that the breaker duty cycle should terminate with the switch in open position.

About the beginning of the duty cycle the old ratings are said to have had for their intent the assumption that the duty cycle should begin with the breaker in the closed position, and that the standard rating of breakers is what is known popularly as two "shots." We are to understand that the breaker is supposed to be on the bus, and if opened once, it may be reclosed on the short, and open once more and then we are done, but we must know that the breaker is capable of being closed in on the short in the beginning. Some men have gone so far as to say that it does not occur, and others say it does not occur often.

There is another position which can be taken, namely, a breaker in a power station, 200,000 kilowatts, closed in on short circuits—and I can testify it does occur at times,—it seems almost preposterous to say that we should withdraw from the specification, that the breaker must be capable of being pulled on, on a short, and opening it, it must be assumed that the breaker was first on the bus.

Recently I sent out a questionnaire on this point and got some replies. Unfortunately, the opinions were about evenly balanced. The Committee instructed me to send out another questionnaire, with the purpose of getting an opinion from every operating man as to whether or not it would be better for the definition, at least the definition given in the American Institute rules, to specify or not specify the breaker as capable of being closed in, on the short. I will draw your attention to the specifications for the 3-shot and 4-shot breakers. In the case of the 3-shot breakers, at the 299th shot, the breaker must be closed in on the short, and the operator is supposed to close them on the first shot on the lower ranges.

We still have the option of operating breakers with the same degree of practical safety we have always had, it is simply putting the definition in the logical form, which will not require justification in the industry, either nationally or internationally.

I want to say that questionnaires will be framed by representatives of the A. I. E. E., the N. E. L. A. and the Power Club, so that there will be no doubt about the way in which this question is presented.

Referring now to these three papers, central station systems now require transmission system equipment of a few years ago for distribution, purposes. Immediate prospects of super-power systems behind this equipment and further electrification of industrial and railway systems beyond, focus our attention on those devices upon which the safety and thereby the practicability of this enormous energy combination depends. This makes particularly conspicuous the oil breaker, the most important of all protective devices.

The knowledge that these tests were being conducted during the past year or two and the realization of their importance has kept us in an anticipatory state of mind, and it is, indeed, gratifying to learn that in the opinion of those most concerned the result of these tests point to successful achievement in breaker design.

I would like to qualify that statement a little bit saying that whereas that may be a bare statement, but regarding the results of these tests, the question is still before us as to what shall we do with the vast number of breakers that we have on our systems, which are, at least, open to suspicion as to their interrupting ability. The various expedients that are being adopted, such as the installation of reactors and sectionalizing of systems are all practical enough, and very expensive, but it seems to me that what we are most interested in is not whether a breaker can be designed to interrupt a small amount of energy, but the question is—Can we afford to depend upon breakers for the isolation of defective portions of our system, or is the result going to be the development of a breaker we can afford to use? Perhaps that is not an Institute matter, but I feel it is at the bottom of a great deal of the trouble which we are now having.

When we reflect that inadequate breakers may transfer system trouble from a remote point into the generating station and possibly on the bus at that point, interrupting service, damaging property and endangering life, it is clear that everything should be done to establish fully the efficacy of oil breakers as a type, otherwise our protective engineering is but a grim travesty. At this point I would like to explain that the word "inadequate" does not mean defective; it means insufficient, which is often as chargeable to the operator as to the manufacturer, perhaps properly more often.

It is essential also to determine the functional capacity of oil breakers as energy interrupting devices in order that other elements of the system or new devices may be made available to compensate or substitute for the conventional types of breakers beyond their established limitations. By that I mean that when some little device which may now be in the minds of research men, makes its appearance and makes big circuit breakers look like a joke, the sooner we know about that the better.

Referring more specifically to the data as published in these papers, several important factors stand out. First, all short circuits were made beyond the closed test breakers. This method of test seems to some of us illogical, particularly so in consideration of the duty characteristics of reclosing breakers which are required to close in on a short as well as to interrupt the short circuit.

I am not advocating the repeated closing of heavy duty breakers. I agree with Mr. MacNeill that it is unimportant, relatively, to the operator, to know what a breaker will do five or ten times. It does not matter whether the breaker stands up or not, but such service as that in a commercial system is beyond the requirements. The effect on the system, drop in voltage, and loss of synchronism, produces a mechanical stress, and weak points which no one suspected, may be developed. I desire to repeat the statement, that is, what we should know is what a breaker will do once. I do not say that we should buy a breaker on that basis, but we should know if breakers, for which we pay thousands of dollars, will do the things they are designed to do in an emergency which occurs seldom.

There should be no uncertainty as to how a breaker in a switch center of a large system will perform if it be closed in on a short circuit; the fact that such an event seldom occurs, notwithstanding. The importance of the successful performance of the breaker under such conditions is of such an order that there should be no question about its functioning. On the other hand, all tests were made with dead metallic shorts. This is an extreme condition which is seldom met with except when the breaker is closed in on a short by reason of some wrong connections. It is difficult to conceive of a dead metallic short (other than grounding devices) simultaneously established on three phases in a modern power house. Cable dielectric faults perhaps come closest to such a condition, but the average cable fault is usually at some distance from the power house. At this point I would like to call the attention of operating men to the great hazard of grounding generating station buses, more particularly the practise of simultaneous three-phase grounding which underlies modern methods.

In the Louis and Bang paper the fact was brought out that 77 per cent of normal voltage was re-established immediately after the arc. That is interesting and together with the statement that the larger percentage of short circuits seemed to break at the zero point corresponding to the time at which the stored energy is a minimum, are very significant, and would undoubtedly be the subject of a very profitable discussion, particularly for those who have in mind future tests on the same general order. If it is a fact having general application that tests may be more properly conducted at a point remote from the generating center, then tests of this sort may be combined with tests on relays, reactors and other protective devices functioning with the breaker. Also, reference to the effect that single and two-phase shorts caused severe vibration of generators, and to the effect that in no case did the generators fall out of step, are in my opinion noteworthy facts having a fundamental bearing on the results recorded in this series of tests.

Please consider these two facts together with the previously stated fact, that the tests were made by means of dead metallic shorts on a system having a solidly grounded neutral.

Now what I desire to bring out is that while we have obtained performance data of great value, in connection with certain types of breakers functioning under effects of short circuits, systematically applied, and obeying very closely their natural decrement laws, with generators supplying the energy in rythmic harmony, and with voltage transients apparently suppressed, that unless more definiteness is given to the effects of short circuits originating as single-phase faults and undergoing cycles of reestablishment, of generators out of phase with one another, as a result of the short and with voltage transients present, we may have our oil breaker rating based on "average" arc amperes at normal voltage brought into question.

In the paper by Mr. Hilliard an italicized statement on the first page seems at first reading to rather tend towards a discounting of the value of these tests by its restricted wording. Most engineers will understand what was intended by this statement, but it will be unfortunate for the art if an interpretation to the effect that these tests were special gains currency, thereby minimizing their value for deductions of a general nature. It is noteworthy that the duty cycle on the breakers included five successive interruptions at two minute intervals instead of the conventional number of two.

Statements that oil deterioration is not the factor which will

determine the number of interruptions that can be made is comforting to know, if it is a fact that has general application. Combining this statement with the expressed assurances of the manufacturers that they are able to prevent the throwing of oil, and with the statements made elsewhere that tanks can be built so there is no danger of bursting, we find that the problem of successful breaker operation is reduced to the maintenance of arcing contacts, which the manufacturer unreservedly applies to oil circuit breakers of any type; this, then, becomes the crux of the whole matter, particularly where the duty cycle of the breaker requires repeated operation.

The paper by Mr. MacNeill imposes less restrictions than the paper by Mr. Hilliard insofar as the making of deductions from the results of these tests is concerned. The switches tested were of the general form of oil breaker built by the Westinghouse Company for many years, the improvement being largely in methods utilized to prevent throwing of oil and the relief of pressure caused by the arc gases. It is of interest to note that the author is able to point out definitely that throughout the test the arc was always ruptured at the zero point of the current wave. This assumption has been questioned at times in the past.

The suggestion of a differential rating for switches on 25 and 60-cycle service is another point which it seems to me to be worth considering in the determination of switch duties.

Attention of committee members is also directed to the statement of the author in the closing section of his paper regarding the effect of sustained voltage in imposing the maximum duty. As is stated, very misleading results are likely to be obtained in calculations of circuit breaker duty or performance where sustained or re-established voltage values are not given proper weight. This point appeals to me particularly in connection with private and committee work where failures of breakers have been reported. I think it is safe to say in general operating systems are woefully short of the proper registering devices to enable definite statements to be made regarding the successful or unsuccessful operation of breakers on system disturbances.

In closing, following a thought suggested by the specification appearing on the first page of this paper, which reads "all tank structures and mechanism parts are dead and can be solidly grounded," in consideration of recent experiences and previous convictions of the operating personnel of our own company and with due regard to the development of iron clad central station switch gear, I believe that the art of developing safe oil breakers on systems backed up by heavy power will be a problem of considerably less magnitude accordingly as we remove solid grounds from proximity to the arc rupturing elements of the present conventional type.

A. A. Meyer: Regarding the risks the central station companies should assume for conducting oil circuit breaker tests, I might call attention to the tests which were made by the Detroit Edison Company about five years ago. These were similar in many repsects to the Baltimore tests, and while they were not so numerous, they were of about the same magnitude.

One feature I think should be pointed out here, viz., that the large connected kv-a. capacity which was mentioned in connection with the Baltimore tests, was not all concentrated right at the point of the short circuit. In addition to the limited generator capacity at the short, there were several inter-connected feeders several miles in length and having an appreciable impedance.

Another item worthy of notice, is the fact that these tests were conducted usually on Sundays or nights, and during light load periods. You will appreciate that the magnetic energy being stored in a generating system during the light load periods, is of a small order and not so detrimental to the opening of the arc by a breaker, as that during the heavy load periods. This was demonstrated in some of the Detroit tests.

I might add that tests on the 24,000-volt circuit breakers, and of such magnitude as conducted at Canton, are being made occasionally in Detroit at the present time. I say occasionally, and also inadvertently, if you please. Our breakers in service have been recently subjected to duty of an order as high as 700,000 kv-a. and without any damage to the breaker.

I am pleased to note that the tests were conducted with the aid of so many measuring instruments. These are very essential in obtaining reliable data, which may be used for comparison with previous results, as well as with results to be obtained in the future.

It is unfortunate that some of the data obtained in these tests are being withheld from publication. Only such data have been published as concerns directly the latest type of breaker developed from these tests. There are considerable more data covering the older types, which have an important bearing on the circuit breakers which are so extensively installed in the various systems at the present time. Operating engineers are vitally concerned in the circuit breakers in service, and should have all information in order to take advantage of any improvements which might be applied to the present equipment. This is being denied and apparently for commercial reasons.

W. L. Wallau: A year ago in Cleveland we made a few tests in a minor way. We were not equipped with oscillographs, but we had certain conditions that we wanted to meet. We wanted to see if certain switches, which were inadequate on our 11,000-volt system, might possibly be used on our 4600-volt power distribution system.

With 125,000 kv-a. connected to the generating station bus, we made tests at a substation some four miles distant. This substation was supplied by seven No. 4/0 cables operating in parallel, and the 4600-volt system for test purposes was supplied by three 3000-kv-a. stepdown banks. The switches themselves were connected to the secondary side of these banks in parallel through about 90 feet of 0000 cable. The load on the station, was about one-third of the generator capacity. These tests were carried out successfully without any undue disturbances on the system. The only trouble that developed was a ground on one cable, which was a self-healing puncture.

What prompted us to make the test was that we had this same condition to meet inadvertently whenever a short circuit occurred on one of our 4600-volt power lines, close to the substation. Why should we not try to learn something from tests? We did learn that the particular switch that we wanted to use was inadequate even for a 4600-volt service. That was due to the larger current which it had to interrupt due to transformation ratio, as compared with the manufacturer's rating at that voltage.

The actual initial short-circuit current was of the order of about 15,000 amperes, and several types of switches were tested, and among them one switch with a very light mechanism which operated very speedily, and that switch stood up better than the others and we were able to repeat a short circuit on that particular switch with four banks of transformers, giving about 18,000 amperes initially.

I think, perhaps, all of us have been a little too conservative in offering our systems for experimental work, too much afraid of what was going to happen to the system. If we start to analyze our own conditions, we will see in our occasional short circuit that we have just as severe conditions as you would meet with on test. We may have a short circuit, which possibly results in a wrecked switch, but we do not wreck all the system, by any means, and do not anticipate we will wreck the system every time we have a short.

In this particular system, on the 11,000-volt bus, it is possible in almost any substation to get an energy supply on short circuit in the neighborhood of half a million kv-a., and as we operate our transmission cables to substations entirely in parallel, it puts a very heavy duty on any of the breakers, and the sub-

station breakers may open under reverse power to clear a fault in the cable fed by seven, eight, ten or even twelve lines.

I want to emphasize Mr. Meyer's point, the papers have not told us much about the troubles experienced. After all, the troubles are what we are interested in mostly, as much as the optimistic results which the manufacturers feel they can obtain later.

Another thing we are interested in knowing is what can we do with the breakers on our systems to modify them so that they can be used where we want them. In the past I have had occasion to report a large number of failures on the G. E. K-12 breaker, and I would like to say the failures reported were not in the nature of criticisms. We knew that the breakers were inadequate for the work they had to do, and we reported that to show how successful they had been in interrupting currents in excess of rating.

A. H. Sweetnam: It would seem to us that no operator could consider an oil circuit breaker, especially if it be on a one or limited shot basis, unless it be with the understanding that the duty cycle be "open, closed and open," as the breaker might at any time be required to close on a faulty line. One large operating company serving certain sparsely settled territory finds it necessary to operate, non-attended substations supplying from 1 to 2 distribution circuits. The transmission lines supplying such substations are fed from an attended substation bus and are equipped with automatic oil circuit breakers which will function in case of faults up to or beyond the non-attended substation. In such cases it is the practise after the automatic transmission line breaker has functioned to reclose it and if it again opens to reclose a second time, after which it is left open until the fault has been located. This plan makes possible the serving of business which otherwise could not be signed on account of high operating costs.

Many lines are radially operated, certain lines being normally in service and others held in reserve. We believe that many operating companies find it necessary to try a line by reclosing after the breaker has opened automatically and this appears to be a case parallel to that cited above; hence our conclusion that the duty cycle be defined as "open, closed, open," as any other definition would require the installation of a breaker designed for heavier duty and consequent greatly increased cost.

A. H. Hull: As you know the Queenston plant now being built will contain five 45,000-kv-a. units. When we started the short-circuit studies, we were contemplating an installation of nine such units. On that basis we estimated we would have on the 12,000-volt circuits, in the case of a fault, approximately 70,000 r. m. s. amperes and in the case of a fault on the high-voltage circuit, approximately 6700 r. m. s. amperes, at 110,000 volts.

I believe that the requirements for circuit breakers for that service are considerably in advance of installations that have been made in hydroelectric power plants. We bought two types of breakers for the 12,000-volt circuits, the Canadian Westinghouse Company's type C-4 and Canadian General Electric Company's type F. H. D. 21-Y.

While it is not anticipated that we will operate with nine units in parallel, there may be times in switching operations on the system when it may be necessary to operate eight or nine units in parallel for a short time. We have not had the opportunity of making short-circuit tests on the system, and we have been rather hesitant about accepting the ratings that have been put on the rupturing capacity of the breakers. We hope in the course of the operation of the plant to get experience with both types of low-tension breakers, that will give us, at least, comparative results, and results from which we can extend the station as now contemplated with considerably larger generating units.

One feature in connection with these breakers, which we considered very important, was strong tanks. Those on the 110,000-volt breakers that are installed are required to stand an internal hydrostatic pressure, with the bushings and cover in place of 250 lbs., per sq. in. The Westinghouse type C-4 breaker tanks are required to stand a pressure of 500 lbs. per sq. in. They have 36-in. diameter tanks. I would like to know from the tests reported from Baltimore, just what pressures were obtained in the tanks on these tests. We have a reference in the paper to the fact that pressure tests were made, and a statement that the pressure approximated one-third of the hydrostatic pressure, for which the structure was designed. That does not tell us very much.

Another feature on which I think we ought to get further information is how the breakers will take care of phase to neutral short circuits.

At Queenston, we are operating now with the generator neutrals solidly grounded. We have had no shorts there, but have had other cases where we had shorts to neutral, and also cases where we had metallic three-phase shorts on which the breaker has been closed. I think further information on the question of phase to neutral shorts is desirable.

A. F. Bang: In connection with the Baltimore oil switch, I would like to point out a few operating features which have a very distinct bearing on the performance of breakers. I refer particularly to the influence of the relay setting, the influence

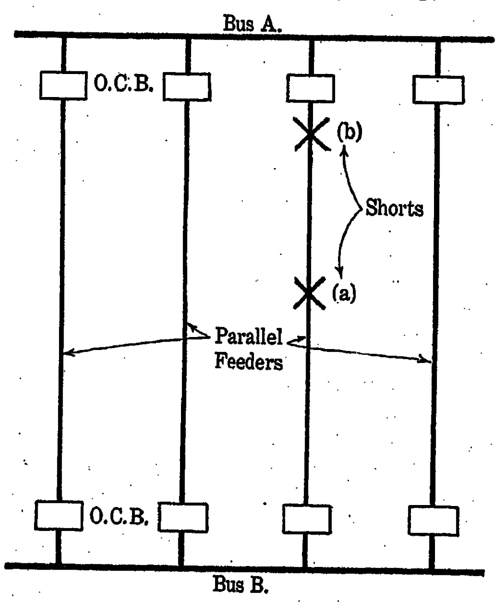

FIG. 1—SINGLE WIRE DIAGRAM OF PARALLEL FEEDERS

of having parallel feeders, and the influence of the arc in an arcing short. I think it is well to call attention to these operating conditions, so that we can realize that at least as far as opening a short circuit the Baltimore tests were actually extremely severe. I think too if we consider these facts, that to some extent they will explain why we actually have been able to get along fairly well for so many years with breakers which we knew were not quite up to the rupturing capacity of the system which we were dealing with.

I will dwell first on the influence of the time element. In most power systems the minimum time of relay operation is about one-quarter of a second, and in many cases that time element is increased the closer you get to the generating station. That, of course, means that where you get the highest current you have the longest time. That is not done intentionally for easing the task of the breaker, but simply in order to secure selective relay action. Incidentally, it means though an easier switching task for the breaker for several reasons. In the first place, a dead short circuit usually begins with a very heavy value and then gradually dies down, due to the demagnetizing of the generators. In some systems the current in one second may perhaps die down

to one-half value. And for the same reason—that is, the demagnetization of the generators—the voltage which will establish itself across the switch contacts, at the moment the arc is broken, will be proportionally reduced. That means only one-quarter of the rupturing task for the switch which you would have had if the breaker tested opened at the first instant.

There is a third item which comes in. If you delay the opening up of the breaker, it is possible that some of the synchronizing equipment may fall out of step. If that happens, that will draw some of the current away from the short, and will keep the voltage down, while the breaker is opening. That, too, means a reduced switch duty. In some cases it is quite possible that the synchronous equipment, which was out of step, may be pulled into step again *after* the breaker has opened up, and when you come to look at it, you cannot understand how a small breaker seemingly successfully broke an enormous amount of current. The fact is that it was favored extremely by circumstances.

Now as to the influence of parallel feeders: These tests in Baltimore were all made on a radial feeder. In many cases we do not have such a condition, but are dealing with a number of parallel feeders, each connected through to a station bus. If a short circuit takes place on one of these feeders it is clear that none of the breakers *A* or *B* (see Fig. 1) will be called upon to interrupt the full amount of the current, but it will be divided in some way between them. If the short is approximately midway between the two stations and the two breakers should happen to open at exactly the same time, evidently each breaker will have only ½ of the current to break. If on the other hand, the short is close to one end of a breaker it is true that the greater current will pass through this breaker and with relays of the time characteristics ordinarily used in such cases, this breaker will open first and break a very heavy current, but as the short still remains on the system, the voltage will still remain low, and not reestablish itself before the second breaker at the other end opens. In other words, the first breaker will rupture a very heavy current but low voltage, and the second breaker will break a higher voltage, but a current considerably reduced by the insertion of the length of the feeder. Under both assumptions we find thus a division and reduction of the switching task.

To my mind the Baltimore tests were also especially severe because they were dead metallic shorts, just as Mr. Jamieson pointed out. If you have an arcing short as you will get both on overhead lines and underground cables, the conditions must be less stable, because you have three arcs in series in that case, one at the short and two in the oil switch. Probably this feature is of more importance when you are dealing with lighter short circuits, where the arcs generally are less stable than when you are dealing with very heavy ones. In Baltimore we still expect to look further into that particular phase of the question, and also some of these questions regarding the influence of paralleling of lines and delayed time settings.

E. R. Stauffacher: These short-circuit tests are indeed interesting to us. We, in the West, are approaching the conditions of the central stations in the East in a number of territories. The main difference, however, is that our operating voltage is much higher.

You have been speaking of interrupting capacities of 500,000 kv-a. and 650,000 kv-a. From some of the results we have had in our stations and from the calculations we have made, the amount of current that certain switches on the system of the Southern California Edison company must interrupt is fully as great.

At our Newmark substation, located near Los Angeles, four 66-kv. double-circuit transmission lines feeding from four different points are brought to a common bus. It has been calculated that there are approximately 6000 amperes flowing at the time of a short circuit on this bus. A few cases have occurred where disastrous results have justified the calculation. It appears as if our 60-kv. network system must, some day, be changed to a 110-kv. system. At the present time both of our 150,000-volt transmission lines are being changed. We are raising the towers and adding insulators and shield rings so that we expect to be operating at 220-kv. by the latter part of this year.

Oil circuit breakers for voltages as high as 220 kv. are somewhat of an experiment. The manufacturers have been very kind in furnishing their best talent and in giving us the latest engineering information on this subject. We are waiting with interest the results of breaking a short circuit of approximately 2000 amperes at 220 kv. which will be the condition on our Big Creek transmission line, for if the switches do not handle the situation it will be quite a serious matter. This condition, that of the use of higher voltage circuit breakers, appears to be the greatest difference between our Pacific Coast and the eastern application of oil circuit breakers.

F. C. Hanker: In recent years, the importance of mechanical strength of structure has been fully recognized, the most important advance in that phase of design resulting from a similar series of tests made in New York and reported to the Institute. These tests differed from the present series in that they were for the purpose of establishing the mechanical sufficiency of the structure under the magnetic stresses resulting from heavy current conditions. The modifications made, following the New York series of tests, have been embodied in the later designs and it is of interest that the types used in the Baltimore series showed no distress from this point.

The oil circuit breaker tests at Baltimore have re-assured the operating companies as to possible hazard from making such tests and they realize that it is essentially a duplication of their operating condition. We trust that in the future other operators will take advantage of the results of these experiments. I was interested in reviewing the field tests that has been made in the past. Mr. Meyer referred to one on the Detroit Edison System in 1915. The test on the Niagara Falls System across the river probably represented the next highest capacity concentrated. This test was made in 1911 and was with from one-quarter and one-fifth of the capacity used at Baltimore. Previous to that, we had tests on machines of single units, isolated on separate bus sections of 11,000 and 12,000 and up to 30,000 kw. concentrated. Some of the tests made across the river on the hydroelectric plant had the cable system connected and in effect were similar to the Baltimore tests except in magnitude.

As Mr. Meyer pointed out, those at Detroit gave essentially the same concentration of power, the only difference being that they were not as extensive as the Baltimore tests. At Baltimore, they had on the order of 170,000 kw. connected. The short-circuit current was limited, as Mr. Louis indicates, by series impedance in order to give the desired values at the Canton substation.

Mr. Meyer mentioned the amount of magnetic energy in the machines. As a matter of fact, that has considerable bearing on the restoration of voltage, but the flux condition in the machine must be the same with the same induced voltage. This is clearly demonstrated in the values of reestablished voltage that were on the order of 80 to 90 per cent of the system voltage. The number of high power tests will probably be limited to a few large systems, and they will certainly be increasing when you consider the amount of interconnection.

Distinct developments have resulted from each series of tests that have been made in the past on systems of operating companies where conditions the same as those obtained under actual operation are found. In the present instance, the changes have been of a minor character, proving that the fundamental principles are correct. Fortunately, sufficient time was available to test the modified structures to definitely prove the correctness of the improvements.

It is difficult to obtain from papers that have been presented an adequate conception of the magnitude of the work that has been done and of its importance to the industry, especially when you consider that the fundamentals of the designs have been unchanged. It is particularly important that the adequacy of

the breaker structure has been confirmed. When you consider, the enormous energy that may be concentrated in an abnormal, the necessity for having a structure that has a large factor of safety in rupturing capacity and mechanical strength to meet the most severe conditions is fully recognized.

In recent years, there has not only been an increasing growth in the size of power stations but a marked increase in the total capacity of systems resulting from interconnections. The advantages from unified operation are so well established that there will be an increase in the total system capacities, making it essential to have adequate interrupting devices to insure continuity of service.

As a result of the uncertainty that has existed in the past, as to the adequacy of the very large circuit breaker structures on moderate voltage systems that are installed indoors, there has been a tendency to consider designs of structures to provide against the possibility of failures in the circuit breaker parts that might cause breakdowns on adjoining circuits. These studies have resulted in two notable examples using the so-called segregated phase layout. At present there are several stations under construction or being designed where careful study has been given to the advantages and disadvantages of the latter schemes. It would be very valuable for the Institute to have the benefit of the conclusions that have been arrived at by the various engineers.

The sufficiency of the breaker structure has been clearly demonstrated in the Baltimore tests and it will be of interest to determine whether operating engineers consider it necessary to resort to phase segregation in order to provide against a spreading of trouble to adjacent circuits by complete separation. The other parts to be considered are the bus structure, the disconnecting switches and the current transformers. A number of failures have resulted from faulty operation of the disconnecting switches and it is necessary that designs should embody features that will overcome such difficulties. In recent installations where switches are mechanically operated and interlocked with the breaker mechanism this should be sufficient precaution against such failure.

In the last few years there has been considerable criticism of the standard rating adopted for circuit breakers following the presentation of the problem in 1918 at the Mid Winter Convention. It is to be hoped that a full discussion is secured so that the requirements of operating companies can be crystallized and ratings be standardized for a minimum number of conditions. In past discussions, it has been difficult for the operators to agree on the ratings necessary to meet the varied conditions of operation for different classes of service. It is to be hoped that the discussions at the present sessions will clarify this situation.

H. H. Dewey: Tests of oil circuit breakers have been made from time to time that have been valuable in giving the manufacturers data on which to base their designs, but often these tests have been so limited as to the amount of energy in the short circuit or the completeness of the data recorded as to leave opportunities for differences of opinion on the interpretation of the results. The tests described lack none of these features and we may well feel that a most important step has been taken toward the ultimate solution of this most important phase in the development of our large power systems.

It seems like heroic methods to subject a power system of 150,000 kw. capacity to a succession of heavy short circuits, but the results of this investigation show that it can be done without serious risk to apparatus or service if done systematically and with due regard to the protection of the system from secondary failures. I have no doubt that other operating companies will be less hesitant in making similar tests in the future.

One of the most gratifying results of the tests, it seems to me, is the indication that the manufacturers have not been so far wrong in their ratings of switches of standard design. Practically all of the switches tested performed well and only slight modifications were necessary to show most satisfactory results.

The rapid growth in the generating capacity of our power systems has put the problem of the selection of oil circuit breakers squarely up to the electrical industry and the greatest difficulty has been encountered in keeping up with the growth of these systems. There are undoubtedly thousands of switches in service today that would fail if a dead short circuit should occur at their terminals. Operating companies are replacing these switches as rapidly as possible, but physical limitations and the expense involved render this necessarily a slow process. It is surprising that as few of these oil circuit breakers have blown up, with disastrous results, as have, but the answer is, doubtless, that the short circuits have not occurred. Some of the reasons why they have not occurred were brought out by Mr. Bang; such as, the fact that not all short circuits are of full theoretical value, the recovery voltage is not always complete, systems may normally be partly segregated, etc.

We are gradually growing to the point where greater and greater short circuits are being imposed on our systems and it is becoming increasingly important that study be given to the initial layout of the system connections, not only so arranging the circuits as to take full advantage of the neutral reactance of apparatus and connecting lines but by judicial use of reactors to keep the short-circuit values to the lowest practical value consistent with good operation.

The tests under discussion showed short-circuit values of the order of one-half million kv-a. There are several systems now operating that may be subjected to short circuits of this value or more and many being designed that will reach a million or a million and one-half kv-a. Oil circuit breakers designed to safely interrupt such values as these must necessarily be large and expensive and the economic problem is becoming a most important one.

The question was raised by Mr. Jamieson and Mr. Meyer, as to the best way of dealing with the problem of old circuit breakers that have been outgrown due to increase of system capacity. This question has been partially answered by both manufacturers by the evidence from the tests that they can materially increase the rupturing capacity of their switches by comparatively inexpensive changes. Where the increase in the required interrupting capacity is great, however, the problem is a very difficult one.

Mr. Jamieson called attention to the desirability of settling on a duty cycle to be used as a standard in selecting oil circuit breakers. The N. E. L. A. and other technical bodies have this matter under active consideration and the difficulties are gradually being clarified. It is hoped that an analysis of the Baltimore test results will throw some further light on the matter and an early settlement may be made.

I hope that as time goes on, we will see further tests similar to those made at Baltimore where elaborate preparations were made to obtain definite and accurate data. Such tests are of inestimable value and the very fact that some 200 short circuits were placed on the system without serious damage to apparatus or service, should lead to further tests of this kind.

M. J. Lowenberg: I have witnessed several cases where oil circuit breakers were closed on a three-phase dead short circuit, in one case at the bus two minutes apart on a system having at the time over 220,000 kw. in generators running and where the breakers functioned successfully without disturbing any synchronous apparatus or service.

Some one asked what we are to do with our old breakers. I think that what we should do is to maintain and inspect them especially after a very heavy duty. It does not cost much to produce very good results in this way. The Interborough Rapid Transit Company have some old type *H* breakers on a system of anywhere from 250,000 to 300,000-kw. generator capacity on the busses with a like amount of synchronous converters, where they have had very heavy short circuits that were cleared in

every case with no serious trouble to the breakers or equipment. This performance is due not only to the character of the breakers but also to the rigid inspection and maintenance of the breakers.

I would like also to call the attention of the manufacturer to breakers (on systems of less than 6600 volts) which should have a better balance than they now have between heating capacity and rupturing capacity. Take for example a breaker operating at 2300 volts. You will find the breaker is limited by heating capacity and not by rupturing capacity.

L. B. Chubbuck: Referring to the oil separator described by Mr. MacNeill it may be of interest to state that separators of this type are furnished with the tank type 12,000-volt breakers at Queenston. One separator 8-inch diameter by 13 inches high is used per pole, the exhaust from the separator to be connected to station vent pipes, to prevent accumulation of gas in the circuit breaker rooms. It is our experience that without such separators, low-tension breakers under severe service, are liable to blow gaskets or throw excessive oil with ordinary vents. Tank structures can be furnished of sufficient strength to meet the arc gas pressures corresponding to the breaker rating. High-speed operation, properly designed and submerged contacts, strong, non-fragile bushings and arc-proof insulating tank linings, are also important factors. The Queenston tank structures are designed for an ultimate strength of 1000 lb. per sq. in. internal pressure and the condenser bushings to meet a cantilever test of 5000 lb. applied at either end of bushing.

We have had a number of instances in Canada of breakers failing, not due to pressure from arc gases, but from gas explosion above the oil. Such failure is not possible with the larger, later designed low-tension breakers, owing to the tank structure strength required to meet their rupturing capacity. However in the case of high-tension breakers we find possible gas explosions the chief hazard to the strength of the breaker, and for this reason furnished the Queenston high-tension breaker tanks of an ultimate strength equivalent to 500 lb. per sq. in. internal pressure.

O. H. Eschholz: Breaker distress has been shown in these tests to be primarily a function of arc energy and the character of arc gas control. While the rupture duty, I wish to call your attention to, of direct-current circuits is dependent upon the formation of an unstable arc, the interruption of the alternating-current circuit requires the prevention of arc reestablishment after zero current has been reached. The former necessitates a continuous increase in arc resistance, the latter an exceedingly rapid change from a medium of low to one of high dielectric strength.

An inspection of the current waves in the various oscillograms secured reveals the important fact that the arc current changes but little during the rupture period. To minimize arc energy and hence breaker distress it is therefore necessary to maintain a low-voltage arc and to decrease arc duration. Various expedients may be adopted, either in the construction of arcing contacts or in the control of pressure variations of the arc enclosing medium, to assure a low arc voltage during current flow. Obviously, a decrease in energy development decreases gas evolution and hence simplifies the problem of preventing arc reignition. It may be of interest in this connection to note that with some of the constructions adopted it was possible to consistently restrict arc duration to one-half cycle when rupturing currents of the order of 20,000 amperes. While of no practical need at the present time, it is interesting to know that by properly choosing the instant of arcing contact separation, the arc durations when interrupting large currents, could be reduced to one-quarter cycle. In such cases it was difficult for observers to distinguish between the character of breaker disturbance when opening on a heavy short or on a dead line.

It is well known that the formation of an arc in a liquid requires first the disintegration of such liquid into its elemental gases. During the subsequent period of arc maintenance, the developed energy must be absorbed by the surrounding medium—a part of this energy causing the continued cracking or disintegration of the oil. During the period of gas development the breaker is subjected to transient hydrostatic pressure waves, dependent upon rate of gas generation and escapes, as well as to somewhat more sustained pressure resulting from gas accumulation and possible ignition in the air space. By reducing the rate of arc energy development, the hydrostatic pressure was decreased and by selectively venting the air space gases in advance of the arc gases, the sustained and ignition pressures were practically eliminated. In the conventional type of dead tank breaker, it is possible to utilize the movement of oil head above the arc gases as a piston to eject the cushioning air space gases. By directing these gases into a suitable separating chamber, it is possible to relieve the breaker rapidly of gas accumulation while preventing an escape of oil and simultaneously permitting cooling of the arc gases below the ignition temperature.

The development of information on other, though less important characteristics may be mentioned such as the effect of catalysts on lowering the ignition temperature of arc gases, variation of arc duration with oil viscosity and the volume of gas generated per kw.-sec. of arc energy for different oils. Such information in conjunction with a better conception of the mechanism of arc rupture not only has contributed to the successful conclusion of these high-current tests but offers a basis for the scientific development of circuit breaker structures of all ratings.

J. D. Hilliard: Mr. B. G. Jamieson in his discussion of the oil circuit breaker papers brings out the importance of the duty cycle in the rating of oil circuit breakers and also the importance of the method of making the tests to determine such rating. Neither of these points has heretofore been discussed to the extent that their importance merits. As a general proposition, all tests of oil circuit breakers should be made under as nearly as possible the identical conditions the breakers are to be subjected to in service. If the breaker is to close under a condition of existing short circuit, then by all means it should be tested under that condition. If the breaker is to be installed where it will have to close and open a short circuit close to the bus bars (zero power factor) then it should be tested under that condition.

If the breaker is to be installed on a system with the neutral either grounded solidly, grounded through a resistance, or ungrounded, then it should be tested under such conditions and in addition *with* and *without* a ground at the point of breakdown. It should be tested with the same operating mechanism which is to operate it in service. If the breaker tested under a particular set of conditions is found to have a certain interrupting capacity, do not assume that under all other conditions it will have the same interrupting capacity because you will be deceiving yourself. If you have made a few shots under a certain set of conditions, you cannot assume that the tests, if continued, will uniformly give the same results. The plot of a set of observations made upon the ordinary oil circuit breaker from low currents up to its maximum rating but under otherwise identical conditions looks like the shot gun pattern of a cylinder bore gun or blunderbus. Certifying to bull's-eyes from such a target is a difficult proposition and besides it is not the bull's-eyes you are after, but the scattered shots on the fringe of the pattern because they represent the spots of maximum gas formation in the breaker and therefore the maximum stresses on the breaker structure.

The foregoing indicates the difficulty of giving an interrupting capacity rating to the ordinary oil circuit breaker. The only absolutely safe thing to do is to specify the rating under the worst possible condition which may exist. It must be expected, however, when such ratings are demanded that the costs will correspond, because the costs of the breaker under the different standards of rating do not change.

Mr. Jamieson draws attention to my italicized statement in the paper. That italicized statement is of considerable import-

ance and was made with a fairly good idea of what the results would have been if conditions had been different; conditions which might easily exist in actual operation of the system, and which might give results much more severe than those observed.

The differential rating of oil circuit breakers operating at 25 and 60 cycles is a debatable question at least to the extent of the ratio of the two frequencies. The time-ampere curve at any frequency is at first ascending, reaches a maximum and then descends with the continual increase of current. The effect noted is due to the inherent blowout effect of the breaker as ordinarily constructed and the fact that several half cycles are required before interruption, the number gradually decreasing with the increase of current is a definite proof that *time*, not half cycles, is the limitation and that the *time* at 60 cycles would be substantially the same as at 25. With the increase of current to a value where one full half cycle is the limit at 25 cycles, then a further increase of current should correspondingly decrease the actual time duration of arc at 60 cycles to less than at 25 cycles, but the magnitude of current required would be such as could be obtained from few generating systems and with an increase of the voltage of the system one would expect the current necessary to interrupt in one-half period to correspondingly increase and it might well be that the actual time limitation would be the break distance between moving and stationary contacts instead of the electro-magnetic blowout effect of the current to be interrupted because the ultimate interruption depends upon the dielectric strength of the medium between the separated electrodes.

The recovery voltage at interruption, together with the phase relation between current and voltage, undoubtedly largely determine the interrupting capacity of the breaker and a study of these recovery voltages under different conditions of operation supply an explanation of many hitherto puzzling phenomena in connection with oil circuit breaker operation. Mr. Meyer notes that most all tests are made either on Sundays or nights after the peak load is over and suspects that the results of tests under these conditions might be different than if they were made under more normal operation conditions. I agree with Mr. Meyer in this belief and think that more tests should be made under normal conditions.

Mr. Wallau's testing experience at Cleveland is not unusual. Certain well recognized factors contributed to the results obtained, and with these factors reversed, the results would have been reversed. It is one more case showing the necessity of making the test conditions the same as the operating conditions.

The General Electric Company did not test any breakers at Baltimore, other than the H-3 and H-6 breakers and the improvements thereon, principally the improvements, because the end sought was to obtain a breaker which would stand repeated short circuits, and this boiled down to obtaining ones which would not throw oil because the inherent interrupting capacity of the old breakers was found to be ample, but the oil throwing property was well known and acknowledged by all. The development was successful and the remodeled breakers are installed in the same cells as the older oil throwing type.

J. B. MacNeill: I wish to state the position of the manufacturers in publishing data on these tests. There had been a feeling that these tests were of a more or less confidential nature, the same as factory tests would be on other lines of apparatus except that when powers such as here used, are employed, factory tests cannot be considered. The feeling was expressed by several operating companies that a large number of new stations were to be built in the near future and that data should be published which would allow the operators to select adequate circuit breakers for such new developments. It is not proper to judge obsolete circuit breakers in many cases by results obtained in Baltimore as these tests were made under the hardest possible conditions obtainable so far as circuit breaker performance is concerned.

Mr. Bang gave in his discussion some of these conditions and he speaks from a full knowledge of this subject as he has done experimental work along these lines.

Mr. Jamieson calls attention to the difference of opinion regarding the duty caused by closing the breaker on the short circuit. The writer did not intend to convey the idea that closing on the short circuit was a negligible matter, but with the type of breaker he was discussing, it seems that the duty of closing on short circuit is relatively light to the duty of opening on short circuit. It is appreciated that the duty of closing of short circuit may differ widely with different breaker constructions.

In connection with Mr. Jamieson's remarks on the duty cycle it should be pointed out that the manufacturers are willing to rate their apparatus on any duty cycle to which the operators as a whole will agree.

Undoubtedly the ratings on duty cycles which involve closing against heavy short circuits will be lower than if the duty involved merely opening the short circuit.

The Electric Power Club has indicated that the ratings of breakers to close against and open short circuits with the more stringent specifications regarding the condition of breaker after test referred to by Mr. Jamieson, will be approximately the same as the ratings which have been given in the past on the so called "two-shot" duty cycle in which the breaker opened the first short circuit and was closed against and opened the second short circuit. This means approximately a de-rating of 20 per cent from present values.

Regarding Mr. Jamieson's comments on repeated closing of heavy short circuits we agree that it is undesirable from an operating point of view to subject systems to repeated shocks. The "five-shot" specifications insisted on by Baltimore Companies was made in view of their experience that imperfections of construction can be disclosed by such a test and that the removal of these imperfections results in superior breakers for any duty cycle; thus, a breaker which will open 20,000 amperes satisfactory 5 times or as was the case in one of the breaker tests, 12 times, undoubtedly has a large factor of safety over 20,000 amperes for less severe duty cycles.

Mr. Meyer refers to tests made by his company on the same general form of breaker covered by the writer in his paper. These tests were of power magnitude comparable with the Baltimore tests and differed principally in that they were not the repeated openings of the short circuits without inspection of the contacts or oil.

The Detroit tests remain to the present time the most important tests that have been made on 24,000-volt circuits.

Mr. A. F. Bang's discussion should be of great interest to operating men, especially as Mr. Bang discusses the possibility of retaining in service by proper system connections, breakers which otherwise would not be serviceable.

The discussion of Mr. O. H. Eshholz is important as he deals with some of the theoretical factors regarding important improvements in construction which were first made possible and later proved out by the Baltimore tests. These tests have allowed us for the first time to study in detail at high powers the exact action of the circuit breakers on short circuit with the aid of complete facilities for analysis. The two operating companies participating in this test, the Pennsylvania Water and Power Company and Consolidated Gas, Electric Light and Power Company of Baltimore have been very patient in allowing the revision of circuit breaker constructions during the course of the tests, and subsequent proving out of alterations. By this method, important results have been secured and it is possible to speak with authority of many features of breaker construction that otherwise would still be in a speculative stage.

Designers of circuit breakers therefore now have a solid foundation of fundamentals to work on so that better distribution of material in designing is possible and increasing rupturing capacity can be had from a given amount of material.

Transmission Line Relay Protection--II

Review of the Subject.—*This paper is divided into three parts, the first part consisting of a list of relay nomenclature according to function and application, the second part being a general discussion on relay protection with special reference to an investigation of the Protective Devices Committee to obtain information on transmission line protective scheme and the third part, an illustrated description of the results of the investigation.*

The thoroughly proved methods have been given scant consideration but the operating results of new schemes have been treated in brief detail with a statement of the condition which led to the adoption of the various schemes. Many of these schemes require the use of special apparatus which is not obtainable in the open market, though in most cases it was possible to use standard apparatus. It is quite probable that some of these special schemes will be adopted by the leading manufacturers with more or less modification.

In the majority of the cases cited, the actual operating results showing the number of correct and incorrect relay operations have been given and it is probable that this is the first time that such a disclosure has been so generously and frankly made.

Standard names for relays as to function and application as well as qualifying terms which always have the same meaning are very desirable. The number of types of relays now in common use are so great that considerable confusion has resulted from a previous lack of uniformity of identifying designations. This confusion will be eliminated if the manufacturers and users of relays employ the terms given in the paper, which have been approved by the Standards Committee of the Institute.

The first paper of a series contemplated by the Protective Devices Committee was presented three years ago. This is the second paper. Both of these deal with transmission line relay protection, and the Committee now plans to broaden its work to include also relays for protection of apparatus with the expectation of presenting additional data before the Institute as the art progresses.

The entire basis of the present paper is the experience of operating companies as reported by their engineers. The general theory of relays has been almost completely disregarded.

The use of combination over-current and directional schemes has become common due to the very satisfactory results that have been obtained with these relays.

Differential current schemes for parallel lines are increasing in popularity on account of their freedom from a-c. potential connections. Their use is limited, however; the differential power method using directional relays is suitable in those cases where the simpler current balance is not. The tendency appears to be in favor of balancing parallel feeders wherever possible to secure freedom from faulty operation on through faults together with quick action in case of trouble on one of the group. A number of different schemes, based generally on the same principle, is described in considerable detail.

The split conductor protection, though apparently successful, does not seem to be extending greatly beyond the early installations in this country, principally on account of the high cost of the cable.

Pilot wire protection, while abandoned by some operators, is being tried out in newer forms by others with some apparent likelihood of future extension.

The use of ground relays has been considerably extended particularly on systems having neutrals grounded through a comparatively high resistance. The application of these ground relays with regard to current and time settings is based on the same principles that apply for the relays connected in the phase. Both over-current and directional relays have been used with apparently successful results. By energizing only in case of accidental ground these relays may be set for much lower current values than the phase relays and in some cases at lower time values. The ground relays may be connected to sheath transformers or in the residual circuit of three current transformers of the usual type. Several applications of ground relays with pilot wire connections have been reported.

A very sensitive potential ground relay scheme for the protection of comparatively isolated circuits has been operating with good results for a number of years.

In one case, in order to avoid the necessity of installing grounding transformers, provision has been made to ground a second phase of the bus when it is shown by potential ground relays that an accidental ground has occurred on one phase. In this way a phase short circuit is produced permitting the faulty section to be isolated by standard over-current and directional relays.

An application of the combination of under-voltage and over-current relays is described. It takes into consideration the feature that the potential would be reduced proportionately as the faults is approached which adds a further degree of selectivity to the ordinary current method.

Accurate calculation of short circuit currents has proved highly desirable and considerable data concerning mathematical and mechanical methods of making these calculations are described.

General principles of relay application and practise concerning relay settings are discussed. Some notes are included relative to foreign practise and some of the outstanding features of installations in use in other countries have been described.

IN the paper on Transmission Line Relay Protection which was presented before the Institute in June 1919 there was included a proposed Relay Nomenclature. This with slight modifications was adopted by the Standards Committee on May 19, 1921. The approved nomenclature is as follows:

Classification According to Functions

Where relays operate in response to changes in more than one condition, all functions should be mentioned.

ELECTRIC PROTECTIVE RELAY. An electric protective relay is an intermediate device, equipped with contacts to open or close an auxiliary circuit, by means of which one circuit is indirectly controlled by a change in conditions in the same or other circuits.

DIRECTIONAL RELAY. A directional relay is one which functions in conformance with direction of power, or voltage, or current, or phase rotation, etc.

POWER-DIRECTIONAL RELAY. A power-directional relay is one which functions in conformance with direction of power.

Note: This includes both uni-directional relays with single-throw contacts and duo-directional relays with double-throw contacts. The reason this name is preferred to "reverse power" is that the device is frequently used to

Presented at the Annual Convention of the A. I. E. E., Niagara Falls, Ontario, June 26-30, 1922.

function under normal direction of power. Furthermore, in some cases the normal condition of the system may permit power to flow in either direction. Relays for use in either alternating- or direct-current circuits are to be classed as power-directional relays.

POLARITY-DIRECTIONAL RELAY. A polarity-directional relay is one which functions by reason of a change in the direction of polarity.

PHASE-ROTATION RELAY. A phase-rotation relay is one which functions by reason of a change in direction of phase rotation.

CURRENT RELAY. A current relay is one which functions at a predetermined value of the current. These may be either over-current relays or under-current relays.

VOLTAGE RELAY. A voltage relay is one which functions at a predetermined value of the voltage. These may be either over-voltage relays or under-voltage relays.

POWER RELAY. A power relay is one which functions at a predetermined value of watts. These may be either over-power relays or under-power relays.

FREQUENCY RELAY. A frequency relay is one which functions at a predetermined value of frequency. These may be either over-frequency relays or under-frequency relays.

TEMPERATURE RELAY. A temperature relay is one which functions at a predetermined temperature in the apparatus protected.

OPEN-PHASE RELAY. An open-phase relay is one which functions by reason of the opening of one phase of a polyphase circuit.

DIFFERENTIAL RELAY. A differential relay is one which functions by reason of the difference between two quantities such as current, or voltage, etc.

Note: This term includes relays heretofore known as "ratio balance relays," "biased," and "percentage differential relays."

CLASSIFICATION ACCORDING TO APPLICATION

LOCKING RELAY. A locking relay is one which renders some other relay or other device inoperative under predetermined values of current, or voltage, etc.

TRIP-FREE RELAY. A trip-free relay is one which prevents holding in an electrically operated device such as a circuit-breaker while an abnormal condition exists on the circuit.

AUXILIARY RELAY. An auxiliary relay is one which assists another relay in the performance of its function and which operates in response to the opening or closing of its operating circuit.

SIGNAL RELAY. A signal relay is an auxiliary relay which operates an audible or visible signal.

GENERAL QUALIFYING TERMS

INVERSE TIME. Inverse time is a qualifying term applied to any relay indicating that there is purposely introduced a delayed action, which delay decreases as the operating force increases.

DEFINITE TIME. Definite time is a qualifying term applied to any relay indicating that there is purposely introduced a delayed action, which delay remains substantially constant regardless of the magnitude of the operating force. (For forces slightly above the minimum operating value the delay may be inverse.)

INSTANTANEOUS. Instantaneous is a qualifying term applied to any relay indicating that no delayed action is purposely introduced.

NOTCHING. Notching is a qualifying term applied to any relay indicating that a number of separate impulses are required to complete operation.

In addition to the standardized nomenclature, used throughout this paper, it was found desirable to adopt uniform terms for use in describing devices and characteristics of devices and systems which have heretofore been known by more than one name.

In order that there may be no misunderstanding as to use of these terms the following definitions are given:

DIFFERENTIAL RELAY. Explanatory note. In a differential relay the resultant force operating the relay, may be obtained by mechanical, magnetic or electrical means. Thus a relay is described as a mechnical differential relay, a magnetic differential relay or an electrical differential relay.

PERCENTAGE DIFFERENTIAL. Percentage differential is a term descriptive of the operating characteristics of one class of differential relay and indicates that the relay requires an increasing difference to cause operation, which difference will approach a definite percentage of either or both of the opposing quantities.

PICK-UP VALUE. The pick-up value, expressed in current, voltage, etc., is the minimum value at which the relay will complete its function.

DROP-OUT VALUE. The drop-out value, expressed in current, voltage, etc. is the maximum value at which the relay starts to rest.

BALANCED AND RESIDUAL CURRENTS. The currents in the several wires of a circuit are divided for convenience into two classes of components, "balanced" and "residual."

The "balanced currents" are those wholly confined to the wires of the circuit. Hence, their algebraic sum is zero at every instant.

The remaining components of the currents in the several wires which exist under conditions other than perfect balance, are termed "residual." The sum of the residual components is the "residual current" of the circuit. It is equivalent to a single-phase current in a circuit having the wires in multiple as one side, and the ground as the other.

Mathematically expressed, the residual current is the vector sum of the currents in the several wires, while the balance currents are those components whose vector sum is zero.

INTRODUCTION

As the quality of the service rendered by central stations becomes better the standard of service demanded by the public becomes higher. The only way of meeting this demand is by constantly improving protective devices and their application so that a fault in the system will be confined to the smallest possible area with the least possible disturbance to the healthy sections of the system.

It was in the hope of seeing such results realized that the Protective Devices Committee, several years ago, began a systematic study of the problem of protection. As a result, a Paper on Transmission Line Relay Protection was presented to the Institute in June 1919, being the first of a proposed series, covering the investigations of the Committee. In this first paper were incorporated a recommendation on standard relay nomenclature, a statement of the methods followed in approved relay practise and descriptions of such schemes as were considered as standard at that time because of successful operation.

No attempt was made to describe the many special schemes then on trial but early in 1920 a request was sent out to a number of operating companies, asking for information on transmission line relay schemes, which were being, or had been, tried out and proved

successful or abandoned as worthless. This particular method was adopted as the most efficient means of adding to the data on hand as presented in the previous paper, and of getting an accurate idea of the latest developments as well as an idea of the general tendency in the art of relay protection.

The Relay Subcommittee of the Protective Devices Committee, has as its function the keeping of an authentic record of the development and operation of various protective relay schemes. It is hoped that by presenting before the Institute, from time to time, such important data as may be gathered, duplication of effort among engineers may be avoided and the standardization of protective relays and schemes, fostered. Most of the central station companies, to whom the request for information was sent, manifested an interest and a desire for cooperation by replying promptly. Replies from others came in more slowly and it is only within the last few months that all the replies were received. On account of this the information given in some of the earlier replies was more or less out of date by the time the last ones came in. Therefore, when the work of compiling the data and coordinating it into the form of a paper was begun, the Committee where necessary asked for additional data on such schemes as it was thought desirable to include in the paper. Request was also made for data on any schemes planned or installed subsequent to the original inquiry. It is, therefore, believed that data contained in this paper are complete up to within a few months of the present date. There are probably some schemes with which the committee was not acquainted and it is possible that some companies may have operating data, besides those given, on schemes which are described.

In the previous paper an attempt was made to emphasize the desirability of setting relays for short-circuit current values, rather than on the basis of load current as was once common practise. Since that time important developments in methods of determining short-circuit current values have been made and it was thought fitting to give, in this paper, a description of the various methods used. Both the mechanical and mathematical methods are discussed with the advantages and limitations of each, and consideration is given to the factors which must be taken into account in making the determination.

Following this it also seemed advisable to add some observations on the best practise in making relay current and time settings as well as on the factors to be considered in making such settings. A few notes are also made regarding foreign practise with comparisons to American practise, where possible.

The recommendation on relay nomenclature made by the Protective Devices Committee in 1919, has been approved, with slight modifications by the Standards Committee and is now finding its way into general use. Having taken this step in the direction of standardization there now appears to be a need for some form of standard symbols for representing various types of protective relays in schematic, single-line and detail diagrams. In going over the diagrams submitted to the Committee, such a great diversity of symbols was found that it was sometimes difficult to understand the schemes and to determine their relation to other schemes. It is believed that a convenient standard symbol can be devised to represent each type of relay, thus eliminating a great deal of confusion and making all diagrams easily readable. It is the intention of the Committee to devote some time to this problem in the near future.

In addition to the difficulty experienced on account of the many symbols used, there was also some trouble in classifying various schemes because of great variety of names used in describing them. In order that such confusion may be avoided in presenting these schemes the Committee has divided them into five main classifications as follows:

1. Schemes using over-current and directional relays in combination.
2. Differential current schemes
3. Differential power schemes
4. Ground relay schemes
5. Schemes using over-current and under-voltage relays in combination.

All the schemes submitted may be placed in one or the other of these classifications. The subdivisions, however, were found to be more difficult and while the Committee has grouped the schemes in what seems to be the most logical manner, it is not intended that the designations used shall be taken as recommendations. It is believed, however, that the standardization of terms used in describing schemes would be very advantageous and it is hoped to make this the subject of a future study by the Committee.

The investigations by the Committee, as covered in both the previous and present papers have been confined altogether to transmission line relay protection. Some study has been made, from time to time, on apparatus protection but this was usually the result of an inquiry on some specific problem and the information was given out in the form of a letter.

It is intended, therefore, next to undertake to collect and coordinate data on the protection of apparatus and on special relay devices and schemes such as are used in remote-controlled and automatic stations. Such data will be presented to the Institute in the form of papers.

In replying to the request for information practically every central station company gave a description of all relay schemes which it has used, both standardized and otherwise. Some schemes which were considered as tried and proved by some companies were described as trial installations by others. It will, therefore, be found that some of the schemes described in this paper as being on trial, may be considered standard

by some engineers. It was thought best, however, to include all schemes reported as being on trial and at least one is described which was discussed in the previous paper.

In comparing these last replies to those received several years ago there was found to be a noticeable increase in the use of the schemes described in the previous paper. It was also apparent that a greater number of companies were using the approved methods of setting and testing relays. Almost every company reported that good results were being obtained with such schemes and not a few reported that older schemes and types of relays which were not giving good results were being replaced by more recent schemes using modern types of relays.

That there is considerable activity in the experimental field is shown by the number of new schemes now on trial. With the increasing size and complexity of the modern power system and with the varied conditions of operation introduced by interconnection and concentration of tremendous amounts of energy in small areas, new problems are constantly arising and new schemes must be devised to take care of the requirements. It is quite noticeable that, where possible, tried and proved schemes are being used but when these fail new ones are devised and tried out. Such schemes usually require a period of a year or more to determine whether they are effective and in the three years since the previous paper a considerable number of schemes have been brought out to take care of conditions not so pertinent at that time. The number of schemes and the record of their operation have been sufficient to determine in a general way the tendency in principle and design of protective relay schemes. As can be seen from the descriptions given later, the trend in development is toward the selection of defective lines by the use of differential schemes operating on the fault or trouble current rather than by relying altogether on the use of progressive time settings and current settings made on the basis of the line current. This is the natural result of the increase in the size of systems as to capacity, area covered, and number of stations operated in parallel. Beyond a certain point progressive time settings necessitate maximum time intervals which are so high as to become impractical, especially where sensitive synchronous apparatus is involved. The need for schemes which do not require progressive time settings and which will disconnect the faulty section with the least possible delay, has thus become imperative. Therefore, the greatest development seems to be in the use of the differential current and differential power principles in which the defective line is disconnected instantaneously and in which the equipment on one section is not affected by trouble in another section. The success with which such schemes are being used gives proof of the soundness of the principle and holds promise of even better results in the future.

Considerable attention has been given to the problem of disconnecting grounded feeders. This problem has become especially important because of the more general practise of grounding of systems, particularly where a comparatively high ground resistance is used, resulting in ground currents which may be less than full load value. This has made it necessary to devise schemes which will disconnect the grounded line before the trouble develops into a phase-to-phase short circuit. Especially is this necessary on overhead lines in order to prevent the trouble from spreading to adjacent circuits.

Another problem, which has resulted in the development of a very effective scheme, is that of detecting and disconnecting a grounded feeder on systems having an ungrounded neutral. In a great many instances it is found impractical to ground a delta system and this development offers a comparatively simple and inexpensive solution to the problem of grounds which might later develop into cross short circuits ordinarily resulting in serious interruptions.

Some schemes which are reported as trial installations are only modifications of schemes which were described as standard in the previous paper and in most cases these modifications were made to take care of some special condition. In describing the schemes an attempt has been made in each case to give the reason or special condition which prompted its development and application, the principle of operation, a description of the apparatus used, a summary of its operating results and its advantages and disadvantages.

The request for information was sent to about sixty operating companies in all parts of this country and Canada and in response thirty-five more or less complete replies were received. Of these reporting companies, thirteen have systems supplying city loads exclusively and twenty-two have either long distance transmission systems or have an extensive high-voltage network. This paper is the result of a careful analysis of the data submitted in the replies and schemes described are representative of the best American practise.

Description of Relay Schemes for the Protection of Transmission Lines

I. Over-current and Directional Schemes. The use of over-current relays, either alone or in combination with directional relays, to obtain protection strictly on the basis of current intensity, time and direction is too well known to warrant repetition. However, two of the more unusual modifications are given.

Inverse Time Over-Current and Directional Relays

One of the large power companies having a system comprised in part of approximately eight sections in ring formation, together with a number of interconnecting circuits into which power is fed at six principal points, has found that in order to secure selective action under various operating conditions a very in-

verse time characteristic was required for the over-current relays. The ordinary method of time grading was not considered satisfactory because with changing generating conditions and the frequent opening of some circuit the general power distribution was sufficiently disturbed to alter the order of the time grading required. Due to the number of lines involved, however, at most of the stations it was found that the circuit in trouble would in nearly all cases carry a materially greater current than any other contributing circuit. Use of an inverse time characteristic which continued to give the necessary degree of selectivity for this natural difference in current over the complete range of probable faults was finally adopted.

In some cases definite minimum time was also required and at one point a rather high definite time was provided for very low current values, changing later into the inverse time. This unusual characteristic was required in order to permit operation at comparatively low current values as these would be limited due to the very long time involved if the fault were at the far end, whereas, for a short circuit close to the circuit breaker in question, the current would be of such large proportions that delay in tripping would be dangerous besides placing in jeopardy the other contributing lines. It was this latter consideration that required the inverse portion.

The directional relays were of standard types applied in accordance with usual practise.

The Use of Automatic Bus Sectionalizing to Reduce the Duty on Oil Circuit Breakers

In at least one case it was reported that the system had grown to such proportions that, in order to use circuit breakers then installed, it was decided to automatically sectionalize the buses in some stations and thereby limit the current to be interrupted in case of a fault. In such schemes no special relays are necessary, the standard over-current directional combination generally being used. General practise, however, seems to require that, wherever possible, circuit breakers shall be capable of interrupting the maximum power which may flow through them in case of a fault.

II. Differential Current Schemes. The balancing of parallel groups so as to provide sensitivity for faults within the group and, at the same time, safeguard against action for all other faults appears very successful. Its popularity is still further increased, whenever conditions permit, by the elimination of all alternating current potential connections as is done in the various differential current schemes reported.

Differential Current Protection for Two Lines

One company uses a differential current relay scheme which is interesting because it is an elementary form of a more complete scheme, operating on the same principle, and described elsewhere.

The application is made to paired 60-kv., 4/0 lines, 175 miles long, forming a bus for a complete transmission system. These lines are connected to power plants at five different points with a total generating capacity of 161,000 kw. Previous to the installation of these relays the transmission system was operated so that each substation was supplied from only one source of energy as attempts to operate the lines in parallel had resulted, in some cases in serious interruptions to service due to the splitting up of the system.

For proper functioning of the relay system more current must flow in the faulty line than in the healthy line. The differential current relay consists of two similar solenoids with movable cores suspended on an arm pivoted at the middle point. Two sets of contacts are mounted in such a manner that the throw of the arm in either direction, due to excess current in one solenoid, will close a contact. One solenoid of a differential current relay and one induction type over-current relay are connected in series with a current transformer. Each set of contacts on the differential relay is connected in series with the contacts of a corres-

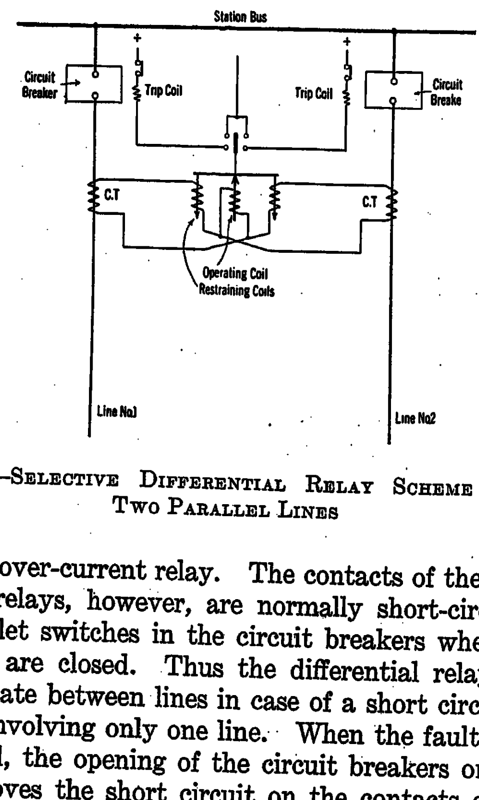

Fig. 1—Selective Differential Relay Scheme for Two Parallel Lines

ponding over-current relay. The contacts of the over-current relays, however, are normally short-circuited by a pallet switches in the circuit breakers when the breakers are closed. Thus the differential relay will discriminate between lines in case of a short circuit or ground involving only one line. When the faulty line is cleared, the opening of the circuit breakers on this line removes the short circuit on the contacts of the over-current relays, and the differential relay, having only one solenoid excited, closes the contacts to complete the tripping circuit. Thus, over-current protection is automatically cut into service on the remaining line when one line is out of service.

Satisfactory operations have resulted from the use of the differential current relay in cases of trouble which it was desired to clear.

The principal advantages of this scheme are the elimination of potential transformers and time settings. It also permits the isolation of the fault in the minimum time.

The disadvantages appear to be the extreme sensitivity under balanced condition which may result in faulty operations. There is also the necessity of providing additional protection for bus or substation troubles if such protection is desired.

This relay scheme will only function properly where an unbalance of currents is assured under all faulty conditions.

Selective Differential Relay Schemes

The relay illustrated in Fig. 1 operates to trip that one of a pair of parallel lines which carries the greater current in case the pair becomes unbalanced due to a fault. The relay in most cases requires an unbalance of at least normal load and for higher currents this unbalance must exceed some percentage of the smaller of the two currents. This is generally in the neighborhood of 25 per cent, thereby automatically compensating for normal unbalancing, such as may be present when slightly different lengths of line are involved, or a difference such as is occasioned by mutual inductance of overhead lines which frequently has a varying effect at times of faults of different characters. This percentage of unbalance is also capable of adjustment in order to further compensate for any known differences in characteristics of the lines involved, it not being necessary to maintain the same slope on both sides.

As mentioned above, this relay operates to open the circuit breaker of the line carrying the greater current. Therefore, it is perhaps always applicable to outgoing parallel circuits which are sufficiently balanced under normal conditions but should never be used on incoming lines where the line in trouble will not carry the greater current as, for instance, would be the case for a substation supplied by no other source of power. This would require that the good line supply whatever current might be taken by the connecting substation load as well as the fault, and would result in tripping the wrong breaker.

The relays consist of three coils whose plungers are attached to a balance arm on which the contacts are mounted. Current through the two end coils tends to hold down their plungers. The center coil is differentially connected or wound and with a current of equal value in the two windings no force is exerted on the plungers. The plunger of this coil has an adjustment for pick up value. When a fault occurs on one line, the force in one end coil and in the middle coil increases, so that the one end coil holds down that end of the arm while the middle coil raises its plunger and pivots the arm about the end coil, thus making contact in the proper direction to trip out the defective line.

The one company reporting the greatest experience, under actual operating conditions, with this type of relay installs them in some instances on incoming lines to buses which are supplied with abundance of other power, thus accounting for the good record reported.

This same company has in some cases four and six parallel lines between stations protected in this way, the lines being grouped in two or three pairs, each pair arranged as indicated in Fig. 1. Any odd lines are provided with time over-current protection having a comparatively low time setting. This appears to have no particular disadvantage where other contributing lines are generally balanced because of the instantaneous action on the balanced groups and the safeguarding against operation of the balanced groups for any fault which might occur in one of these odd circuits. Time over-current protection is automatically provided when one circuit of the balanced group is out of service.

There are 34 of these installations protecting 17 pairs of lines, some underground and some overhead and some combinations of underground and overhead. These circuits which have been in service for about 2½ years have been subjected to 37 faults, all of which have been cleared correctly without affecting other lines. On the other hand, 900 additional relay operations were reported on other contributing lines, involving a total of 1500 miles of circuits, in no case of which did these selective differential relays operate incorrectly. On

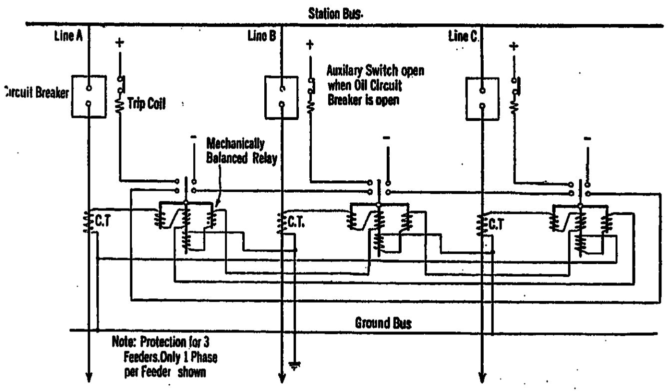

FIG. 2—SCHEMATIC DIAGRAM OF SELECTIVE DIFFERENTIAL RELAY SCHEME

that part of the system not protected in this way this company reports 85 per cent correct operation, counting doubtful operations in general as being incorrect.

A second company has very recently installed equipment similar to that shown in Fig. 1, except that it is modified to include a fourth similar relay, connected in the same manner, to the neutral lead of the current transformers to operate more sensitively in case of grounds. No operating data are yet available.

The third company, reporting the use of these relays, made no particular comment regarding their operation. The general statement that all relays on the system operated 90 per cent correctly does not give any clear indication of the success of this particular installation.

This same general method of protection has also been extended in the case of one company to the protection of three lines in parallel as illustrated in Fig. 2. It will be noted that in this case each line is balanced with each of the other two lines so that in order to disconnect one breaker it must carry a greater current than

either of the two companion lines. This is insured by the tripping contact connections which are made so that both relays connected to the line in trouble must operate before its breaker can be tripped. It will be observed that this furnishes an additional slight advantage over the simple two-line group although the extra relays and connections are in most cases considered unnecessary.

The three open-wire lines, on which this scheme is used, were installed to operate in parallel with four split-conductor cables between a generating station and an important substation, and protection for the open-wire lines, comparable to that afforded the cables, was desired. It may be mentioned, as a matter of interest, that in order to parallel these open-wire lines and split-conductor cables, special precautions had to be taken on account of the large difference in reactance. By using external reactance it was possible to adjust them so that the characteristics were approximately the same, thus making parallel operation practical.

These three circuits also have over-current relays to clear bus short circuits and to give protection when only one or two lines are in service. When two or three lines are in service both types of protection are used but when only one line is in service the balanced relays are cut out. As it is sometimes necessary to operate with only one of these lines in service it was found convenient to install a single switch which will break the trip circuits to all the selective differential relays so that it will not be necessary for the operators to open a number of test switches to cut the relays out of service.

The relays are tested by passing current through one of the end coils and one winding of the middle coil, the plunger of the latter being adjusted for the desired pick up value. The phasing of the relays is most conveniently checked with a four quadrant power factor meter as described on page 851 of the A. I. E. E. TRANSACTIONS for 1919.

These installations have been in service since August 1919, and while there has been only one operation this was a correct one. A pothead failed and the defective line was cleared successfully without taking any other line with it.

Insofar as this particular company is concerned no tests have been made to duplicate operating conditions and as there has been but one case of trouble since the installation, the evidence is not considered sufficient to form conclusions regarding the selectivity of the scheme when called upon to isolate the faulty line of the three, nor is there sufficient data to indicate any advantages or disadvantages in operating characteristics. It is, however, considered to have the following inherent characteristics:

1. Instantaneous selectivity.
2. Freedom from potential transformer connections.
3. It has a percentage differential action which automatically compensates for normal unbalancing.
4. It does not afford protection against bus short circuits, requiring additional relays if such protection is desired.
5. Protection is not given when only one line is in service, requiring additional relays if such protection is desired.
6. It cannot be applied at the substation end of duplicate lines where there is no additional source of power at the substation end, as in such a case the fault currents in the two lines will be equal.
7. It is somewhat complicated and expensive in wiring when used on more than three lines.

No changes are contemplated to improve the installation though it will be retained until more data are obtained. It is believed that the failure of the relays to operate on numerous though short circuits indicates that they are satisfactory in this respect.

Selective Differential Scheme Using Induction-Type Relay

Another company reports that it has already completed the trial of a selective differential scheme which it now considers thoroughly proved. It differs in

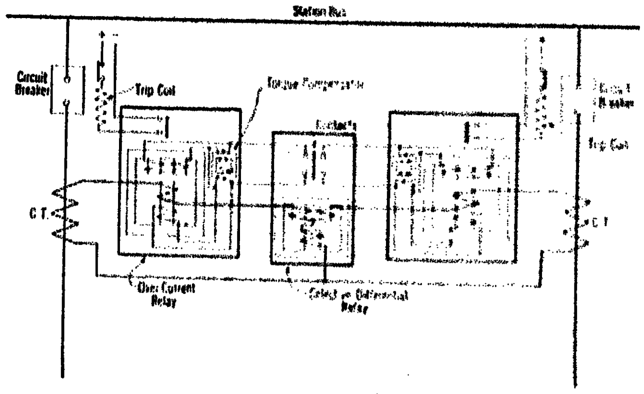

FIG. 3—SELECTIVE DIFFERENTIAL SCHEME USING INDUCTION-TYPE RELAY

principle from the foregoing in that induction type relays are used, although it is applied to duplicate lines in practically the same manner.

Referring to Fig. 3, the scheme makes use of one differential relay connected between the two lines with an over-current relay in each line, so that the system will be sectionalized even if trouble should occur on the station bus. This also makes each line automatic after its companion line has been cut out of service. It will be observed that the differential relay does not directly trip the circuit breaker, but is arranged to decrease the time setting of the proper over-current relay, thus allowing this latter relay to trip out its circuit breaker. The over-current relay is of that induction type which is equipped with the so-called "torque compensator" for the purpose of giving it a definite time of operation. This "torque compensator" is short-circuited by the operation of the differential relay, thus allowing the over-current relay to operate very quickly. When one line is out of service,

the differential relay is disconnected and the over-current relay will operate in the time for which it is set.

There are about thirteen pairs of lines protected on both ends by these relays, some of which have been in service for three years. There have been about 50

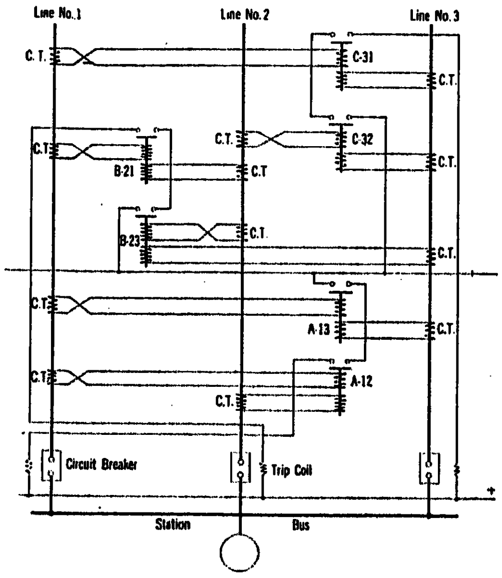

Fig. 4—Schematic Diagram of Differential Current Relay System as Used on Three Parallel Lines

correct operations and no interruptions to service due to incorrect operations, although one pair of lines which are not duplicates, and therefore not balanced, have tripped out several times on through short circuits. Improvements are now being made which are expected to overcome this difficulty.

This scheme has the advantage of being quick in operation and it does not require the use of potential transformers. It is particularly useful on tie lines between generating stations.

It has the disadvantage, inherent to all differential schemes of a like nature, in that it requires interlocking circuits between the circuit breakers to prevent operation when only one line is in service. It likewise cannot be used on the substation end of duplicate lines unless there is an additional source of power in the substation.

When used on a system which is grounded through a high resistance four relays may be used, three being for the purpose of clearing phase short circuits and the fourth, wound to operate on smaller currents and connected in the neutral wire between the two banks of current transformers, for clearing faults to ground.

Differential Current System for the Protection of Three or More Parallel Lines[1]

One company reports the installation of a differential current system for the protection of three or more parallel lines. It was adopted because of the desirability of selecting and clearing the defective line instantaneously, on account of the extremely sensitive character of the synchronous load on the system. It was installed first on four parallel feeders between a generating station and a substation. These feeders operate at 12,000 volts and are ungrounded, the system being delta connected. Later it was installed on four 60,000-volt lines 80 miles long. This part of the system was also delta connected and ungrounded.

The principle of this system of protection is based upon the fact that the current of a line becomes unbalanced relative to the same phases of other parallel lines when a fault occurs on it, whereas the current in the other parallel lines will remain balanced with respect to each other. This will hold true for a short circuit at any point on a system of three or more parallel lines provided their characteristics are not appreciably different. Therefore, an arrangement of differential relays coupling a feeder with other parallel feeders and having the trip circuits of these relays interconnected in such a way that their joint action will trip the unbalanced feeder, will be able to select and clear such a faulty feeder without disturbing the remainder of the system. The action of the relays will occur either simultaneously at both ends of the line or in succession depending upon the location of the fault.

Fig. 4 shows a schematic diagram of the scheme, operating on this principle as applied to three parallel lines. Line 1, for instance, is protected by the joint action of the two differential relays *A*-12 and *A*-13 responding to a line current difference between the lines.

Whenever a fault develops in Line 2 or 3, Line 1 becomes unbalanced with respect to the faulty line

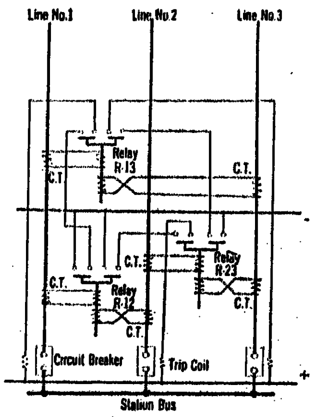

Fig. 5—Schematic Diagram of Differential Current Relay System for Three Lines Using One Relay per Line

and causes the corresponding relay to trip. Line 1 will remain balanced, however, with the other sound line, and as a result the sound relay will remain open thus preventing Line 1 from being tripped out. Should the fault be on Line 1, it will become unbalanced with respect to Lines 2 and 3, resulting in the action of

1. "Relay Protective Features of Toronto Power Company's Transmission and Distribution System" by P. Ackerman. The Engineering Institute of Canada. April 14, 1921.

relays A-12 and A-13 and tripping out the defective line. In a like manner, relays B-23 and B-21 provide protection for Line 2 and relays C-32 and C-31 for Line 3.

With the arrangement shown in Fig. 4, six differential relays are required for the protection of a three line system. It will be observed, however, that in the whole combination, two relays each form differential relays for the same two lines, the only difference being that the trip contacts of the two relays are inserted in two different trip circuits. By modifying the system as shown in Fig. 5, the number of relays required may be reduced by one-half. In this, each relay has two independent trip contacts, each contact being inserted in one of the trip circuits of the two lines from which the relay is energized. In actual practise only one current transformer is used for each line. The schematic arrangement showing each relay coil being fed from a separate current transformer, was chosen only to show clearly the relation between the various lines and relays.

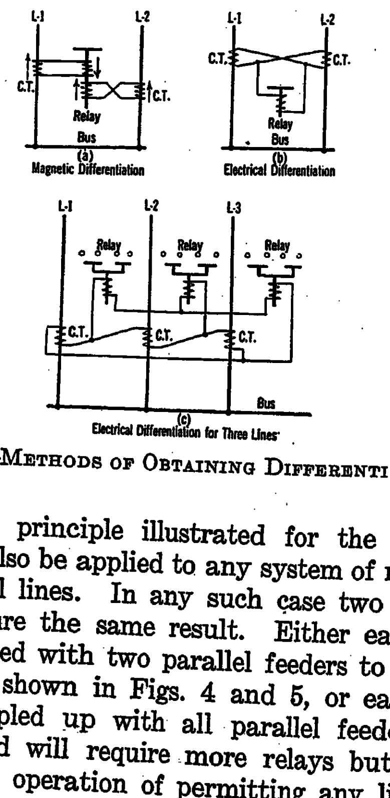

FIG. 6—METHODS OF OBTAINING DIFFERENTIATION

The same principle illustrated for the three-line system can also be applied to any system of more than three parallel lines. In any such case two ways are open to secure the same result. Either each feeder can be coupled with two parallel feeders to form the combination shown in Figs. 4 and 5, or each feeder may be coupled up with all parallel feeders. The latter method will require more relays but has the advantage in operation of permitting any line to be disconnected without disturbing the effectiveness of the protection so long as three lines remain in service.

Where two lines only are left in service, the protection will not be affected by through short circuits, but for short circuits within the section both lines are opened without discrimination.

With only one line in service a short circuit at any point on the system may open this line instantaneously.

All the differential relays shown in the foregoing diagram have been of the magnetic differentiation type, that is, relays with two independent current coils and normally bucking each other as shown in Fig. 6, (a). In a similar way electrical differentiation can be employed by connecting the current transformers in series and shunting the relay coil across them as shown in Fig. 6, (b). Fig. 6 (c) shows three-line protection employing electrical differentiation.

This scheme was installed on the four 60,000-volt lines in 1916 and remained in service until 1918 when this system was changed to two 90,000-volt lines. It then became inapplicable and was superseded by a scheme of double line protection, as described elsewhere.

As proof of its effective operation during the time of service the following summary of operation is given:

Thirty-two short-circuited lines were cleared successfully without a single case of incorrect operation, where one of the parallel lines only was in trouble. There was one case of trouble, involving two lines in a short circuit, which caused a total interruption. Only three lines were in service and the relays cleared both the faulty lines correctly, throwing the total load on the remaining line which tripped due to overload.

The scheme has been very effective in reducing the amount of synchronous load lost due to trouble. In twenty-eight out of the thirty-three cases less than 5 per cent of the synchronous load was dropped and in two other cases the loss was less than 10 per cent.

This scheme has also been installed on the 12,000-volt distribution system for all groups of three parallel feeders. The installation was based on the satisfactory results obtained on the 60,000-volt system and was put in with the double object of trying, in case of cable failure, to save the particular substation from total interruption and to obtain instantaneous clearance thus saving the remainder of the system from serious secondary disturbances.

On several occasions since this 12,000-volt installation, cable faults have been cleared successfully without loss of load. In some other cases the relay scheme has been unable to operate properly because of the failure of other apparatus. The less fortunate performance of the 12,000-volt system, therefore, cannot be attributed to the failure of the relays to function properly. The results on the 60,000-volt system are considered sufficient proof of the correctness of the principle and its effectiveness.

The chief disadvantages of this scheme are that it is somewhat complicated as to wiring, especially on more than three lines, and when only two lines are in service it is indiscriminating. Additional relays must also be provided to take care of bus short circuits if such protection is desired and with only one line in operation the differential relay setting must be above full-load current.

It has, however, the advantages of being free from the complications and uncertainty of action inherent to schemes using potential and is less expensive, especially on high-voltage systems.

Differential Current Scheme for the Protection of Two Parallel Lines[2]

One company reported the installation of a differential current system of protection for two parallel lines having generators or synchronous capacity at both ends. It was developed because of the necessity of obtaining some scheme which would clear the faulty one of the two parallel lines instantaneously. Such action was necessary on account of the very sensitive nature of the synchronous load on the system. The Nicholson arc extinguisher was previously used and it was found capable of saving interruption in about 75 per cent of all lightning short circuits but, as in practically all cases most of the synchronous load was dropped, the benefit derived from this device was only partial. From records of section operation of two circuits on a single tower line it was deduced that in only about 25 per cent of all lightning short circuits were both lines affected simultaneously. Thus in 75 per cent of the lightning short circuits a system of double line protection could be expected to clear the faulty line without interruption to the system.

Power directional relays, even if differentially connected, were not favored for this service because of the sluggishness and uncertainty of action on short circuits near the station. The Mertz-Price system was also excluded for practical and commercial reasons because of the length of the line.

A solution was, therefore, sought in a plain current differentiation between the same phases of two parallel lines, taking advantage of that fact that, with synchronous capacity at both ends, a short-circuited line will manifest itself by drawing more current than the good line. This will hold true for a short circuit at any point between stations and a relay actuated by the excess current to trip the faulty line and simultaneously prevent the sound line from tripping, can select and clear the faulty line without affecting the service over the other line.

A schematic diagram of such a relay is given in Fig. 7 (a). The relay consists of two instantaneous elements so interlocked that the contacts of only one can be closed at a time. Short circuits outside the section so protected would act on the two elements with about equal force so that theoretically neither could make contact. In actual practise, however, one would invariably overcome the other and result in an incorrect operation. In order to overcome this difficulty an additional single-coil relay, energized by the differential current between the two lines, is used. This is shown in Fig. 7 (b), and its contacts are connected in series with those of the two-coil differential relays so that only joint action of the two can trip a circuit breaker.

2. "Relay Protective Features of Toronto Power Company's Transmission and Distribution System" by P. Ackerman. The Engineering Institute of Canada. April 14, 1921.

Thus any through short circuit, resulting in an approximately balanced current flow in the two lines, cannot actuate the single-coil differential relay. The trip circuits will, therefore, remain open even if the two-coil differential relay should be moved into one of the two contact positions.

In the case of a fault on one of the two lines, however, there will always be sufficient differential current between lines to actuate the single-coil relay and thus select, jointly with the two-coil differential relay, the faulty line.

With only these two relays there are certain conditions of short circuit under which the sound line would be tripped out immediately after the faulty line had tripped out at one end. It is, therefore, essential that the trip circuit of the sound line be opened before

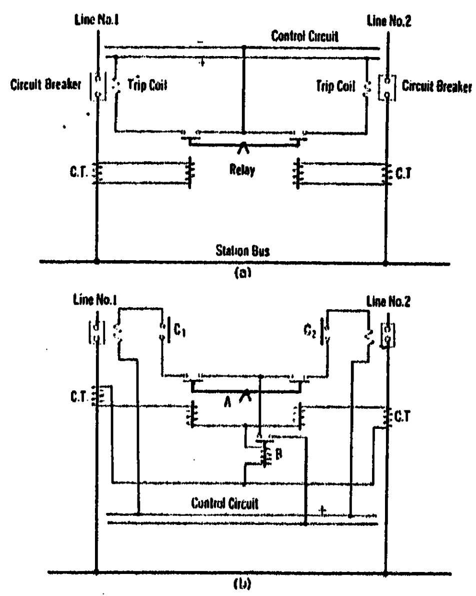

FIG. 7—SCHEMATIC DIAGRAM OF DIFFERENTIAL CURRENT RELAY SYSTEM FOR TWO PARALLEL LINES WITH GENERATOR OR SYNCHRONOUS CAPACITY AT BOTH ENDS

the faulty line has cleared. To do this an electrically controlled locking relay was adopted, energized by the oil circuit-breaker control in such a way that it opens the trip circuit of its line whenever the opposite line circuit breaker opens, and vice versa.

Referring again to Fig. 7 (b), *A* represents the relay which selects the faulty line and *B* represents the single-coil differential relay which prevents incorrect operation of the two-coil relay in case of through short circuits. *C*-1 and *C*-2 represent the automatic locking relays operated by the electrical control of the opposite line circuit breakers to prevent the sound line from opening immediately after the faulty line in case of short circuits at the extreme ends of the section.

Thus all conditions are taken care of and the scheme has proved effective for any kind of line short circuit when only one line was in trouble. It was installed first on two pairs of 60,000-volt lines, 80 miles long, and was operated in conjunction with the differential

current scheme for three or more parallel lines, as described elsewhere, until these four lines were changed to two 90,000-volt lines when the other scheme became inapplicable. This method of operation was followed about two years and as long as three or four lines were available the double line protection was used only during lightning storms or whenever other operating conditions arose which left only two lines in service. During lightning storms only two lines were operated as, on account of the insulators, only two were considered lightning safe.

Since the change to the 90,000-volt double line system the scheme has been in constant service. Operating records were available only from 1917 through eleven months of 1920, and during this time ninety-seven short circuits were cleared without a single failure, so long as only one line was involved. These short circuits were both single and three-phase and at every possible location between the two extreme ends of the lines. The reduction in the amount of synchronous load dropped during trouble was also very noticeable, being less than 30 per cent in all cases except eight and in most cases less than 15 per cent.

During this time there were fourteen cases of trouble in which the short circuit involved both lines and the relays were unable to function. Double-line short circuits were naturally to be expected because both circuits were on the same pole line.

The chief advantage of this scheme lies in its freedom from the use of potential transformers. This is especially desirable on high-voltage systems on account of the cost of these transformers. As disadvantages the following may be mentioned:

1. It is complicated in wiring and depends upon the correct functioning of three relays, each having a set of contacts in series.

2. Will not operate on bus short circuits, and additional relays must be provided if such protection is desired.

3. The last line is non-automatic unless the locking relays are arranged for automatic reclosing after a definite time interval. The last line would then have instantaneous protection provided the relays were set above the full-load current of the line, but would be affected by through short circuits.

Split-Conductor Cable System

One company reports four installations of split-conductor cable as follows:

1. Four 350,000-cir. mil cables between generating and substation.

2. Two 350,000-cir. mil cables between substations.

3. Two 2/0 cables between generating station and customer's substation.

4. Two 250,000-cir. mil cables between substation and customer's substation.

On Installation No. 1 the feeders are tie lines connecting a generating station with an important substation, and a scheme which would disconnect a defective line at an earlier stage in the development of the fault and more quickly than is possible with over-current and uni-directional relays, was required in

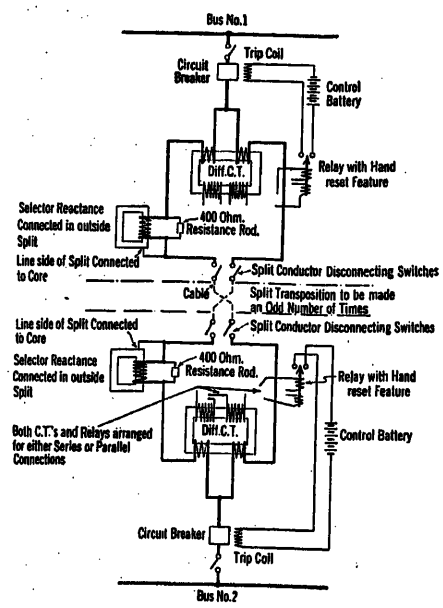

FIG. 8—SCHEMATIC DIAGRAM OF SPLIT CONDUCTOR SCHEME

order to reduce as much as possible the disturbance to such an important part of the system. Split-conductor protection gave promise of better satisfying these conditions than any other scheme. The other installations are paired radial lines and were installed

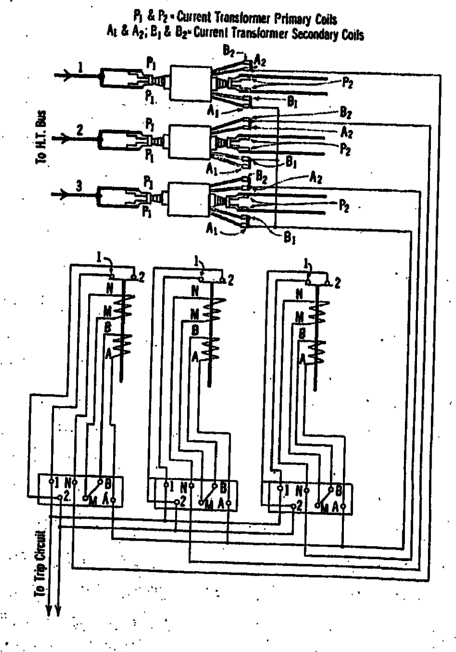

FIG. 9—TYPICAL WIRING DIAGRAM—SPLIT CONDUCTOR SCHEME

mainly to try out the scheme in other localities and under different conditions. Installations No. 3 and No. 4 supply customers who demand the least possible disturbance to their service.

A schematic diagram of the installation is given in Fig. 8 and a typical wiring diagram in Fig. 9.

The differential current transformers are made up of two primary windings, differentially wound, and a single secondary winding divided into two sections, giving a ratio of 4 to 1 when in series and 8 to 1 when in parallel.

Single-pole, instantaneous, over-current relays of the two-coil type with hand-reset contacts are used.

The reactance coils are of the iron-core type with a 500-ohm resistance in parallel, and the value of the reactance depends upon the length and size of the cable. They are of about the same size and form as the current transformers.

The lines of installation No. 1 are all operated in parallel. The other installations are paired radial lines, the lines of each pair being operated in parallel.

The relays may be tested for current balance by inserting a low scale ammeter in series with the relay winding while the cable is heavily loaded. The oil circuit breaker may be tripped at any time by opening one of the split disconnecting switches. It has been found that a setting for 10 per cent unbalance works out satisfactorily.

The time that each of these installations have been in service is as follows:

Installation No. 1	Feb. 20, 1918 to present date	
" No. 2	Sept. 29, 1917 " " "	
" No. 3	Jan. 6, 1918 " Aug. 21, 1920	
" No. 4	Sept. 29, 1917 " Dec. 28, 1918	

All these split-conductor installations have proved satifactory but only installations No. 1 and No. 2 are now in service. Installation No. 3 was discontinued after a cable failure, as split-conductor cable could not be obtained in as short a time as was necessary which necessitated its replacement by standard cable. Installation No. 4 supplied service to a large customer who closed down his plant after completing war contracts.

As proof of the effectiveness of the split-conductor scheme of protection the following summary of operation was given.

Installation No. 1—There have been no incorrect operations. There have been six correct operations.

Installation No. 2—There have been two incorrect operations. In the first case a fault on a line between the generating station and another sub-station opened both lines at both ends. In the second case the oil circuit breaker on another line at the generating station failed and opened both split conductor lines at both ends. Of the four split conductor installations, this is the only one to have incorrect operation and its is believed that there is an unbalance somewhere in the connections which was not evident when checked by the usual methods and which caused the relays to operate under heavy surge conditions or on through short circuits. This is to be carefully checked, by actual test if necessary. There have been no cable failures and, therefore, no correct operations.

Installation No. 3—No faulty operations have taken place. There have been three correct operations, in each instance the faulty line being tripped out without opening any other lines.

Installation No. 4—No cable or apparatus failures or operations, either faulty or correct have occurred.

In every case of cable failure the line was cleared at such an early stage in the development of the fault that there was no perceptible voltage dip or other form of system disturbance.

Up to the present time no tests have been made to duplicate operating conditions and the operations which have occurred indicate neither the necessity of such tests nor the need of any change in the trial installations except as mentioned in the summary of operations of installation No. 2.

From the experience which this company has had with this scheme of protection it is considered superior to the over-current and uni-directional scheme in the following respects:

1. It does not require tapered time settings for selectivity and thus may have any number of substations in a loop or in tandem.

2. It does not require the calculation of short-circuit currents for relay settings.

3. The cable is disconnected at an early stage in the development of the fault, generally before the cable is badly damaged and with practically no dip in the voltage or shock to the system.

4. A breakdown in the primary winding of the differential current transformer or in the reactance coil causes the line to trip out, thus indicating an apparatus breakdown at the time of its occurrence.

5. The scheme is applicable to any number of lines and additional lines may be added without any change in the wiring or relay settings of the lines in service.

It is also considered to have the following disadvantages:

1. It is more expensive by about 20 per cent than standard cable with over-current and directional protection.

2. It requires special apparatus. The reactance coils, differential current transformers, double disconnecting switches and cable are special and are usually of slow delivery, which may cause considerable delay and inconvenience in case of breakdown, unless sufficient material is carried in stock to take care of any emergency.

3. It does not protect against bus short circuits, necessitating over-current relays if such protection is desired.

Pilot-Wire Scheme Using Differential Relays

One of the companies has tried a pilot-wire scheme on the balanced voltage principle, that is the e. m. fs. of the current transformers at each end of the pilot wire are opposed to each other. However, after a thorough test of this scheme, it has been superseded by another pilot-wire system which its originator has called a

balanced differential system. This system makes use of a special differential relay having two coils with equal turns, and connected so that under normal operation the currents through these two coils are equal but in opposite directions. By reference to Fig. 10,

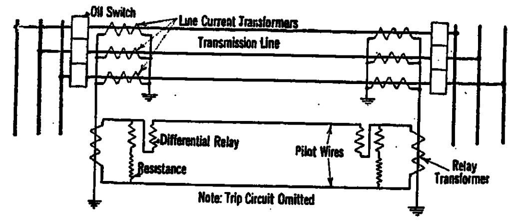

FIG. 10—DIFFERENTIAL RELAY SCHEME—TWO PILOT WIRES

it will be observed that the current from one of the current transformers divides into two equal parts, one part going through one coil of the relay, thence through the pilot wire to the other station, while the other half of the current flows through the relay and through a resistance which is adjusted to be equal to that of the pilot wire. It is easy to see that under normal conditions, no matter how heavy the current may be through the feeder, there will be no unbalanced current through the relay attempting to operate it. However when trouble occurs in the feeder, the current from the transformer at one end of the pilot wire will oppose the transformer at the other end, and, therefore, it will not divide evenly, relatively less current flowing through the pilot wire and more through the resistance so that the magnetic balance of the relay will be upset, causing it to operate.

The system shown in Fig. 10 with two pilot wires will operate only when the cable fault involves current flowing to ground, but the system shown in Fig. 11, which requires three pilot wires, will operate no matter what may be the nature of the fault. It has been estimated that to protect a 5000-ft section of cable, the cost of the two-wire installation would be 90 per

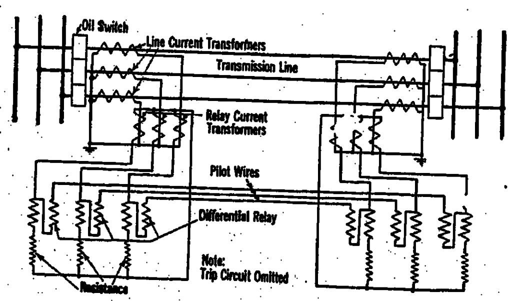

FIG. 11—DIFFERENTIAL RELAY SCHEME—THREE PILOT WIRES

cent, and the cost of a three-wire installation 110 per cent of the cost of a standard installation of directional relays. For a 10,000-ft. length of cable, the cost would be respectively 135 per cent and 170 per cent of the cost of a directional relay installation.

This company's network is quite extensive and it was feared that on many of their loops, where a number of substations are in series, the total time setting required on some of the over-current relays, in order that they might be properly selective, would be so high that the conventional over-current directional scheme would not be suitable. This pilot-wire scheme was therefore selected for use on certain sections to secure instantaneous operation and thereby reduce the time required on other relays. Furthermore, since most cable troubles start on a breakdown to ground, this scheme will, in the majority of cases, disconnect the faulty cable before the trouble has developed into a short circuit.

Since August 1918, the scheme using two pilot wires has been applied to 60 lines and the three-pilot-wire scheme to four lines. There have been 28 correct and 12 incorrect operations, the latter being due largely to the defective apparatus which was used on the first few installations. It is interesting to observe the causes of the false operations, which can be grouped as follows:

Defective apparatus and connections	6
Errors in making connections.......	4
Unbalance in the current circuit due to instrument installations.......	2
Total................	12

During the past two years there have been only two incorrect operations and it is reasonable to expect even less in the future.

The advantages of this scheme are:

1. Complete independence of relays on one line from all others.

2. Selective time settings are not required as the action is instantaneous.

3. High current settings are not required and short-circuit current calculations are unnecessary.

4. Special cable is not required as in the case of the split-conductor scheme.

5. The balancing operation is simple, requiring merely the adjustment of the series resistance.

6. Standard current transformers may be used and no high potential is induced in the line-current transformers.

7. The complexity of the network offers no difficulty in the application of the scheme except in the case of tapped lines.

The one disadvantage of this scheme lies in the cost of the pilot wire. For long transmission lines, induction type relays are preferable but for short lines or for a network this pilot-wire scheme has many advantages.

Differential Pilot Wire

One company reported that differential protection, using pilot wires, was originally tried out on several 110-kv. line sections but that it was abandoned because of very frequent interruptions which could not be satisfactorily explained.

On account of the high voltage of the system it was desirable to disconnect a faulty circuit instantaneously and this scheme was devised in the hope that it would meet the requirements. A schematic diagram of the installation is shown in Fig. 12. The longest section upon which it was installed was 51 miles and the shortest 13 miles. The neutral of the system was at first ungrounded, but was later grounded through a water resistance. One ground was located in the

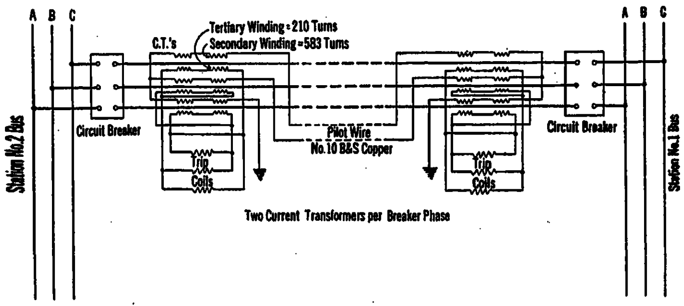

Fig. 12—Schematic Diagram of Differential Pilot Wire Relay System

neutral of the step-up transformers and the other in the neutral of the step-down transformers at two places in the system.

The special equipment required for the scheme consisted of bushing-type current transformers with secondary and tertiary windings. Ordinary alternating-current trip coils of rather high impedance were used as relays.

Referring to Fig. 12, the operation was as follows:

Under ordinary conditions of flow of power, the current flowing out of the circuit at the receiving end should be equal to that flowing into it at the transmitting end. Under these conditions, the voltage induced in the secondaries of the bushing type current transformers would be equal and opposite, and currents proportional to the line current would flow in the delta-connected tertiary windings, with no tendency to flow through the trip coils in parallel with them, since the resultant of the line currents would be zero. Thus, when any current flowed from the transmitting end without reaching the receiving end, as would be the result of a fault, the system would be unbalanced, and current would be forced through the trip coils to operate the circuit breakers.

The scheme was in service about two years. No adequate records of the various tests or operations are now available, but it was abandoned as unsatisfactory about 1913. The use of the ground for one conductor of the pilot-wire system may have been partly responsible for the defective operation of this scheme. This may apply, especially, on account of exposure to the power circuit which would normally indicate the desirability of proper relative transpositions in the pilot-wire circuit. It is also possible that an attempt was made to have the equipment too sensitive, and as inverse time over-current relays with mechanical trip were used on the same lines, it is probable that these operated simultaneously with the differential relays and thus destroyed selectivity.

This scheme is described chiefly as a matter of interest since it constitutes the only reported attempt to use such a scheme on a high-voltage overhead system.

III. Differential Power Schemes. The differential current schemes just described, though usually simple in equipment and installation are subject in some cases to disadvantage in that the line in trouble does not carry the greater current. Differential power protective schemes for parallel lines, however, are discriminating in their action in all cases and can be relied upon when the effectiveness of the simpler schemes may be doubtful.

A Modification of the Differential Power Scheme

One company reports the installation of the fundamental scheme described in the paper on Transmission Line Relay Protection in 1919, but the application has been modified by the introduction of auxiliary transformers across the secondaries of the current transformers. These are used first as balancing transformers, different ratios being provided so that differences in the main current transformer secondary currents may be compensated for; second, to permit grounding of the main current transformer secondaries without danger of interference with the operation of the relays; and third, under heavy short circuits the auxiliary transformers become saturated and limit the current flowing to the relays, thus preventing the tendency of the relays to "chatter".

In this installation elaborate arrangements have been made to substitute plain over-current for the differential power protection when operating changes require and provision has been made, by means of a differential direct-current relay and contactors arranged as a bridge, automatically to open the current transformer loop when only one line is in service, thus leaving plain directional protection on the line.

No operating results for this installation were supplied and it is described chiefly as an interesting modification of a well-known scheme.

Differential Duo-Directional Relay Schemes

Several companies reported installations of differential duo-directional relays. A simplified diagram of this scheme is shown in Fig. 13. No special equipment is required, standard over-current and directional relays, with double-throw contacts on the directional element, being used. The principle of operation of the scheme is the same as that described in the paper on Transmission Line Relay Protection in 1919.

It may also be well to point out that if protection against balanced or bus faults is desired, over-current

relays may be inserted in each current transformer secondary circuit to take care of such requirements.

Outside of the usual phasing tests as made in the standard uni-directional relay installation, there are no special precautions necessary except to make a check for zero current by inserting a low-reading ammeter in series with the relay current coil while the lines are heavily loaded.

One company reported two trial installations of these relays which were installed because of a desire to find a balanced scheme, applicable to two lines which would not require tapered settings for selectivity and would not be affected by through short circuits.

Installation No. 1 has been in service since April 1919. Up to June 1921, there were twenty-five operations, two of which were correct and twenty-three faulty.

Of the two correct operations, one occurred during a sleet storm, one line being out of service. The other opened at both ends and two phases were found to be faulty. No other lines came out, and although classed as a correct operation it is not a fair trial of the scheme as applied to paired line protection. The other correct operation occurred during an electrical storm.

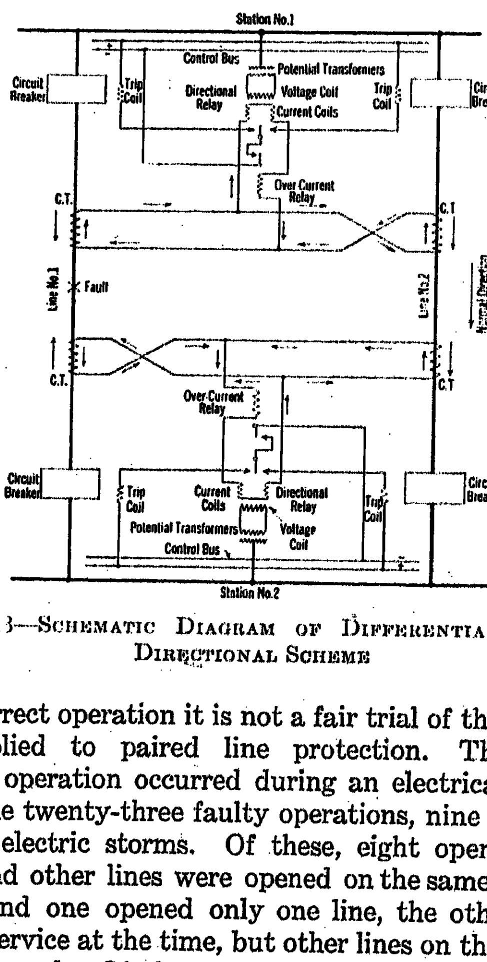

FIG. 13—SCHEMATIC DIAGRAM OF DIFFERENTIAL DUO-DIRECTIONAL SCHEME

Of the twenty-three faulty operations, nine occurred during electric storms. Of these, eight opened both lines and other lines were opened on the same disturbance, and one opened only one line, the other being out of service at the time, but other lines on the system were opened. Of the remaining fourteen operations, there were three cases where both lines were opened but no others, and eleven cases where both lines were opened with others.

Installation No. 2 was put into service in July 1919 and up to July 1921 there were twelve operations, three being correct and nine faulty.

In one of the three correct operations one of the paired lines was out of service at the time so the operation was similar to that of installation No. 1. In another operation faults occurred on both lines and both were cleared. The third operation was the only case of a fault occurring on one line of the pair, in which the faulty line was cleared and the healthy line remained in service.

Of the nine faulty operations, two occurred during electric storms. No cause was found but both lines were opened and other lines were opened in one of these cases. Of the remaining seven operations both lines were tripped out and in three of these cases other lines were also opened.

The results obtained from the operation of these trial installations, up to June 1921, were not satisfactory. There seemed to be a greater tendency for the relays to operate on through short circuits and during electric storms than with the standard directional scheme using two relays. It was desired, however, to give the installations a further trial. It was thought that the wattmeter element to which the double contacts are attached, having less than one-sixteenth inch movement from one contact position to the other, upon clearing the faulty line rebounds from one contact to the other and thus trips out the healthy line. It was, therefore, decided to install locking relays which would make inoperative, for a definite time, the oil circuit breaker trip on one line when the relays are actuated to trip the other line of the pair. In this way it was hoped to overcome the difficulty.

These locking relays were put in service on installation No. 1 in June 1921, and up to March 1922 there were nine operations, six of which were satisfactory and three faulty. Of the six correct operations two occurred during storms and four were due to flashovers. Of the three faulty operations, one occurred during an electrical storm, with one line of the pair out of service, a fault on another line caused the remaining line of the pair to trip out. In another case both lines tripped out when one line was tried out after a correct operation which was due to operating conditions and not the fault of the relay. In the third case an end fault on one line tripped both lines out. The relays have been reset for this end fault condition.

On installation No. 2 the locking relays were put into service in July 1921 and to March 1922 there has been one operation. This occurred during an electric storm and was satisfactory.

From these last operating results it would seem that the locking relays have, to a large extent, overcome the difficulties originally experienced. It is intended, therefore, to retain both installations and give them further trial.

Except in the matter of lessened panel space and the slightly smaller investment required for the duo-directional equipment over the double unidirectional

equipment, this company considers that the trial installations have shown no advantage.

Another company reports the installation of nine groups of these duo-directional relays. Locking relays are not used on any of these installations and the operating records show that over a period of fifteen months after they were put into service, the operation was correct in about 70 per cent of the cases of trouble. These results were not considered entirely satisfactory but the installations are to be retained with the intention of further improving them.

A third company reported the installation of eleven sets of these relays which were originally installed without locking relays, but these are now being added. Although operating records were not available to show successful and faulty operations, the equipment is reported as having proved satisfactory. A number of difficulties has been encountered but all were not attributed to causes inherent in relays but to external faults such as defects in wiring and burnouts.

A fourth company reports the use of two groups of these relays but no definite operating records were given so that it was not possible to determine whether the installation was satisfactory.

The fifth reported that four groups of these relays were in use but the operating results as given were not sufficiently definite to determine what success had been obtained.

Differential Power Scheme Using Bus Section Circuit Breaker

One power company reports the use of a bus-section circuit breaker tripped by over-current relays to provide protection in case of a bus or other balanced fault. An auxiliary switch then serves to inject additional time when this section circuit breaker opens, practically resulting in time over-current and directional protection until the circuits are again paralleled by the section circuit breaker.

Except in the case of balanced faults the conventional differential power scheme is used and the method of sectionalizing the bus has the advantage of maintaining service over one line and on approximately one-half the feeders in the station in case of bus failure.

IV. Ground Relay Schemes.

When a system neutral is grounded through a comparatively high resistance the usual over-current relay set for short-circuit protection may not be able to operate in case of ground faults. It appears to be accepted practise in such instances to connect a "residual" relay in the neutral lead of the current transformer secondaries. This relay will be energized only in case of a ground on the system and accordingly may be set for a very much lower value than the "phase" relays. These residual relays may be given time and current grading in the same manner as the phase relays. The general practise is to use phase relays in each of the three phases and the residual relay in the neutral. This is recommended on account of the fact that the third phase relay provides added insurance of protection in case of either phase short circuits or faults to ground.

Pilot Wire Protection against Grounds

On a 23,000-volt cable system looping frequently through substations and further interconnected into a network so extensive and complicated as to involve rather high and difficult settings, the pilot wire protective scheme shown in Fig. 14 has been installed in five of the shorter sections with a sixth now being added.

From the diagram it will be noted that the protective equipment is connected to the neutral circuit of the main current transformers and that practically no current will flow in any of the tertiary circuits under normal conditions or under abnormal conditions not involving a ground. This insures against any possibility of operation for overloads or for any faults which do not go to ground. This characteristic may be considered a disadvantage by some engineers but the operating company in this case feels that the proportion of faults which do not either start with, or become,

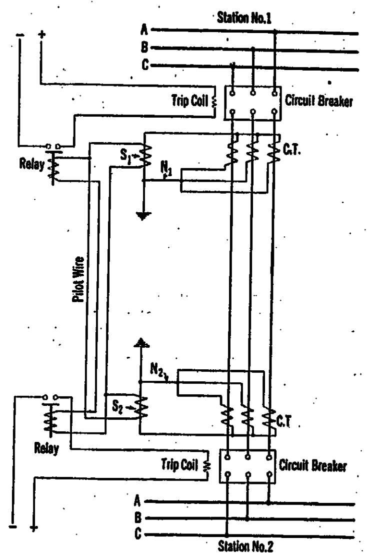

Fig. 14—Diagram Showing Scheme of Pilot Wire Protection Against Grounds

grounds is sufficiently small to justify the reduction in equipment secured and the additional safeguard against operation on through faults.

If a ground is assumed as occurring on some more remote section, equal currents will flow in the neutral circuits N_1 and N_2; secondary current transformers S_1 and S_2 connected in these circuits (principally to permit grounding of the main current transformer secondaries for safety reasons) will then cause a current to circulate through pilot wires A and B. No current flows through the relays, however, due to the use of the third pilot wire R which permits connecting this relay circuit to equal potential points regardless of the drop in the other two pilot conductors. If, on the other hand, the ground should occur on the section

under consideration there will again be currents in the neutral but in this case they will be unequal or opposed and accordingly a current approximately proportional to the fault current will flow through the relays and pilot conductor *R*. This will cause relays to operate and the circuit to be isolated.

These five sections have been in service from one to two years. During this time none of these cables have failed. Therefore positive data on the operation of this equipment are lacking. A number of artificial faults have been applied, and the relays operated correctly in every case.

The advantages of this scheme have been given above. Granting that protection against grounds is all that is required the only practical disadvantage consists in the additional cost of the third pilot wire.

Selective Ground Relay Scheme

One company reported the trial installation of a selective ground relay scheme which was adopted with the expectation that faults of slow development would be cleared at an earlier stage than is possible with phase relays, thus preventing the trouble from being communicated to nearby lines and preventing the system from being subjected to severe shock.

The installation was made on five lines and the voltage is 26,400 with the neutral solidly grounded, at the generating station.

A schematic diagram of the installation is shown in Fig. 15. It will be observed that the ground relay is connected in the neutral of the current transformer bank

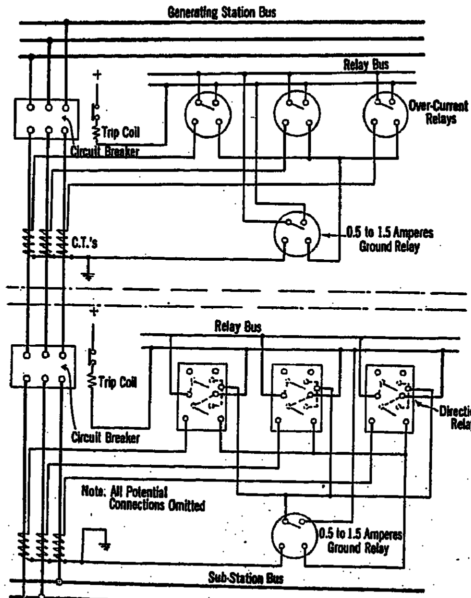

FIG. 15—DIAGRAM OF SELECTIVE GROUND RELAY SCHEME

and that where over-current relays are used their contacts are paralleled with those of the ground relays. When the over-current directional combination is used the ground relay contacts are arranged to short circuit the over-current element, thus leaving the wattmeter element to discriminate as to direction of power flow. No special equipment is necessary except that the directional relays are equipped with an extra terminal which taps the trip circuit between the contacts on the two elements.

The ground relays are induction type over-current, having gears interposed between the disk-shaft and the contacts. They have a minimum operating current

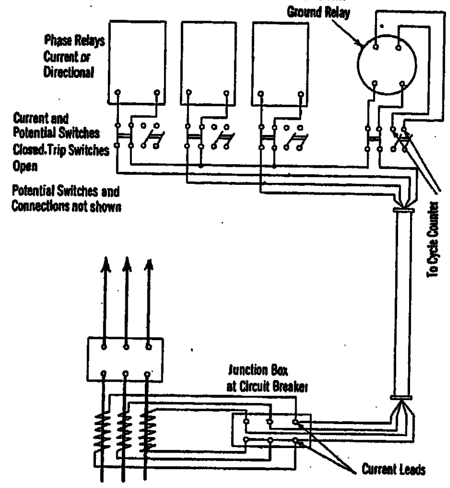

FIG. 16—METHOD OF TESTING GROUND RELAYS WHEN USED WITH BUSHING-TYPE CURRENT TRANSFORMERS

range of from 0.5 to 2.5 amperes and the energy consumed is low, being in the neighborhood of 2 to 3 volt-amperes. The current transformers are of the standard through or bushing type.

The relays are set by applying test current to the secondary terminals of one of the current transformers, with the three phase relays and the ground relays in circuit, as shown in Fig. 16. The secondary test current is determined by dividing the primary ground current by the turn ratio of the current transformers. By this method of testing, the exciting current of the current transformers and the shunting effect of the circuit formed by the two current transformers and phase relays on the other two phases are taken into consideration. With bushing-type current transformers these factors greatly modify the setting unless allowance is made by calculation or by the test method.

These installations have been in service from December 28, 1920 to the present time. Prior to January 1921 there were two correct operations both of which indicate that the ground relays operated at an early stage in the development of the fault.

Since January 1921, a 150-ohm ground resistance has been installed limiting the ground current to 100 amperes. The following summary of operations show the results which have been obtained: Up to March 1922, there were seventeen operations, four of which were faulty and thirteen correct. In the case of the faulty operations, two lines, not on the same pole line, operated upon a fault or flashover on one of these lines.

l Relay System

pany reports a ground relay system rised to protect underground three- cables from excessive potential strains tor insulation of the other phases when os on one phase. The cables are operated at 15,000 volts and each line is isolated from other parts of the system. Since the system is ungrounded practically no ground current flows when a ground occurs but the potential between the other conductors and sheath is raised from star to line voltage.

A schematic diagram of the installation is shown in Fig. 17. No special equipment is used, all apparatus being standard. The relay is of the over-current induction type and has a minimum operating current range of 0.5 to 1.5 amperes.

Referring to Fig. 17, when a ground occurs on *A*, for example, the potential transformer on that phase becomes short circuited, since the primary side of the potential transformers are connected in star and the neutral grounded. This in turn causes a current of low value to circulate through the potential transformer secondaries which are connected in delta through the over-current relay. Thus the relay will operate for a ground on any phase and clear the defective line.

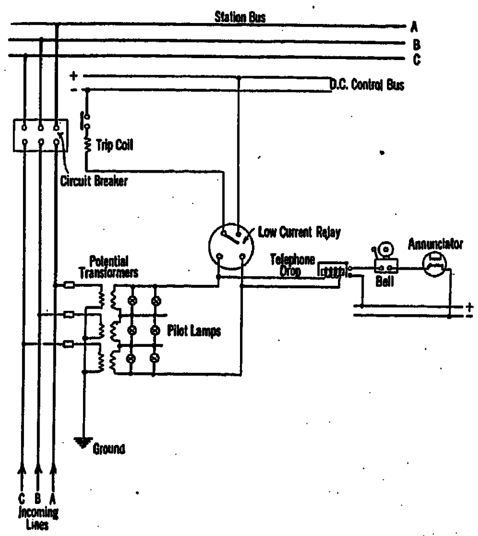

Fig. 17—Schematic Diagram of Potential Ground Relay System

This installation has been in operation since 1917, though no operating data are given for the period prior to 1919. During 1919 and 1920 there were 18 cases of correct operation and 2 cases of incorrect operation.

While the operation of the scheme has proved satisfactory it has been abandoned in favor of a scheme which will discriminate between lines and thus permit paralleling.

The installation has a threefold advantage in that it is simple in detail, is very quick to remove the trouble and functions without requiring any appreciable current to be flowing in the fault.

Its one great disadvantage is that, in case of a ground all the apparatus which it protects is disconnected. It, therefore, prevents the paralleling of feeders, as in an interconnected network or on parallel feeders all lines are likely to be opened on account of static unbalance.

Ground Selector Relay Scheme[3]

In order to overcome troubles due to grounds on a 12,000-volt ungrounded distribution system, one company reports the installation of a ground selector scheme. The distribution system in question consists of approximately 80 miles of underground and the same amount of overhead distribution all fed from the same bus bar. Because of the extent of the system, grounds were quite frequent and cross short circuits sometimes developed before the ground could be located and cleared. This usually meant an interruption to a more or less extensive portion of the system. Some means of detecting and clearing the ground immediately upon its development was, therefore, very desirable and since the system was delta-connected this meant either the installation of grounding transformers

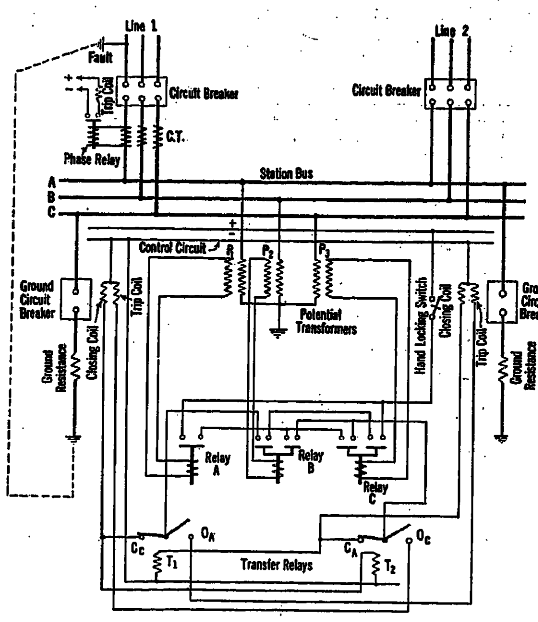

Fig. 18—Schematic Diagram of Ground Selector Relay System

or the development of some means of accomplishing the same results. After a thorough study of the situation it was decided to adopt the ground selector scheme shown in Fig. 18.

The principle of this ground selector is that any ground occurring on the system will immediately be developed into a short circuit by automatically grounding another phase at the base station and artificially completing a short circuit path. Short circuit current will then flow out into the fault, operating the phase relays and clearing the defective feeder in the same manner as if it was short-circuited. The artificial ground is made at the base station bus through an oil circuit breaker which is automatically opened as soon as the defective feeder is cleared, thus restoring the system to the normal condition. The circuit breaker is connected to ground through a very low resistance water rheostat which does not appreciably affect the magnitude of the fault current under the most limited current conditions, but has the advantage of sustaining the bus bar voltage in case of grounds near the base station, thus helping to keep the synchronous load in step.

Referring to Fig. 18, the essential features of the scheme are as follows:

The primaries of the three potential transformers are connected in star and the neutral point grounded. The secondaries of these transformers are each connected to an over-voltage relay, the action of any two of which will close the proper ground circuit breaker. So-called transfer relays are provided to insure the automatic opening of the circuit breaker as soon as the grounded feeder has been cleared.

Normally the three phases of the system will be balanced to ground, the potential on the transformers being the same and equal to 58 per cent of the voltage between phases. A ground on one phase will tend to lower the voltage on the corresponding transformer and the voltage on the other two phases will tend to rise to line voltage of 1.73 per cent of the normal voltage to ground. The over-voltage on the two sound phases operates the corresponding over-voltage relays and closes the ground circuit breaker.

As a specific example, assume a ground on Phase *A* of Line 1. This results in a high voltage on phases *B* and *C*, operating their corresponding relays and closing the ground circuit breaker on phase *C*. There is then a complete short circuit between phases *A* and *C* and the phase relays clear the faulty line. This leaves the grounding circuit breaker closed, resulting in a ground on phase *C*, and except for the transfer relay the other ground circuit breaker would close, due to the high voltage on phases *A* and *B*, and cause a bus short circuit. The transfer relay, however, locks the closing circuit of the second ground circuit breaker immediately upon the closing of the first one and at the same time prepares for the tripping of the one which has been closed. When the ground circuit breaker on phase *C* closes it energizes the coil of the transfer relay *T*-2, throwing the lever over into the other contact position. In this position of the lever, high voltage on phases *A* and *B* will trip the ground circuit breaker on phase *C* and reestablish normal conditions instead of wrongly closing phase *A* to ground through the other circuit breaker. In a like manner a defective feeder which may become grounded on phase *B* or *C*, will be cleared and normal conditions reestablished.

Other features which are not shown in the diagram but which are added to make the device practical are as follows:

A differential potential relay, responding only to unbalanced potential to ground, to prevent the over-voltage relays from operating on balanced over-voltage.

3. "Relay Protective Features of The Toronto Power Company's Transmission and Distribution System" by P. Ackerman. The Engineering Institute of Canada. April 1921.

Such action would not, in itself, be harmful, since the transfer relays would prevent the closing of the ground circuit breakers, but it would necessitate resetting the device, as the transfer relays are not automatically reset. It has been found advantageous to limit the device to one operation since automatic resetting might cause trouble if a ground should develop into a short circuit and clear the feeder before the ground circuit breaker is completely closed. The transfer relays are, therefore, arranged for hand resetting.

The ground circuit breakers are equipped with over-current relays set high enough to permit the feeder phase relays to operate before the ground circuit breaker opens. They are also provided with complete electric control which permits the operator to operate them manually if occasion arises. In addition, a hand locking switch is provided so that the automatic features can be removed without interfering with the hand control of the grounding circuit breaker.

This ground selector scheme was put into service in 1918 and its operation has been very satisfactory. During a period covering something over two years, operating records show that it effectively cleared a total of 86 grounds. Of these 86 cases of trouble, 40 were classed as permanent and were due to such causes as cable troubles, bad insulators, bad current transformers, operators' mistakes and testing faulty feeders. The remaining 46 were classed as transient troubles and were due to lightning and unknown causes probably customers' grounds or outside interference.

During this same period there were 41 momentary, self-clearing grounds, due to unknown causes, starting the ground selector but clearing before the ground circuit breaker closed.

The advantage of this ground selector scheme seems to be in the cost as compared to other schemes. The two alternative schemes for accomplishing the same result are as follows:

1. The installation of low reactance grounding transformers of large capacity so that sufficient current to operate the phase relays would be obtained, even on very remote grounds.

2. The installation of smaller capacity grounding transformers of higher reactance and the addition of special ground relays of low setting, which would take care of limited ground current.

The first was undesirable, in the case of the reporting company, on account of the inherent high cost of the high-capacity transformers and the second was equally undesirable because of the expensive relay and current transformer equipment required. Additional current transformers would have been necessary because all those available were fully loaded and the addition of new ones would have introduced complications on account of space limitations. The idea of grounding transformers was, therefore, abandoned in favor of the ground selector scheme.

The chief disadvantage is the loss of the advantage of a permanently grounded system. There is also the possible disadvantage of having no ground protection in case a ground should occur before the device is reset after an operation.

V. The Under-Voltage and Over-Current Combination. When a short circuit occurs on any part of a system the potential will be a minimum at the point of fault, increasing as the source is approached. This, therefore, provides another means of discrimination, which, in combination with over-current devices, may, under favorable circumstances such as long overhead lines, greatly increase the certainty of selectivity.

In the report of the Protective Devices Committee, submitted June 24, 1919, entitled "Transmission Line Relay Protection," there was described a method of automatically sectionalizing transmission lines, which made use of under-voltage and over-current relays. One of the companies installed this system about twelve years ago, and it has been estimated that the operation of the system, as far as the relays are concerned, has been about 85 per cent of perfect. However, this installation was made before reliable directional relays had been produced, and consequently, it does not contain any directional element, as a result, the circuit breakers on the incoming line, as well as on the defective outgoing line at each substation, were frequently tripped open so that on many cases of line trouble the substations at both ends of the defective line were lost. However, this was considered quite an improvement over previous conditions because it restricted the trouble to one section of the system, which is an important one and supplies an important industrial community. This scheme is now being superseded by conventional over-current and directional relays, but the Committee considers it of importance because it is a pioneer application of a protective relay principle which will, without doubt, soon be given another trial using more highly developed apparatus of greater refinement.

The Calculation of Short-Circuit Currents

A fault on a system produces an abnormal condition, which has no relation to normal loads and overloads, and in order to obtain selective action from over-current and directional relays, it is necessary to set them for the currents flowing under this condition. Feeder over loads can be taken care of by attention on the part of the operators.

This necessitates the calculation of short-circuit current values as a basis for relay settings. These calculations have been covered by numerous writers, so that this article will only give a description of a generally used method with references for those who desire further to investigate the subject.

Practically all short-circuit current calculations are made with reactance alone, resistance and capacity being neglected. In general, neglecting resistance and capacity does not produce an appreciable error except in certain types of systems. This reduces the calculations to an application of Ohm's and Kirchoff's

laws, using reactance in place of resistance. One method is to express the reactance of all generators, transformers, lines and other apparatus in ohms from one phase to neutral, and by adding up the reactance from the point of short circuit, to and including the generators, and dividing the sum into the voltage to neutral, the instantaneous value of the short-circuit current is found. This is the principle of the usual methods of calculations, but in systems having two or more different voltages it is necessary to express all the reactances in terms of one voltage and as the reactance of most apparatus is expressed in terms of percentage which is independent of voltage, and as line reactance in ohms can be easily converted into a percentage basis, the percentage method is generally preferred.

This method is described in an article by H. R. Wilson on page 475 of the *G. E. Review* for June 1916, in an article by W. W. Lewis, page 140, *G. E. Review* of February 1919, and in the article on "Rating and Selec-

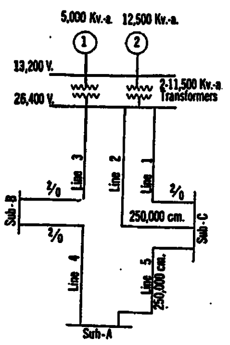

FIG. 19—LAYOUT ASSUMED TO ILLUSTRATE CALCULATION OF SHORT-CIRCUIT CURRENT

tion of Oil Circuit Breakers" by Messrs. Hewlett, Mahoney and Burnham on page 123, TRANSACTIONS of A. I. E. E. 1918.

A brief description of this method is as follows:

All reactance of generators, lines, transformers, reactance coils and other apparatus is expressed as per cent reactance at a common kv-a. base, arbitrarily selected. The various reactances are converted up or down as the case may be, to this base. The combined reactance from the generator neutrals to the point of short circuit is determined and it is assumed that the entire voltage of the generators is used between these two points. Then

1. Instantaneous kv-a.

$$= \frac{\text{kv-a. base}}{\text{reactance to point of fault}}$$

Example. With the layout given in Fig. 19 the calculations are as follows:

Line (1)—35,300 ft.
Spacing $24 \times 24 \times 34\ S = 27$ in.
Reactance per 1000 ft. = 0.1191 ohms
Total ohms reactance = 4.2
Per cent reactance on 10,000 kv-a. base = 6.0

In the same manner:

	Length	Spacing inches	Ohms reactance	Per cent reactance on 10,000 kv-a. base
Line (2)...	34,000 ft.	24 × 40 × 64	4.12	5.9
(3)...	56,000 ft.	24 × 24 × 34	6.70	9.6
(4)...	19,900 ft.	24 × 24 × 34	2.37	3.4
(5)...	33,400 ft.	24 × 40 × 64	4.04	5.8

REACTANCE OF APPARATUS

Apparatus	Kv-a. rating	Per cent Reactance	Per cent reactance on 10,000 kv-a. base
Generator No. 1......	5000	5	10.0
" " 2......	12500	12	9.6
Transformer " 1......	11500	5.75	5.0
" " 2......	11500	5.75	5.0

2. Reactance of the two generators in parallel
$= 1/10 + 1/9.6 = 1/X \qquad X = 4.9$ per cent
3. Reactance of the two transformers
$1/5 + 1/5 = 1/X \qquad X = 2.5$ per cent
4. Reactance of Lines 1 and 2 in parallel
$1/6 + 1/5.9 = 1/X \qquad X = 2.98$ per cent
5. Reactance of Line 3 + Line 4
$9.6 + 3.4 = 13.0$ per cent
6. Reactance of (4) + Line 5
$2.98 + 5.8 = 8.78$ per cent
7. Reactance of (5) in parallel with (6)

$$\frac{1}{13.0} + \frac{1}{8.78} = 1/X \qquad X = 5.3 \text{ per cent}$$

8. Reactance from Generators to Bus A
$(2) + (3) + (7) = 4.9 + 2.5 + 5.3$
$= 12.7$ per cent
9. Instantaneous Short-circuit kv-a.

$$\text{From (1)} = \frac{10000 \times 100}{12.7} = 78800$$

The instantaneous value decreases to the sustained short circuit value at a rate depending on the amount of reactance, generator characteristics, power factor of load on the generator at the time of the fault and other factors. Curves plotted from oscillograms taken on standard generators showing the current decrease for different values of reactance, are given in the paper by Messrs. Hewlett, Mahoney and Burnham, "Rating and Selection of Oil Circuit Breakers," on page 122 of the 1918 TRANSACTIONS of the A. I. E. E.

If the short circuit value given above is to be used with a relay, intended to operate under these conditions in 1.2 seconds, the usual method is to set the relay for the current value at the end of the interval. To use the decrement curves, it is necessary to use the reactance of the point of short circuit based on the total generating capacity. Converting the instantaneous short circuit kv-a. (9) to a per cent reactance based on the total generating capacity of the system.

Per cent reactance at 17500 kv-a.

$$= \frac{17500}{78800} \times 100 = 22.2 \text{ per cent.}$$

Referring to the decrement curves for 22.2 per cent reactance and 1.2 seconds the number of times full load current is found to be 2.52. Therefore, short circuit current at 1.2 seconds

$$= \frac{2.52 \times \text{gen. kv-a.} \times 1000}{1.73 \times \text{line voltage}}$$

$$= \frac{2.25 \times 17{,}500 \times 1000}{1.73 \times 26{,}400} = 964 \text{ amperes}$$

When the system has lines other than in parallel-tandem arrangement or is fed by more than one generating station, the solution becomes more difficult and if the network is complicated, the process becomes too tedious to be practical. Simple network solutions

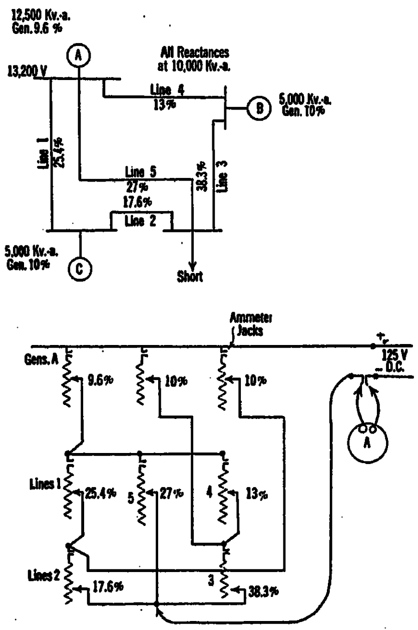

FIG. 20—TYPICAL LAYOUT AND SET-UP FOR CALCULATING TABLE

are given in the two references above and methods of solving networks are described in articles by R. D. Evans and Charles Fortescue on pages 345 and 350 respectively in the *Electric Journal* of August 1919.

Calculating Table. The difficulty in the complete mathematical method lies in determining the system reactance to the point of short circuit, and the distribution of current among the many lines and generators. The calculating table covers this step in the process.

The table consists of a number of adjustable rheostats that are given an arbitrary rating. The original table and many built since, have the rheostats rated at 125 volts and a normal current of 0.2 ampere. The rheostats are calibrated and marked with some form of scale so that with 125 volts applied across the resistance the 0.2 ampere point is 100 per cent reactance, the 0.4 ampere point 50 per cent, etc., resistances of the value of 500 to 1200 ohms being used giving a reactance range from 0 to 80 per cent and 0 to 180 per cent approximately. Leads enable the resistances to be interconnected as the generators and various elements of a system. One end of the generator rheostat is connected to one side of the 125 volt source and the point of short circuit is connected to the other side. An ammeter jack in each rheostat circuit allows the current to be read with an ammeter.

The set-up of a more complicated problem is given in Fig. 20.

The ammeter inserted in the negative lead reads 1.7 amperes and, since 0.2 amperes is equal to 100 per cent reactance on the table basis, 1.7/2 = 8.5 times the table base in kv-a. The readings for all elements are as follows:

		Generators			Lines				
	Total	A	B	C	1	2	3	4	5
Actual readings.	1.7	0.56	0.46	0.694	0.068	0.76	0.396	0.058	0.532
No. of times normal..........	8.5	2.8	2.3	3.47	0.34	3.8	1.98	0.29	2.66

It is interesting to note that the flow over line 4, is from *B* towards *A*. This is directly indicated by the ammeter in the table set-up.

Instantaneous kv-a. = 8.5 × 10,000 = 85,000

Instantaneous amperes at 13,200 volts = 3720

Generating capacity = 22,500

Per cent reactance on generating capacity base

$$= \frac{22{,}500}{85000} \times 100 = 26.5 \text{ per cent.}$$

The distribution of the current in any part of the network may be determined as follows:

Current over line 2

$$= 3720 \times 3.8/8.5 = 1660 \text{ amperes}$$

The remaining part of the calculations and the use of the decrement curves are exactly the same as in the mathematical solution.

The original calculating table was described in the *G. E. review* page 901—August 1916. Other tables have been described in the *G. E. Review* of February 1919, page 140—August 1920, page 669 and *Electric Journal* August 1919, page 345. The first tables were actually in the form of tables, the later ones are in the form of a panel or cabinet.

In the latest boards, the plugging is done with telephone jacks and cord circuits, which makes a somewhat more compact arrangement and the leads of each rheostat are looped through telephone keys within reach of the operator so that the current in any part of the table may be read by the pressing of a key, without "plugging" an ammeter jack in circuit, as was necessary in the first designs.

One of the latest tables built is shown in Figs. 21 and 22.

This table was built by the testing department of the Commonwealth Edison Company, and consists of an oak cabinet, in the lower portion of which are mounted 60 adjustable rheostats, five on each of twelve panels; 60 pairs of telephone switchboard cords, connected through switch keys to the rheostats; a flush type ammeter and voltmeter; a reversing switch and shunt selector switch for the ammeter and the main switch for the table. On the upper panel are 30 horizontal rows of jacks, each row forming a bus, but except for the lower two rows not permanently connected to the lower part of the table. The first and second rows are the positive and negative buses of the table and are connected to terminal blocks at each end and to the voltmeter and the main switch.

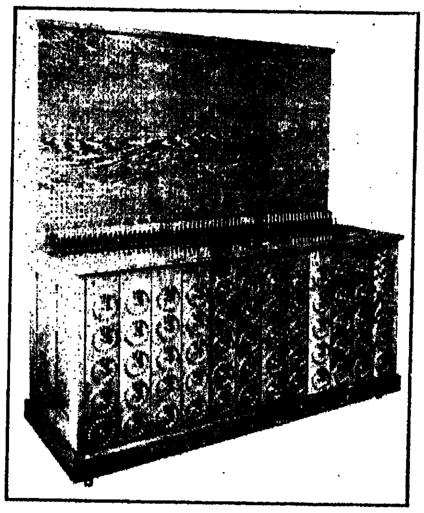

FIG. 21—VIEW OF A LATE DESIGN OF CALCULATING TABLE

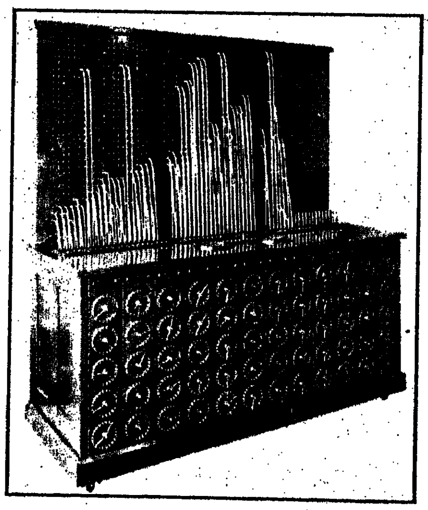

FIG. 22—CALCULATING TABLE SET UP FOR SYSTEM SHOWN IN FIG. 25

The rheostats each consist of four enameled resistance units, two of 500 ohms each with 100-ohm taps, and two of 50 ohms each with 10-ohm taps. Each rheostat is therefore adjustable from 0 to 1100 ohms in steps of 10 ohms. The mounting of the resistance units is shown in Fig. 23.

The switch keys in the circuit of each pair of cords and rheostat furnish means for readily connecting these circuits to the ammeter bus. A wiring diagram is shown in Fig. 24. Only one circuit is shown in this diagram, as all the others are similar.

The arrangement of horizontal busses on the upper panel makes unnecessary any crossing of cords. This is a feature possessed by no other table, and is possible regardless of the arrangement of the lines or station busses represented on the table. More jacks are required by this design, but the setting up and working of the table are greatly simplified, the chances of making errors greatly reduced, and the set-up is always readily traced or checked. Fig. 22 shows the table set up to represent the network in Fig. 25.

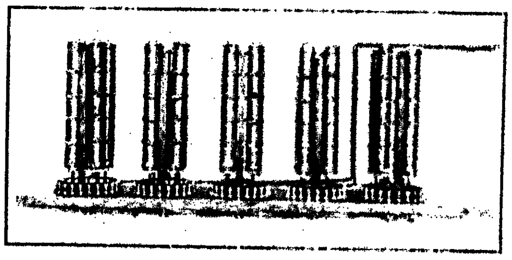

FIG. 23—RESISTANCE UNIT OF CALCULATING TABLE SHOWN IN FIG. 21

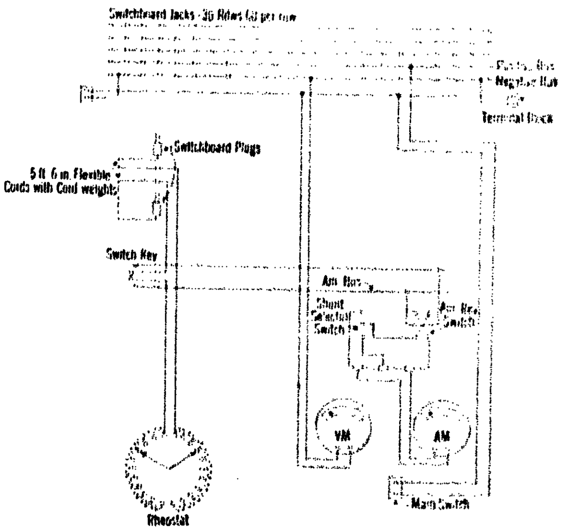

FIG. 24—DIAGRAM OF CONNECTIONS—CALCULATING TABLE

Since the photographs were taken, there have been added card holders in each row of jacks, mounted in the two vertical blank spaces on the upper panel, in which slips may be inserted, giving the names of the station or substation for the set-up; also brass dial plates for each rheostat, giving the number of the rheostat and the number of each step.

A few companies have made tables with fixed resist-

ances, each resistance representing a specific line, generator, etc. in the system. Where the elements in a system are not numerous and in cases where changes are not frequent, this cuts down the cost of the table considerably. In one form of a calculating "board" using fixed resistances, the resistance to the point of short circuit is measured by a self-contained Wheatstone bridge. The current distribution may be calculated by obtaining the potential drops at the various points in the network.

The tables and boards have been found valuable for calculating short-circuit currents for the selection of oil circuit breakers as the method of calculation is the same as described here. The table also forms an easy way to determine the size of reactance coils necessary in designing station bus layouts, as the resistances repre-

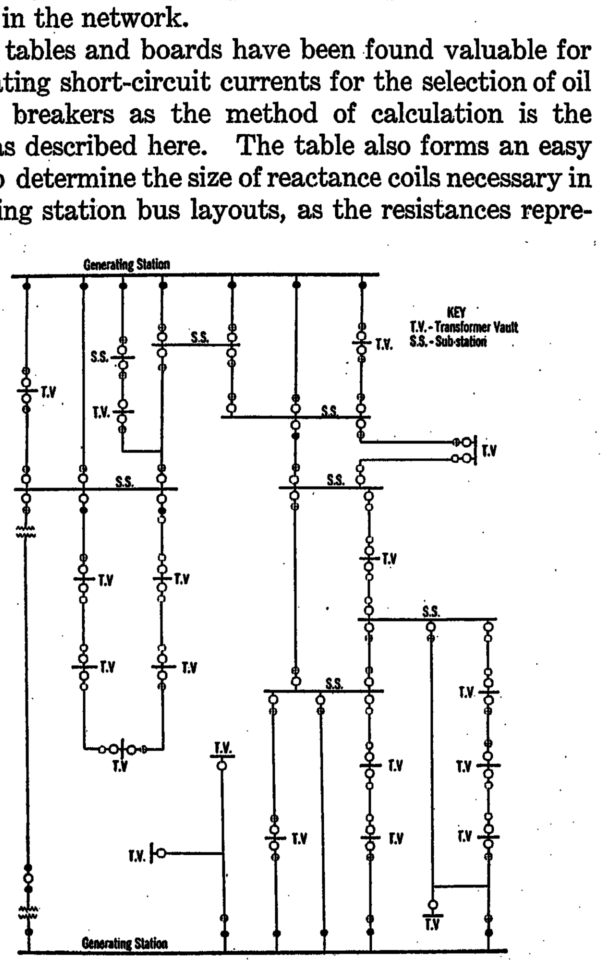

FIG. 25—DIAGRAM OF SYSTEM SET-UP ON TABLE IN FIG. 22

senting the reactance coils can be varied until the short-circuit value is reduced to the amount that the oil circuit breakers can safely interrupt. Various schemes can be quickly set up and the relative effectiveness of the reactors determined.

Inasmuch as the use of the table necessitates neglecting either the resistance or reactance of the various system elements, voltage measurements are not accurate in general.

The error in neglecting the resistance depends on the type of system. Where there are numerous reactance coils or transformers between the generators and the various substation busses, the error is not appreciable. In the article by H. R. Wilson on page 478 of the *G. E. Review* for June 1916, previously referred to as open wire system with 13,200-volt and 2300-volt generators, 88,000 volt lines and step-up and step-down transformers, the error between the resistance—reactance calculations and the reactance calculations, is 2 per cent. In a system where there are no transformers or reactance coils this error becomes greater. The magnitude of this error will depend on the system and a study of this condition for a system consisting of cables or for a system without reactance coils or transformers, should be made to see if the table may be used with a fair degree of accuracy. For a complicated network, however, the table is practically the only solution, but it is well to determine approximately the amount of the error.

The error between the mathematical solution (neglecting resistance) and the similar table solution varies with the number of elements in the set-up and the values of reactance used to set the rheostats. Where the reactance values were such that the rheostats were set well up on the scale, and when there were a number of elements in the set-up, the table figures have checked the mathematical calculations to 1 per cent or less. If possible the table kv-a. base should be changed to obtain reactance figures that will bring the rheostat pointers well up on the scale, values of 50 per cent or more being preferable to 5 to 20 per cent.

In regard to errors it should be remembered that the table figures do not need to be of a high degree of accuracy, as there is considerable error in the reactance values, especially the open wire figures, and the variations in operating conditions are generally so great that the errors in the table and those due to neglecting resistances, are not appreciable.

In obtaining reactance values on generators from the manufacturers, it is important that the reactance obtained be the transient or inherent value and that it be applicable to the decrement curves. It is quite common to furnish the synchronous or sustained value of reactance unless otherwise specified.

A close study of operating conditions is required to determine the generating capacity to be used in the calculations, as there is generally a variation of capacity during each 24 hours, during the week and during the year.

In addition to taking into consideration the variation of capacity in stations, it is also necessary to study the effect of stations that may be entirely shut down during part of a period, only being operated during the peak, or in case of emergency.

A close study of the line operation is also necessary, as the relay scheme and operating scheme must go hand in hand, for neither can obtain the best results independently. One changed method of operation may destroy the effectiveness a well-designed relay scheme, whereas some other change in operation would result in more effective protection. Relays that require time and current settings for selectivity cannot always be set to meet every possible operating condition. Therefore settings that fit the normal conditions and

as many of the emergency variable conditions as possible should be used. Likewise operation rules cannot always be made to fit the relay schemes, but if the operators are kept advised as to the field that the scheme covers, they will, where possible, pick out emergency connections and make other operating changes to fit in this field. Also if informed of these conditions, when it is necessary to go outside of the limit of the relay scheme the operators will know what to expect and will be able more quickly to locate any trouble or faults. In general, for selective relay protection it is best to operate the system with all lines in service and to eliminate, insofar as possible, special conditions such as split busses.

Whether it is necessary to take into account the synchronous load on the system depends on its relative capacity with regard to the total generating capacity. Motor-generators and synchronous converters that have an interconnected d-c. system tending to keep up their speed have a much greater effect than synchronous condensers that have only their inertia to attempt to maintain their speed.

Relay Application

Relays are applied to transmission systems in order that customers may be given continuous service and that the revenue lost by the power company through interruptions may be a minimum. Protection supplied, to apparatus is of secondary importance and is a field which is not covered by this paper, although properly designed transmission relay schemes correctly applied are a distinct advantage in this respect, as the strains on apparatus are reduced by the time limitation imposed by the line relays.

Each relay system and each piece of apparatus entering into the make-up of the system has definite characteristics and limitations. In a like manner each transmission system, and in fact each line making up that system, has definite characteristics which distinguish it from other lines or systems. Satisfactory applications cannot be made without complete knowledge of the characteristics of the protective relays and associated apparatus and of the transmission system and lines to which the applications are to be made. Adequate relay schemes have been condemned through the failure of the application engineer to recognize and weigh all of the factors involved. In some cases difficulty is experienced in isolating or evaluating a factor until after an installation is in service, or an error is made in application, but careful analysis of operating records, supplemented when necessary by tests, will reveal the weakness in the scheme or the value of the factor which was omitted from consideration with the result that the installation may then be corrected or a more suitable scheme installed. At least one case of this type was reported by an operating company and subsequent results show that the diagnosis, made after a number of faulty operations, was correct.

There is a tendency at times, to complicate installations by the use of auxiliary devices to make relays perform operations which are the functions of the operators. The attempt to endow protective relays with judgment in addition to the usual function of discrimination leads to disastrous results through the failure of the auxiliaries to function properly. Maintenance charges are high on such installations, reliability is sacrificed to intricacy, and the service rendered is not commensurate with the cost.

Many relay schemes are, of a necessity, complicated but the trend should be toward simplicity and, other things being equal, the simplest installation selected.

One other item which is frequently overlooked is the phasing out of installations before cutting into service. This work can be done most intelligently by the engineer in charge of relay applications, or at least under his supervision. One company reports that it is its practise to have three independent checks on phasing made before cutting an installation into service. These checks are made under load conditions, first, by the engineer in charge of construction or his representative; second, by the testing department; and third, by the engineer in charge of protection, or his representative. In this way the work of the various departments is properly coordinated.

General Practise in Relay Settings and Tests

Emphasis should be placed upon the necessity of having one person in authority to determine what current and time settings shall be given to all important relays on the system. The testing and adjusting of the relays, after the settings have been determined, need not be so centralized but it seems to be the usual practise and, as outlined in a preceding paragraph, would appear desirable.

The man who determines the relay settings must be in close touch with the operating department so as to be acquainted with all of the operating conditions, weak spots in the system, such as inadequate circuit breakers and lines, and important loads which must be given preference when laying out the protective scheme. Usually the relay man is a member of the engineering department or, less frequently, of the operating department. Another method is to handle protection of the system through a committee consisting of one or more members from each of the interested departments. The personnel of such a committee will depend to a great extent upon the organization of the company.

The use of inaccurate current transformers such as the low-ratio through or bushing type, may necessitate special consideration when determining the current settings of relays, but after the relays are installed no difficulty need be encountered in testing the assembled equipment if the method mentioned in the previous paper is followed. In this connection, it may be well to point out that even with transformers of these types, the phase angle error will seldom prevent the use of directional relays.

Potential transformers do not, as a rule, enter the problem of setting relays except in cases where the phase relation between the high-tension line and the relay potential bus is shifted 30 degrees by the introduction of star-delta transformers which may make it necessary to adopt some expedient to secure the proper phase relation and voltage value for directional relays.

Practically all circuit breakers now being manufactured will open the circuit in less than 0.25 second so successive relays may be given a time difference of 0.5 second and thus allow a wide margin of safety. Smaller time intervals are being used in a few cases but this is not usually advisable unless each circuit breaker has been individually calibrated and is given frequent inspection. The increasing attention which is being given to the problem of automatic sectionalizing is emphasizing the importance of careful adjustment and inspection of the circuit breakers.

Many companies test their important relays with a cycle counter at the time of installation and thereafter at intervals of six months or a year depending upon the importance of the service and the location of the relay. This test is made regardless of the care and accuracy of the factory calibration because of the very nature of the installation which places considerable responsibility on a single piece of apparatus which will receive little attention after it is once installed and therefore should be thoroughly tested and verified before it is placed in service. Furthermore, a test of the relay with current makes certain that it is in good mechanical condition and if the current is applied near the current transformers the condition of the wiring is also verified.

Notes on Foreign Practise

A larger proportion of the transmission systems in European countries consist of closely spaced conductors than is common practise in America, as the density of population, relatively short distances and lower voltages make this form of transmission more desirable. As a result, differential current schemes of protection have received more attention and a number of principles utilized which are entirely different from those found in American practise.

In England, in particular, more attention seems to have been given to differential schemes than any other form of relay protective equipment, and the development of over-current and directional relays has lagged accordingly. Originally, pilot-wire protection was preferred, then split-conductor, and at present the preference seems to be returning to pilot wire. Methods of eliminating capacity effects in pilot wires and the relatively cheaper first cost as compared with the split conductor, would account for the reversion. The English schemes lead in diversity of principles employed for selecting the faulty line but in methods of application and the development of devices, American practise seems to be superior.

The influence of developments in the art in each country is beginning to be felt in the other country and it is to be hoped that some of the basic principles established in England will be adopted in America, as the English engineers have already adopted some of the American schemes. In this connection it is interesting to find that one company in the Far East, operating under the supervision of an English engineer, installed during the recent war, the American adaptation of the split-conductor scheme for closely spaced conductors. The special oil circuit breaker consisting of six poles (two in each phase) to clear trouble on end faults as used in English practise, was not obtainable, so, after visiting the American installations, the modified scheme was adopted consisting of standard three pole circuit breakers and end reactors to assist in clearing end faults.

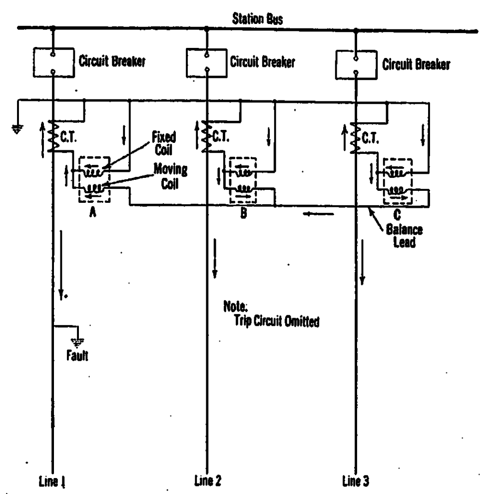

Fig. 26—A Typical Differential Scheme as Used in English Practise

Many of the English schemes require the use of special conductors and their use is not economically justified except in special cases, because of the large capital expenditure required to obtain only slightly better protection than is obtainable by other and cheaper means. There are, however, a number of other schemes which do not use special conductors and which are desirable because of the stability obtainable with very low settings. A typical example of this form of protection applicable only to outgoing lines is shown in the single line diagram, Fig. 26.[4]

The relays employed in this scheme are the directional current type having a fixed coil and a movable coil. Under normal operating conditions the current from each transformer circulates through the fixed coil of its relay. The moving coil connected to the balance lead is not excited. If the faulty line 1, carries the greatest current as would be the case in an installation

4. Automatic Protective Devices for Alternating Current System. A. E. McColl. Jour. Inst. of Elec. Eng., July 1920 page 525.

on three parallel lines, the balance of the secondary circuit is disturbed, the residual current flowing through the balance lead and moving coils in such directions as to operate the relay with its fixed coil connected to the faulty line and restrain the other relays. The greater discrimination obtained by introducing a definite restraint upon relays connected to healthy lines during abnormal conditions is a principle which should be given consideration in this country for both transmission line and apparatus protection.

In other countries also, recognition is being given to the advantages of differential protection. In Spain there is a transmission system supplying a territory of some 16,000 sq. km. (6177.6 sq. mi.) with a load of 152,700 kw. in 1921 consisting of a network of 110-kv. and 25-kv. lines. On the 110-kv. system there are nine installations of differentially-connected directional relays and two installations of differentially-connected over-current relays. In the 25-kv. system there are two installations of differentially-connected over-current relays. This company is also installing ground relays on the 110-kv. lines to obviate difficulties which it has experienced with the failure of phase relays to operate quickly on ground faults during light load periods and at such times as the differential protection is inoperative due to a line being out of service. These ground relays will have very low settings and the company states that the relays are expected to clear grounded lines before the fault develops into a short circuit between phases.

A relay[5] in which the time element is a function of line voltage has been developed and placed on the market, an installation being considered on one of the high-voltage, single-phase systems in Switzerland. These relays have a potential coil restraining element, the amount of restraint being directly proportional to the line distance between the fault and the relay, thus, those relays nearest the fault will select the proper line as they are subject to the minimum restraint.

Operating Records

There is one suggestion which may well be emphasized and which followed, will undoubtedly increase the value of the work of the committee besides increasing its efficiency and making the work less burdensome. In analyzing the replies from the various reporting companies it was found that some were much more comprehensive than others. From further analysis it became evident that the most difficult ones were from companies who apparently did not have any *good method* of keeping a complete record of interruptions and relay operations. Companies who kept such records were able to answer, definitely, questions to which others could give only vague replies. This lack of definite information was less noticeable in the descriptions of equipment and schemes than in operating results. This would seem to indicate that each company thoroughly investigates the apparatus and schemes before installation and keeps a record of the installation, but that, in a great many cases, adequate operating records are not kept. The engineer in charge of the relay system may know, in a general way, the results that he is getting from his protective equipment but unless a record, giving each detail of operation of the apparatus involved, is kept it will be difficult to determine the effectiveness and next to impossible to make a report showing whether satisfactory results are being obtained from any scheme.

It has been the experience of some of the largest companies in the country that such a record is invaluable in determining the worth of various protective schemes and in choosing the method of protecting new lines. Since beginning to record and compare operating results it has been found possible to determine without difficulty the cause for a great many incorrect operations and to increase the efficiency of protection.

It is the operating data which determine the value of any protective scheme and that such data may be more easily collected and analyzed, the Protective Devices Committee is prompted to suggest a form of Interruption Analysis Sheet, as shown in Fig. 27. A form similar to this has been used with very satisfactory results by several operating companies.

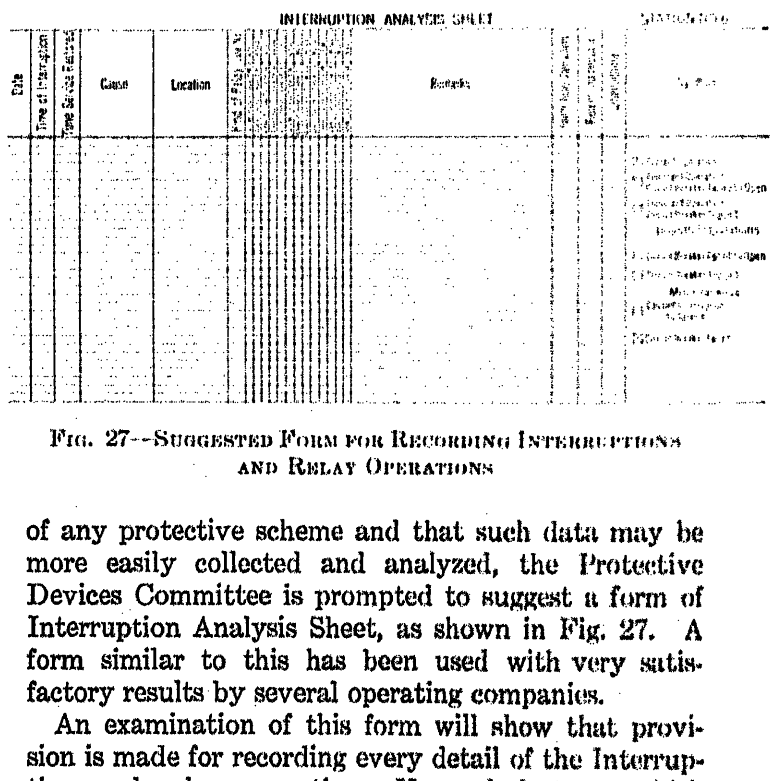

Fig. 27—Suggested Form for Recording Interruptions and Relay Operations

An examination of this form will show that provision is made for recording every detail of the Interruption and relay operation. Unusual features which cannot conveniently be classified may be entered under the heading of "Remarks". A sheet is made up for each station and a cross index with other stations which may be involved can be obtained by referring to them under "Remarks". Each incoming and outgoing feeder is identified with the type of relay by which it is protected, and space is provided for recording and conclusions drawn from the analysis; that is, whether an interruption may have been caused from faulty relay operation, inadequate relay protection or other cause, or whether it was unavoidable.

The form shown is, of course, subject to modifications

5. *E. T. Z.* No. 50, 1919 and January 16, 1920.

to meet various conditions but it is felt that an Interruption Analysis Sheet, embodying these essential features will permit the keeping of all the details of operating records in a compact and easily comparable form.

It is, therefore, recommended that operating engineers give this suggestion serious consideration, as it is of greatest importance that the operating companies know exactly what results are being obtained in order that such schemes as do not give adequate protection may be replaced by more effective schemes, thus stimulating progress and weeding out such schemes and devices as have not proven satisfactory.

It is to be hoped that the foregoing descriptions of schemes and practises in transmission line relay protection will result in a clearer understanding among engineers of the present state of the art. It is the purpose of the series of papers on Protective Relays to keep operating engineers informed as to what is available for meeting each and every operating requirement and to keep designing engineers in close touch with the problems met in the operating field. In order to fulfill this purpose the Protective Devices Committee must have the full cooperation of both the operating and the designing engineers. The cooperation which has been given and the interest which has been shown in the work have been very gratifying.

Discussion

E. R. Stauffacher: The nomenclature and classification of various relays and the acceptance of this nomenclature by the Standards Committee of the A. I. E. E. is a distinct step forward. Relays are assuming more and more importance in their application to central station systems, not only where the load is largely concentrated, but where it is spread over a large territory covering, for example, one-half of a large state. In both cases it is quite necessary that the defective section of such a system be localized, even though in some cases it may take a couple of days for a patrolman to go over the line which is in trouble. The big job is to drop the defective section as soon as possible before it upsets the remainder of the system.

I have referred in a former discussion, to the difference in the Pacific Coast conditions as compared with the eastern conditions and I wish to mention now that the lines are quite long in some cases; 240 miles in our particular case being the longest line. We have only comparatively recently begun the application of modern relays to our system, and are just beginning to learn something of their fine points as well as their limitations.

We have a peculiar condition with our 150-kv. Big Creek line. Mysterious flashovers occur that are not associated with any particular kind of weather, any part of the day, nor any part of the night. It appears to be a hopeless task to find a reason for the flashovers and to eliminate them, so the next thing to do is to get rid of the defective section in our most important transmission line, even though we have to go counter to the opinion of some of the more conservative engineers. It has been decided, therefore, that when the line is changed to 220-kv. operation that the current balanced method will be used for eliminating defective sections. We are only planning to eliminate the first defective section. If the first section should go out on account of trouble and the second section should also get into trouble later, this second section will not be isolated by relays applied to the transmission line, but will be handled by means of a field-killing device on the generators at the power house. Current flowing to ground will operate certain contact-making ammeters which will cause a motor attached to an auxiliary "trouble" rheostat to cut resistance in the generator field as long as current is flowing to ground; and as soon as the ground current ceases to flow the contact-making ammeter will reverse its contacts and the motor will reverse, bringing the generators up to full voltage. Under present conditions, this operation is performed by hand and takes an average of approximately 15 seconds to handle a flashover. There it not much difficulty in handling a flashover manually when one or two power plants only, located two hundred-fifty miles away from the load are operating, but when we have three, four, and ultimately as many as eight power plants attached to one or two transmission lines, it will be necessary to have some automatic means of lowering the voltage in case the second transmission line gets in trouble.

Mr. Hester has emphasized the necessity of the manufacturers and the operating men getting closer together and has pointed out the fact that the operating men misapply a relay occasionally and I think that point is very well taken. We, in the west, located so far from the large manufacturing companies, find it particularly difficult to keep up with the latest applications, so I certainly would voice what Mr. Hester says—that a closer cooperation between the manufacturing company and the operating engineer would help a great deal in securing the best possible application of relay protection.

R. Bailey: I notice, in reading the paper, one thing which is emphasized throughout, and that is the tendency to do away to a great extent with time settings, working more with the balanced condition, where a defective line is removed from the system instantly. The elimination of the time delay has the disadvantage of causing the circuit breaker to open before the short-circuit current can decrease but it seems to me there is a good deal to be gained by removing the defective section so quickly that the synchronous equipment will not fall out of step. In many cases a cable failure may start as a breakdown to ground and the use of time delay relays may allow this fault to develop into a severe short circuit before the oil circuit breaker opens, thus increasing the duty required of the breaker and leading possibly to a system disturbance.

Most of the schemes presented, I believe, are open to the objection that they do not protect against the failure of a station bus, but it looks to me as if this is not a serious objection, as there have not been many cases of bus failure, due no doubt to the precautions taken to obtain liberal design and sturdy construction of busses.

Most of the differential or current balance schemes are applicable where three or four lines are operated in parallel, but where it is a case of operating just two lines in this manner, the schemes do not work out very well. This is a real objection because on a number of systems it is the practise to operate just two lines on the same bus section rather than three or four in order to limit short-circuit currents. While it is true you can get better continuity of service with three or four lines in parallel, the magnitude of short-circuit currents may prohibit this practise. Then, again, the differential scheme usually involves interconnection of transformer secondary leads, which is not in accordance with the idea of completely sectionalizing equipment to prevent the communication of trouble from one line to another.

Most substations are provided with double busses, which further complicates the application of differential relay protective systems, and in some instances make it inadvisable to use a scheme of this sort.

In one place in the paper a scheme is suggested which involves grounding one phase of the system at the time of a ground on another phase of the same line in order to cause the excess current

relays to operate. While this will no doubt separate the line from the system it may cause a serious disturbance and it would therefore appear to be advisable to provide other means for isolating such a line.

In closing I wish to emphasize the need for simplicity of all relay protective systems. A number of them which will theoretically, do the work intended are rather complicated and therefore difficult to keep in condition, resulting possibly in failure to function. It is rather unfortunate that in some cases such systems are not given more care in the design and installation, and in their maintenance afterwards. This condition seems to be due to the fact it is not realized that the relay protective systems are far more important than the investment involved would indicate.

Paul Ackerman: Relay protection is a wholly defensive measure and does not appear to produce any revenue. As a result it is usually very difficult to requisition the necessary money for such expenditures. Yet there is nothing more important than an effective relay protection to assure safety to a power system and to avoid expensive tie-ups to industries and disastrous destruction to power companies' properties.

Today, relay engineering is still about in the same stage as circuit breaker engineering was some ten years ago. In those days the size of a circuit breaker to be chosen and the money to be spent was determined by the importance or unimportance of the respective new feeder. Today, we fully realize that the oil switch to be chosen depends entirely on the main system to which the respective feeder will be connected.

Relay protection is mostly handled in a fashion similar to that in which circuit breakers were chosen some years back, the feeder to be protected only being considered. Yet an effective relay protection is possible only if in each case the main system as well as the respective feeder are given careful consideration.

Regarding the differential current schemes described in the paper, I am gratified to see that this principle has received general consideration within the last few years.

It was as far back as 1912 when I conceived of the scheme illustrated in Fig. 4, and ever since I have been working along similar lines despite great opposition.

The objections then raised were the same as those mentioned in the paper, that is, complication of wiring and interconnection of current transformer secondaries of different lines. The best proof that these objections are not very serious lies in the fact that those who raised the greatest objections originally are today the most ardent supporters of these protective schemes.

There is no doubt that all differential current schemes are complicated in wiring, but it must be remembered that wiring connections are made once only and if properly made are permanent and safe so that no trouble should be experienced from this cause. The relays themselves on the other hand, can be made of such elementary construction that they are usually much safer than the more complicated time-limit over-current or directional relays

The checking of phase relations is usually much simpler and more definite on differential current schemes than on directional relays.

The paper mentions also as one objection of the differential current scheme the fact that they require several relay contacts in series. In this respect, it may be pointed out that no fear from this cause need be entertained as long as the relays are of simple structure. The best proof of this is to be found in the fact that of the several hundred relay actions of the different schemes illustrated in Figs. 4 to 7, there is not a single failure which could be attributed to this cause.

From my experience, it is usually safer to adopt a scheme with simple relays and several contacts in series rather than reduce the number of contacts at the expense of a more complicated relay. Such complication in the relay structure is invariably required if a similar effect is to be obtained. A comparison of Fig. 1 and 7B is an example of this kind. The two schemes are fundamentally the same except that Fig. 7 attains the results by two relays with the contacts in series to each other whereas in Fig. 1 a relay has been developed which requires only one contact, combining the two functions cleverly in one relay, thus, however complicating the relay structure.

The paper mentions another drawback of differential current schemes being the fact that they are unable to take care of bus bar short circuits and that for this purpose additional overload protection is required. In this respect I might say that the power companies will have to realize that they will never be able to obtain a relay which can perform all the required functions and accordingly they will have to accustom themselves that several different type relays will have to be installed on the same switches in order to cover all possible conditions. I might mention as an example that I have come across cases where I considered it essential to install as many as 5 or 6 different types of relays on the same line.

With respect to the various differential current schemes, illustrated in Figs. 1, 3 and 7 used for double line protection, it will be noticed that they are based on the same fundamental facts but that the means employed are different.

Schemes shown in Figs. 3 and 7 report provision of blocking of the protection of the remaining line after one line has opened. The description for Fig. 1 leaves the impression that no such blocking is provided. If such is the case, I would point out that under certain conditions where the current setting of the relays must be made very low, this omission may lead to trouble.

It must also be clearly understood that the various differential current schemes have certain limitations which have to be kept well in mind.

Open-circuited phases for instance, have the tendency of tripping the wrong line unless the relays are set higher than the total load fed over the two lines.

There are also conditions arising where an arc sometimes clears after one line end has been opened. Under such condition, the danger exists again that the other end of the other line may open wrongly and thus cause a total interruption. This danger exists wherever the recovery current may be heavy and where the relays have comparatively low current setting.

These limitations are of little consequence on underground systems where open circuits and self extinction of arcs are very rare. Also on copper lines where cable breaks are rare or on short overhead lines of pin type construction where arc extinction is less to be feared, little trouble should be experienced with differential current protection.

The conditions are somewhat different on long overhead lines, particularly with aluminum cables where breaks are more likely to happen, and where arc extinction is more pronounced.

The above is clearly indicated by the fact that the protective scheme as per Fig. 7 has given practically 100 per cent effectiveness on single line shorts on a 90,000-volt pin type copper line whereas the effectiveness seems only to be about 80 per cent on some other lines of aluminum and suspension construction.

Regarding the differential current protection for 3 and more lines as illustrated in Figs. 4, 5 and 6, I would like to point out the effectiveness and simplicity of this scheme. The simplicity lies chiefly in the fact that relays of the simplest type can be used and that no blocking relays are required. The wiring, though somewhat complicated, can be made fairly simple, particularly on 3-feeder protection, especially if scheme 6c is used. The scheme adapts itself particularly to underground distribution where substations are very often fed over three or more cables. In such cases, it is usually very rare that operation is maintained with only two, or one feeder, or under any such condition one is usually satisfied to have a protection on two feeders which at least does not operate wrongly on through short circuit, while mostly it may be acceptable to cause an interruption under such operating conditions in case of trouble in one of the two cables.

For any such case, this scheme is splendidly adapted and

decidedly advantageous compared with scheme, Fig. 2, as to cost as well as simplicity of relay equipment.

Regarding the merits of directional relays combined with overcurrent relays, it is quite evident that considerable improvements have been made on the directional relays, making them operative down to very low voltage. Modern connections also leave the directional relay effective on single-phase shorts. Still the facts remain that the arrangement should be used cautiously and reluctantly on higher voltage systems, and particularly overhead lines since under such conditions single-phase short circuits often develop rapidly into three-phase short circuits, thus making the action of the directional relay doubtful unless the arrangement is such that sufficient voltage is left on the relays to operate effectively.

No doubt for certain conditions there are no other means available at the present time. The best proof of the limitation of this principle, however, can be seen in the fact that the differential current schemes have been able to make such rapid headway within the past few years.

Regarding the split-conductor principle and the pilot wire principle, I must confess that I have no sympathy with these principles as far as their application for transmission and distribution lines are concerned, except possibly for very short runs.

Both principles in themselves are ideal in view of the fact of clearing both ends of the faulty apparatus simultaneously. For generator and transformer protection they are ideal and deserve more general use.

For line protection, however, the complication, the hazard and the cost are becoming excessive as soon as the lines or cables exceed one mile in length and it is my firm belief that under such conditions they are not able to compete with the differential current schemes, with the exception of very special cases.

The advantage claimed for the split-conductor and pilot wire scheme of having no interconnection between adjacent lines is in my opinion far more than counteracted by the complication and hazard introduced in the split-conductor cable and in the pilot wires respectively.

It is also claimed that the split-conductor or pilot wire schemes are able to limit the damage on cables and the effect of the disturbance on the system because they are supposed to clear the fault before a complete breakdown has occurred. I believe that this view is erroneous. I cannot conceive of any fault, after having developed sufficient current to operate even the most sensitive relay to take longer than 0.3 sec., which is the rupture time of the oil switch, until it has completely broken down. In my opinion, a dead short circuit is developed within a small fraction of a second after any appreciable current has started to flow through the fault, so that the short in practically any case should be completely developed before the oil switch had a chance to open, even if tripped by the most sensitive relay. The limited damage, therefore, in my opinion is caused by the rapid clearance of the short by the quick acting breaker but not by clearing the short premature to the complete breakdown.

Very similar results are observed from the action of differential current protection; flash-overs on overhead lines, cleared by the differential current protection, never damage the insulator sufficiently to disable the line permanently unless the insulator punctures. Cable faults are cleared without undue damage but just sufficient to permit detection.

Split-conductor and pilot wire schemes, therefore, are in no way superior to differential current schemes in that respect.

With respect to the ground selector, I would like to comment on one statement of the report. The paper mentions that the chief disadvantage of the ground selector would appear to be the loss of the advantage of the permanently grounded system. In my opinion, the reverse of this statement is rather correct.

Ungrounded neutral has always been found preferable in many respects, chiefly in regard to transformer connection and the total number of interruptions. The chief drawback was the difficulty of locating grounded feeders and the damaging effect caused by lasting grounds.

The preference given to grounded neutrals is entirely due to a desire to overcome the above serious trouble. This is true at least for voltages up to 60,000 volts.

The ground selector performs on the ungrounded system the same duty for which the grounded neutral has been introduced but with the benefit of being able to retain the advantages obtained from an ungrounded system.

The ungrounded system, therefore, equipped with a ground selector, combines in my opinion the advantages of the ungrounded and grounded system without, however, having any of the disadvantages of either system. The results on the 12,000-volt Toronto distribution show particularly how great a number of self-clearing grounds are given a chance to clear without any disturbance whatever, whereas with a grounded neutral each one of the self clearing grounds would have meant a voltage disturbance and a partial interruption.

Regarding the keeping of records on the functioning of relays, it cannot sufficiently be emphasized that it is very essential to collect as exhaustive information as possible. It is very important, however, to try to obtain the correct information.

For instance, a total interruption on a double line system protected by a double line protection can be caused either by a double line short circuit or by wrong relay action.

Past experience has made the operating man so suspicious of wrong relay actions that he is inclined to dismiss any such case without further investigation by considering it simply a wrong relay action, whereas possibly the relays were acting to the best of their ability.

Short circuits across two lines built on the same tower line or in close vicinity on the same right-of-way are not as unusual as thought. Such possibilities must be given careful consideration before blaming the relays.

On the other hand, each case of wrong relay action must be carefully studied to find the reason for such behavior. Only thus will it be possible to gradually develop the necessary improvements.

In closing, I wish to emphasize that we must not be lured into the belief that we are about to enter the stage where protective schemes are available to cover all the various conditions. On the contrary, we have only just started to realize that our old protective schemes are obsolete. Much hard work will still have to be done to develop the standard of perfection which will be required on systems such as the super-power scheme.

It must also be remembered that the various protective relays of a system have to be properly coordinated and that this can only be done by having this matter centralized in the hands of one man who will be able to concentrate his whole thought on this one problem.

It is also essential that each system be studied on its own merits, also each individual problem. To copy other companies' practise, without careful analysis of the fitness to the conditions under consideration, may lead to very disastrous results since a scheme may be fully effective in one system and a failure in another one. The work of the Relay Committee acquainting us with different schemes must be accepted with that fact in view as otherwise the Committee reports may become misleading.

E. M. Wood: Possibly you may be interested in a description of some rather unique features of relay protection we have in the Queenston power house. You will notice from Mr. Gaby's paper that we have used the current differential relay system to a large extent to protect the busses and other equipment in the station. We have found in some other power houses that we have trouble quite frequently on the busses and it was considered necessary to protect them.

The scheme which is used can be shown in diagram (See Fig. 1). We have this on the generator, on the 12-kv. bus, and high-tension bus, and on the transformer bank. The relays used are plunger type and give quick operation in order to cut out defect-

ive equipment as quickly as possible, and if possible leave the rest in. On the outgoing lines, we have the inverse-time overload induction type of relay. It is our intention to use current differential protection on parallel outgoing lines to the same substation.

A study of the plant characteristics seemed to indicate that there would be a danger, under certain conditions of partial rejection of load, that the machines would drift apart. We have therefore used inverse-time overload relays between bus sections.

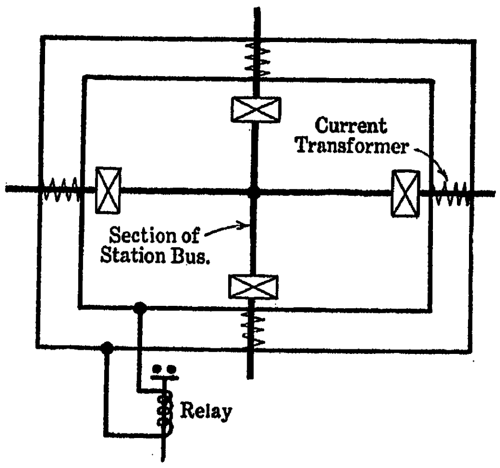

Fig. 1

In the case of the current differential relay there is always a certain suspicion that possibly it will operate when it should not. In order to overcome that, we have taken considerable pains to get current transformers that maintain their ratio. Secondary connections between current transformers are kept short and the long runs to the control arm carry only the residual current.

There is also installed a reverse-current relay of the spring restrained instantaneous three-element induction type on each generator intended to trip out in case of careless synchronizing. As our differential groups of current transformers do not include the delta bus and low-tension terminals on the transformers we have installed a ground relay to trip in case of ground on that section of the wiring. To date the relays today have operated as they were intended to operate, and have not operated when they were not intended to do so.

R. N. Conwell: In the announcement of this paper the statement was made that "relays do not constitute a profitable business." Undoubtedly, the writer of that phase had in mind development and manufacture of relays. The question, "Do relays constitute a profitable business for power companies?" may be answered just as definitely if accurate interruption and relay operation records are kept.

The question has been answered by one operating company and it is hoped that the presentation of the results of the analysis by which the answer was obtained, will lead other companies to make similar analysis.

The interruption and relay operation records for a five-year period on thirteen typical substations or about 15 per cent of the total number of substations in the system were examined and all interruptions which were unavoidable or not chargeable to relay protection eliminated. These interruptions included those due to operating mistakes, failure of oil circuit breakers, bus short circuits, failure of control or excitation sources and similar causes.

The relay protection in 1917 was no better nor worse than that to be found on many systems today. Intensive relay work in the field was started in the spring of 1918. The table shows the results of this work.

NUMBER OF AVOIDABLE INTERRUPTIONS

Substation	1917	1918	1919	1920	1921
A	26	7	9	4	0
B	15	6	4	1	0
C	8	4	3	3	0
D	7	3	1	0	0
E	17	12	3	1	1
F	35	37	9	12*	6
G	26	7	8	2	0
H	22	21	7	10*	2
I	18	41	9	16*	3
J	23	8	8	6	0
K	11	0	2	0	0
L	48	22	5	12*	9
M	15	3	5	3	0
Total interruptions	270	171	73	70	21
Total cases of trouble	288	302	185	212	130
Interruptions per case of trouble	.94	.57	.39	.33	.16
Lost revenue	$8500	..	..		$150

*Increase due to the most severe lightning season in the history of the company.

Capital Expenditure for Improved protection	$25,000.00	
Fixed charges at 15%	3,750.00	
Engineering, maintenance and testing	1,300.00	
Annual charge (13 substations)	$8,050.00	
Recovered Revenue basis for 1917-1921 figures		$8,350.00
Annual profit		$300.00

On the basis of these figures, relay installations in this company "do constitute a profitable business" for in addition to a small cash dividend, they pay a much larger additional dividend in the reduction of damage to apparatus and equipment, and the increase in the good will of actual and prospective customers, by insuring continuity of service.

There is an interesting point in connection with Mr. Ackerman's discussion on the question of the grounded neutral. On this particular system, which consists of 13,000 and 26,000-volt lines, covering quite a considerable territory, the neutral was grounded in November 1918, and you will note the decrease of the cases with trouble after the grounding of the neutral, I think that this decrease is strictly chargeable to the grounding of the neutral.

A. H. Sweetnam: One of the larger central station companies has made during the past year rather extensive application

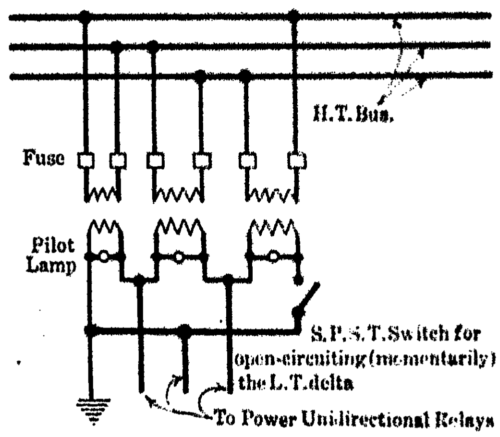

Fig. 2

of power unidirectional relays. The system so protected consists largely of multiple lines, supplying a number of substations in series.

There have been two cases of incorrect operation—**that is,** the unidirectional relays in one station have operated when the fault (a cable failure) was found beyond the station in which the relay operation occurred. In each case it was later found that

one potential transformer fuse was blown resulting in changed relation between current and potential in the individual relays.

To avoid the probability of a repetition of such incorrect performance it was suggested to the manufacturer that three potential transformers be operated in closed delta with six primary fuses. The reply advised that this plan would be entirely feasible but that no difficulty would be experienced if a change were made to the fuse supplied by this particular manufacturer.

Notwithstanding this recommendation, the practise of this company now contemplates the use of three potential transformers and six primary fuses. It may be said that with six fuses the fatal day is only somewhat deferred, as with one fuse blown normal operation will be experienced until the second fuse fails. In this case, however, it is the practise to install a pilot lamp directly across the secondary of each potential transformer and install a s. p. s. t. switch in the low-tension delta connection. In this way at intervals such as may be considered advisable the continuity of primary fuses may be checked. (See Fig. 2.)

E. P. Peck: One of the biggest sources of trouble or failures in the operation of relays that we have experienced was not due to the relays themselves but due to the changes in the number of generators at the station. In the season of the year when there are high water periods most of the load is carried on the water power plants, and in the season of low water periods, most of the load is carried on the steam plants,—a condition which makes it almost impossible to make the proper relay application. This month we may be operating through our low period of the day with five machines in service in the hydro plant. The relays at the station and on the line must be set so that if one line is out of service, the other line is perfectly suitable for carrying the load without danger of an interruption. Next month, when the effect of the extremely high water that some of us have had has passed over, we may be operating only one, or at most two, generators in the hydro plant with most of the load carried by the steam plant. We cannot go over the system and reset all of our relays, consequently during cases of trouble our relays may not function. We have not had any advice from the relay engineers as to what to do to take care of that trouble.

Quite a number of our relays were set in a waterproof case out of doors to save wiring, and on these we had some particularly serious cases of relay failure. We found there was a little corrosion at some critical point, which caused the relay to fail. As a result of one or two cases of that kind, we have inaugurated a system of testing all relays, wiring and circuit breakers on the system that can possibly be tested, every week. Starting at twelve o'clock midnight on Saturday we test every circuit breaker on the system that can be tripped, by closing the relay contacts. That practise has caught a large number of things that would have caused trouble.

Near the end of the paper (Dec. JOURNAL), there is an interruption analysis sheet form given. I suggest that the name of the form be changed. A good many of us are keeping interruption analysis records now, and the interruption analysis records are very different from relay operation records. I think the better heading for that sheet would be "relay operating records" so that the stenographers will not always be pulling out the wrong report when you want the relay operating record.

W. H. Cole: Some four years ago I presented a paper at a meeting of the Institute on "The Experience of the Boston Edison Company with Balanced Protection," including our experience since 1913 with split-conductor cables. At that time our operating experience was rather limited, but at this date we can say that we have had an operating experience with split-conductor cables approximating 600 mile-years.

Everything brought out in the original paper regarding advantages and troubles incident to the use of these cables has been confirmed by more extensive experience in the last four years. All the favorable results have been continued. A great many of the doubtful relay actions have been cleared up, so that they are now considered normal and creditable.

As I analyze the situation, the principal disadvantage of split-conductor cable, or pilot-wire protection is the extra cost of construction and installation. These costs are admittedly high, but by many transmission engineers are considered to be well warranted. However, other protective schemes are being applied utilizing standard conductor lines with nearly the same advantages derived from split-conductor cables or pilot-wire schemes.

One serious objection to the use of split-conductor cables and pilot-wire schemes is that more duct space is required, which in many cases is vital, particularly in this country where the conduit system is standardized. It is obvious in the one case that split-conductor cables will be larger in diameter for a given capacity than standard cables, and in the other case pilot cables require duct space for their installation. Both systems of protection may be so arranged as to give ideal protection. The remaining question is what are they actually worth. The pilot-wire scheme has been improved very much in recent years and some of the original objections are eliminated, so that it may be said that it is coming back into its own, especially where no duct space is required, as in foreign practise where the pilot wire is laid in the open ground adjacent to the corresponding power cable.

One of the objections to the split-conductor raised abroad by large undertakings is that they usually lay a telephone cable with all power cable installations. In making up the telephone cable they find it convenient to combine the telephone conductors with pilot conductors in one cable, thus accomplishing two results with one cable. With the pilot-wire system of protection, as improved by Beard & Hunter, the combination of pilot wires and telephone wires has brought the total cost down to less than the cost of split-conductor construction. It seems that the whole question is one of economics, but engineers, who have ever had any large experience with split-conductor cables and pilot-wire schemes, generally agree that such systems are ideal.

O. C. Traver: Mr. Ackerman remarked in connection with the balanced schemes described for the protection of two parallel lines that if one of them should become accidentally open-circuited, it would have a tendency to open the other good line. While this is true there does not seem to be any material hardship resulting in practise. Furthermore, I believe the difficulty equally true of the other schemes mentioned by Mr. Ackerman as well as any balancing scheme when two lines are involved. In the same way when three lines are balanced practically any of the schemes described in the paper will properly take care of the matter in substantially the same manner as the one referred to by Mr. Ackerman.

I would like to add a word of caution in regard to the adjustment of relays used in the protection of systems with comparatively high resistance from neutral to ground. This warning is not intended in any way as an alarm, because in many cases the system has excellent possibilities. I know, however, that in a number of instances where ground current has been limited by resistance some of the resulting effects have been overlooked. Particularly in those cases where grounding transformers are located at some place other than the generating source, the intensities of the currents and the directions of power in case of grounds are entirely different from those resulting from phase to phase shorts. It, therefore, requires in most cases a complete separate analysis of the proper current and time settings and a very careful check on the question of directional relays.

H. T. Plumb: We will cite an instance where relays worked successfully. Five years ago relays were applied to the principal three-phase transmission line in Utah, operating at 130,000 volts and transmitting power from the plants in Idaho to Salt Lake City, 135 miles. Settings for the relays were worked out on a calculating table. These settings have not been changed in five years and the relays have given practically 100 per cent performance. There has been only one failure which is possibly chargeable to the relay. This is conclusive proof that these relays work.

With regard to the remarks of Mr. Stauffacher and his difficulty with curious short circuits this transmission line of which I speak was subject to very peculiar and many short circuits or flashovers between conductors. There were various theories for these failures. Some thought it might be due to the numerous swarms of small flies out of a nearby swamp. Others imagined many curious things were the cause of the trouble, but they never were sure of the cause. That was nine years ago and the trouble has not recurred. The most generally accepted theory is that the short circuits were caused by large birds, and that these birds did not leave evidence as to what had actually happened. It hardly seems possible that birds could receive the full line pressure, 130,000 volts, get away with a few burned feathers, and never leave anything else behind. In any event it seems that experience with the live wires taught these big birds how to alight on the towers, and to fold their wings so that they will not make a short circuit. Young birds might start the trouble again until they learn to be cautious.

L. N. Crichton: I would like to emphasize the question of simplicity in relay installations. It is easy if you work long enough and painstakingly enough to devise a scheme which will fit every requirement of a complicated system. But sometimes you find you have overlooked something, and other times you find that the scheme is so complicated that the men who operate it do not maintain it properly. In reading this report, it is important to remember that many operating companies have gotten over the trial period, and they no longer have any *trial* relays. One of the largest operating companies has 342 sections of lines protected by carefully designed relay schemes. This requires 1845 relays and 644 automatic circuit breakers. Bear in mind that this refers only to the devices for automatically sectionalizing the network and that these figures do not include the devices for protecting apparatus. This extensive relay system is justified not only by the improved service rendered, but also by the saving in copper which results from the close interconnection of feeders. Incidently, this system uses only the simplest schemes of relay connections. Now, by way of prophecy, the calculating table will become of less importance and the more or less laborious calculations now necessary to determine the proper relay settings will decrease as the relay art advances. Relays are being developed which will determine the location of short circuits and will operate only when the trouble is close to them. Elaborate calculations will not be necessary since each relay will make its own calculations when the trouble occurs.

It is possible that a description of such a relay will shortly be presented under the auspices of the Relay Sub-Committee.

W. R. Bullard: The description of the ground selector relay scheme of which Fig. 18 is a wiring diagram is particularly interesting because of its similarity to the operation of the so-called "arcing ground suppressor." However, the results accomplished by the latter are just the reverse of those described in this paper in that the arcing ground suppressor is used to ground the leg on which the fault occurs (instead of an opposite leg.) It therefore suppresses the arc and prevents it from producing a short circuit. Up to the present time the chief application of this type of apparatus has been in connection with distribution systems. A number of these suppressors are in actual use on such systems and have apparently been giving remarkably good service for several years. Their main advantage lies in their ability to eliminate the occurrence of a large number of short circuits and thereby reduce the number of outages. However, there is no apparent reason why the same scheme could not be applied to transmission. Such application would seem to be a more logical one than that of the scheme mentioned in this paper, since the effect would be to minimize the disturbances on the transmission system instead of deliberately creating them.

The authors lay particular stress upon the development of balanced protection for parallel lines. These schemes have a considerable number of advantages, the chief one being that of minimizing the necessity for a large number of selective time settings. However, one great disadvantage of some of these schemes lies in the necessity of keeping all the feeders of a group in service to secure the proper operation of the system. I am sorry that more space has not been given in this paper to detailed description of operating conditions under which these schemes have been used, and specific methods of over coming this difficulty.

Referring to the various schemes which have been developed for ground protection, the chief advantage of this form of protection lies in the ability in some cases to use extremely low time settings thereby disconnecting the faulty unit before a phase to phase short circuit has had time to develop. It is stated in the review preceding the paper that the application of these relays with regard to current and time settings is based on the same principles that apply to relays used for short-circuit protection. However, it should be noted that where two or more selective time settings are used, the purpose of the special protection is in danger of being defeated by the greater time taken to clear the fault. It would therefore appear that the only real solution to the problem in this case would be the combination of ground relays with other more expensive schemes, such as pilot wire and other such systems.

S. W. Mauger: Too little attention was formerly paid to the subject of protection of lines both by designers and operators, the former not being able to appreciate the requirements, until the operators awoke to the necessity of further study and placed the condition more clearly before the designers.

In many cases, relays were simply considered as auxiliary devices to cause circuit breakers to open in case of trouble. The broad subject of continuity of service was not thought of in connection with relays which indeed were thought of only as *interrupting* continuity.

Modern relays, although comparatively insignificant in themselves, when properly applied, make it possible to maintain continuity of service with stations interconnected to give maximum efficiency of conductors. This may result in some cases in the saving of thousands of dollars in investment, as the multiplying of circuits and the isolating of stations to avoid general shut downs is obviated.

As a result of the awakening to the real needs which were becoming more and more serious due to expanding systems, the manufacturers in cooperation with the operators went into the subject intensively and at considerable expense and they are now able to furnish relays to meet practically all conditions. There is still much work to do on the part of the manufacturers but they are alive to this fact.

Many operating companies are giving the matter serious attention, but it is feared that there are many more who are not and it is hoped that the relay paper under discussion will be earnestly studied by all operating companies. I would particularly stress the matter under the headings of "The Calculation of Short-Circuit Currents," "Relay Application," "General Practise in Relay Settings and Tests" and "Operating Records."

Power Development on the Colorado River

And its Relation to Irrigation and Flood Control

BY O. C. MERRILL

Executive Secretary, Federal Power Commission

, of the Subject.—*The Colorado River drains an area*
) square miles in the States of Wyoming, Colorado, Utah,
nd New Mexico, Arizona and California, and in the
States of Sonora and Lower California. It is the third

immediate problem on the river is, therefore, flood pro-
this valley. Such protection can be secured by a storage
ither at the head or at the foot of the middle section. The
appears the more immediately available. The upper site
wever, afford adequate flood protection and give irrigation
for many years, and would, in addition, control the
tion for power development. The location of the primary
storage on the river is an important matter and may determine the
whole course of power development.

The rate of power development on the Colorado is a question of markets. With the exception of the mining district of Arizona, which might absorb 100,000 horse power, there is no present market in the basin sufficient to justify large-scale development. The most available outside market is Southern California which apparently could furnish sufficient demand for the initiation of power development on a considerable scale. Extension of such development in the future would involve interconnection, common control, and long-distance transmission.

Applications involving the Colorado and aggregating four and one-half million horse power are on file with the Federal Power Commission which has suspended action awaiting decisions upon collateral matters. The individual states have control over the appropriation of waters within their limits. To avoid the danger of future interstate litigation over water rights, the Colorado River Commission was created under authority of Act of Congress to work out a "compact" or "treaty" between the several States. It has not yet reached any conclusions. The stream also is international and irrigation rights in Mexico are involved. Finally, there is conflict over the question whether development shall be made by private capital or by the Government. These various conflicts of interests and of agencies are likely to postpone for a considerable time the solution of the problem of Colorado River development.

CONTENTS

INTRODUCTION

of the most important and interesting of ur present day engineering problems is the ontrol and development of the Colorado River. est and importance arise from the fact that es the irrigation of millions of acres of land, luction of millions of water horse power, and tection from floods of millions of dollars of values, and that it affects the general economic of seven of our States and two of the states of It is of interest also in its political relations this term in its etymological, not its ordinary Seven sovereign states claim in the use of the f the Colorado rights which in the aggregate eed its possibilities. Its waters can not be se without the sanction of the states in which is proposed and without the concurrent sanc- he Federal Government which owns the lands y for such use and which possesses a general control over the river from the fact that it is an international stream. It remains to be seen to what extent political considerations will modify engineering considerations in the solution of the problem.

The two main branches of the Colorado rise, the one in southwestern Wyoming, the other, in central Colorado. The length of the river from the headwaters of the Green to the Gulf of California is about 1750 miles. Its basin with an area of about 250,000 square miles includes practically all of Arizona, nearly one-half of Colorado and of Utah, one-fifth of Wyoming and of New Mexico, one-tenth of Nevada, and a narrow strip in California along the California-Arizona boundary. The Imperial Valley in California, though not topographically a part of the Colorado basin, should also be included because of its dependence upon the waters of the river and because of its intimate relation to the general problem of river control. Of the area of the basin some five million acres, or about one acre in 30, appear economically irrigable. Claims, however, have been made that there is a much larger amount of available irrigable land. The annual run-off of the

ed before the Washington Section of the A. I. E. E., 1922, and at the Pacific Coast Convention of the ., Vancouver, B. C., August 8-11, 1922.

river at Yuma averages about 18 million acre-feet. The average discharge is about 24,000 cubic feet per second, with variations from a minimum of 4000 second-feet to a maximum of 150,000 second-feet on the main river, and to 240,000 second-feet by inclusion of the Gila. The steep slope of the river and its large volume make it capable of producing some six million water horse power, or two-thirds as much as is developed in the United States today.

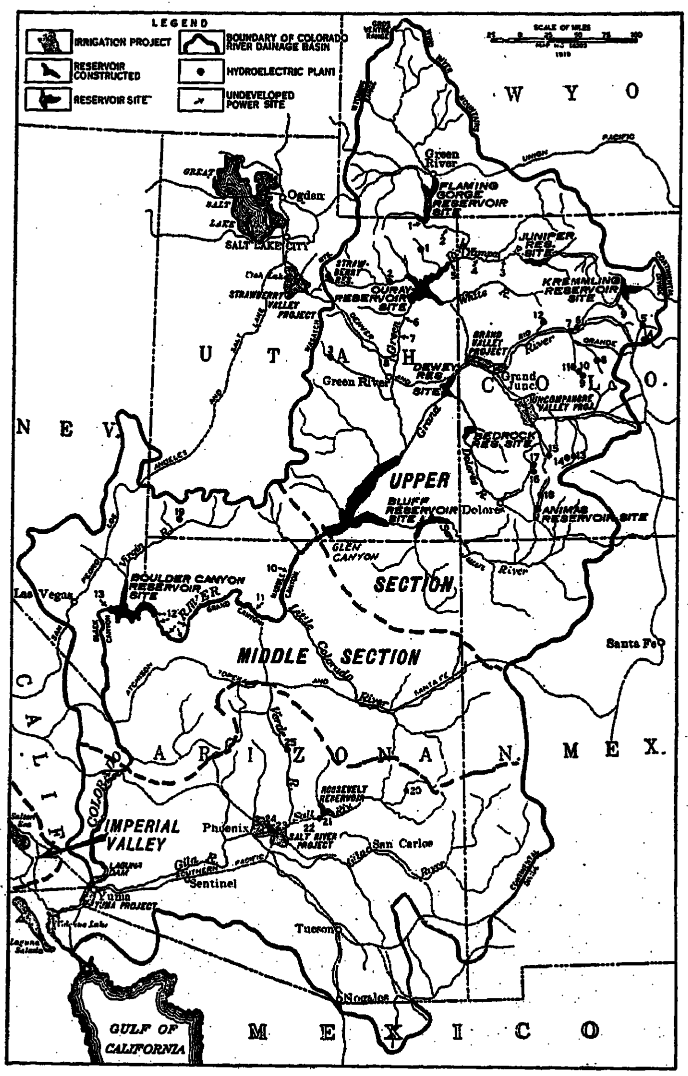

Fig. 1—Colorado River Basin
Divided into sections.

Three Main Sections of River

A discussion of the general problems of the Colorado will be made clearer if we divide the river into three sections and consider the characteristics of these sections and their relations to each other. (See Fig. 1).

The upper section from the headwaters to the Utah-Arizona line, just below the mouth of the San Juan, comprises about 40 per cent of the area of the basin and affords about 87 per cent of the total run-off, or an average of about 15,000,000 acre-feet per annum. In this section are some 2,500,000 acres of irrigable land, one-half of the estimated total in the basin. It also has power possibilities aggregating 2,000,000 horse power. In this section, both upon the main stream and upon its tributaries, are many favorable reseorvir sites by means of which it would be practicable to regulate the flow of streams for irrigation within the section, or for power development both within the section and outside, or, if desirable, for flood control on the lower river. In so far as the tributaries are involved, these several uses would conflict to a considerable degree and only a careful study of the whole section could determine the best combination of uses. At the lower end of the section is the so-called Glen Canyon reservoir site which has an important bearing on all developments and uses of water below.

The middle section from the mouth of the San Juan to the mouth of the Williams comprises about 35 per cent of the area of the basin and supplies about 7 per cent of the annual run-off. There are no irrigable lands along the river in this section and only some 250,000 acres on the tributaries, none of which can be reached from the main river. In this section, however, there is a total drop of about 3000 feet, capable, if fully utilizing the average annual run-off entering the section, of producing 4,000,000 horse power. Except for the Boulder Canyon site near the lower end of the section, which would have no effect on the greater part of this section, there appear to be no storage sites capable of providing any considerable amount of seasonal storage. Dams erected for power development would be primarily for the purpose of concentrating head and of providing pondage for daily load regulation. Seasonal regulation would be dependent upon storage in the upper section.

The lower section from the mouth of the Williams River to the Gulf and including the drainage of the Gila and the Imperial and Coachella valleys in California, comprises some 25 per cent of the total area of the basin and furnishes about 6 per cent of the average annual run-off. Its power possibilities are relatively unimportant, but it contains some 2,250,000 acres of irrigable land, the most fertile and most valuable in the basin, of which a large part is periodically endangered by floods. There appear to be no reservoir sites of consequence below Boulder Canyon on the main river, but there are such sites on the Gila which could be used both for irrigation and for controlling the Gila floods.

Viewed solely from the physical standpoint, the upper section of the basin might have its primary development directed either toward irrigation or toward water power; or it might, as it probably will, have a combination of these two uses. On the other hand, the middle section, with the exception of storage below the mouth of the Virgin and of relatively small irrigable areas on the tributaries, is suitable only for power development. Equally clearly, the waters reaching the lower section should be devoted primarily if not exclusively

to irrigation, and the storage sites should be employed for irrigation or flood control or both.

Flood Control Problem

The most immediately pressing problem on the Colorado River is flood control for the protection of the Imperial Valley in California. I shall not attempt, however, to discuss it in detail, but merely to present certain aspects of that problem in the relation they bear to water power and to a general plan of river development.

The Gulf of California originally extended northwesterly into what is now the State of California. The silt-laden water of the river gradually formed a delta cone extending across the Gulf, cutting off the northern end and deflecting the flow of the river to the south. The waters inclosed in the northern end evaporated leaving the depression known as Imperial Valley and the Salton Sea with its surface 250 feet below sea level. The silt-formed delta is unstable. The river is constantly depositing more sediment and shifting its channel back and forth over the flat ridge—some 30 feet above sea level—which forms the crest of the delta, and there is danger at each flood season that it may break northward into the Imperial Valley instead of continuing southward into the Gulf. The river did break through in 1905 and for more than a year and a half discharged into Salton Sea before it was turned back with great difficulty and expense into its old channel. The levees which were later built to protect the valley have several times been awash in periods of floods. It is necessary to raise them about a foot a year to keep pace with the rise of the river channel, and it is only a matter of time until the river will break through again unless steps are taken to control the floods. The situation is further complicated by the fact that the works for protecting the Imperial Valley are situated in Mexico. It is this condition of affairs which has placed primary emphasis on flood control in all plans for the development of the Colorado River.

Flood conditions on the lower Colorado may be caused either by high water on the main river or high water on the Gila. Flood conditions on the main river occur annually in the summer season, due to the melting of snows on the headwaters of the streams, and continue on the average from two to three months. The maximum flood from the main river in the years of record, 1902 to 1914, inclusive, has been 150,000 second-feet. The average mean monthly discharge during the three high months of May, June and July, for this same period of record has been: May, 42,600; June, 73,100; and July, 43,500 second-feet. While the floods from the Gila approach in magnitude those of the main river, they occur in the winter season, are caused by local rains, and are of short duration. Should it happen, however, by any combination of circumstances that extreme flood conditions on the Gila should coincide with similar conditions on the main river, a break through into the Imperial Valley would be almost inevitable.

On account of the volume of water involved it is apparent that protection from Colorado River floods can be had only by storage and by storage of large capacity. It is also apparent that full immunity from flood damages can be had only by storage on the Gila as well as storage on the Colorado. Since, however, storage on the Gila has only an indirect relation to the general problem of the Colorado River, it will be given no further consideration here.

There appear to be three practicable locations for flood control reservoirs of the capacity necessary. These are on the headwater tributaries, on the main river at Glen Canyon, and on the main river at Boulder Canyon. Storage on the headwaters would require

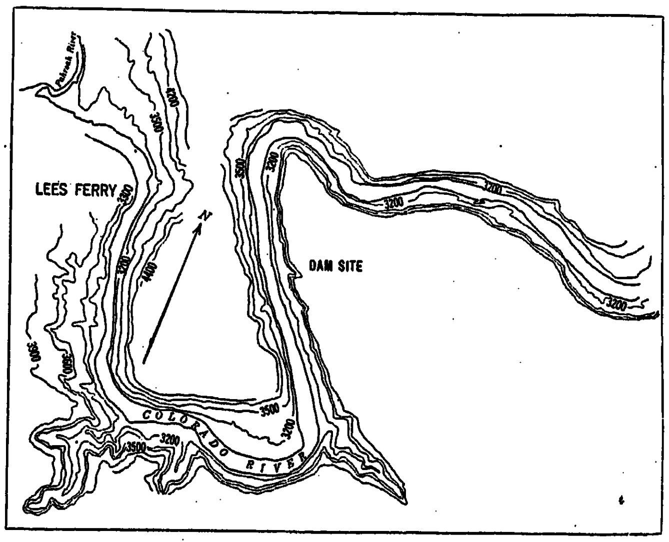

Fig. 2—Glen Canyon Dam Site
Site of proposed power development at Lees Ferry, Arizona.

several reservoirs and even though practicable from a purely flood-control standpoint, such a plan involves at least two serious objections. The operation of such reservoirs to meet the needs of the lower river would be likely to interfere to a considerable degree with the use of the waters for irrigation in the upper section and to a less degree for power development, depending upon their location and their manner of operation. If duplication of investment is to be avoided flood control reservoirs must also provide irrigation storage for the lower river. To operate for this purpose reservoirs located hundreds of miles above the lands to be irrigated would be an extremely difficult problem and would inevitably result in wastage of water and consequently in a storage capacity greater than would otherwise be necessary.

Adequate storage for both flood control and irrigation could apparently be had at the Glen Canyon site at the Utah-Arizona line. (Fig. 2.) From an irrigation standpoint this site presents similar objections,

though less in degree, to sites on the headwaters since the reservoirs would still be a considerable distance from the lands to be irrigated. From a flood-control standpoint, however, it appears adequate. It would intercept 87 per cent of the run-off of the basin, and would include every tributary of consequence above the Gila, except the Little Colorado. This stream is subject only to flash floods and enters the main river so far above the Imperial Valley that its floods can not be considered as dangerous. Storage at this point is of sufficient capacity to provide for power development and irrigation as well as for flood control, and hence would not interfere with, but would be a distinct aid to power development in the middle section.

engineering problems of magnitude. To provide the proposed minimum storage capacity of 21,000,000 acre-feet at Boulder Canyon and an equal amount at Glen Canyon will require dams of unprecedented height. Preliminary plans propose a masonry dam at Boulder Canyon some 530 feet in height above the river channel. When it is realized that the river channel has a depth of 135 feet below water level, that the river flows through a narrow canyon, and that floods in excess of 100,000 second-feet are likely to be encountered during construction, the magnitude of the engineering problems to be met will be appreciated.

Detailed investigation, particularly borings, have not yet been made of the Glen Canyon site, and the

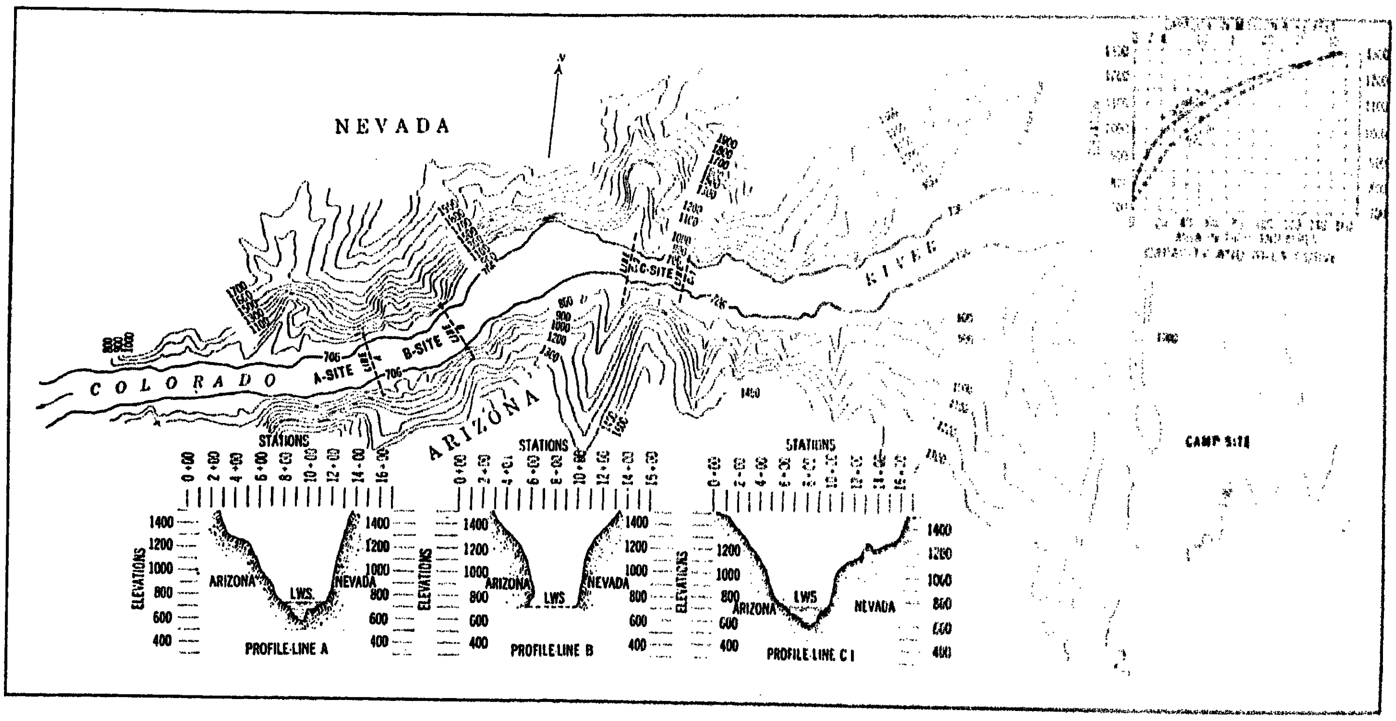

Fig. 3—Boulder Canyon Dam Sites
Topography and Profiles.

The proposed Boulder Canyon site (Fig. 3) has certain distinct advantages over all other sites if considered wholly from the standpoint of the flood control and irrigation requirements of the Imperial Valley. It is comparatively near to the irrigable lands, and operation difficulties would be reduced to a minimum. It will intercept all floods on the river, except those from the Gila. It would even be possible to ameliorate flood conditions from the Gila by stopping all discharge from the main river while the Gila is in flood. If nothing but the flood control and irrigation requirements of the Imperial Valley were to be considered, there would appear to be no doubt of the superior advantages of the Boulder Canyon site. When, however, consideration is given to the problem of development of the river as whole, the situation is by no means so clear.

Both the Glen Canyon and the Boulder Canyon sites are likely eventually to be built, and both present type of dam has therefore not been determined. If foundation conditions are not more unfavorable, this site should from the construction standpoint have certain distinct advantages over the Boulder Canyon site. The river forms a double loop at the dam site, one-half of which is 28,000 feet around but at its narrowest parts only 3600 feet across at water level, and only 2000 feet at 500 feet above water level. This condition provides better opportunity for handling water during construction than at Boulder Canyon and also affords better opportunity for constructing outlet works and spillway independent of the dam by carrying the one through and the other over the narrow section which separates the two sides of the loop.

Irrigation Problem

When we consider the relation of irrigation to power development we find that only about one acre in thirty

i the Colorado basin is irrigable, but that it has power esources more than sufficient to meet its needs for enerations. Since it is likely to require all the agricultural products that its lands can supply long before has put to use all its potential water powers, it would ppear the part of wisdom to dedicate the waters of s streams to irrigation to the extent they can be fficiently used for such purpose, leaving water-power evelopment to take the second place. If reasonably onservative practises are followed and all unnecessary aste avoided, there appears to be ample water in the olorado and its tributaries to irrigate all lands within onomic reach of the streams. The problem of water upply for such purposes is, therefore, one of equitable istribution; and this is the problem which the Colorado River Commission has been created to solve. shall not discuss it further than to say that, if irrigaon be assumed as the dominant use, there would still e opportunity to develop hundreds of thousands of orse power in the upper basin under properly eveloped plans and that, from the water which would e released from the upper section for the irrigation equirements of the lower section, there would still be vailable millions of horse power in the middle section. Since there will be no irrigation development in the iddle section of the river other than the probability f the provision of irrigation storage at the lower end f the section, and since no water will be withdrawn om the river in this section for such purpose, there will e no conflict between irrigation and power. In the pper section, however, such conflict is certain to xist. Not only will water be permanently withdrawn om the river, but storage reservoirs can not be fully sed for both purposes. For this reason, as well as on ccount of the greater volume of water and the greater all, the middle section is the most favorable for power evelopment. But power development on the Colorado, as well as irrigation and flood control, requires easonal storage. This is necessary not only to produce regulated flow, but also, in the canyon section at east, to provide a protection against floods, for the arrowness of the river channel and the consequent estricted spillway length is likely to produce depths f discharge in flood season that might seriously restrict he height of dams that it would be save to construct. On account of topographic conditions sufficient apacity for seasonal regulation can not be secured in he middle section except at Boulder Canyon, and that f course is available only for use at that site or below. 'or the greater part of the section storage must be ither at the head of the section or in the upper river. f it proves feasible of construction, Glen Canyon eservoir is peculiarly well adapted for the purpose. t is situated at the crest of the steep canyon slope and ppears to have a capacity sufficient to equate the ow of the river over a series of years.

The fact that this reservoir must eventually be uilt in connection with power developments below and that when built it is likely of itself to solve the flood problem of the main river has naturally raised the question, why build both Glen Canyon and Boulder Canyon, or if both, why build the latter first. The construction of Glen Canyon reservoir by eliminating flood conditions would make the construction of all dams in the river below far easier, cheaper, and safer. Nothing which may be done at Boulder Canyon will obviate in any degree the eventual necessity for Glen Canyon reservoir or reduce the difficulties of other construction in the canyon above. On the other hand, if Glen Canyon is built, the greater part of Boulder Canyon storage—as storage—would become useless. It would seem, therefore, that the prior construction of this dam could be justified only on one or both of two grounds. Either that the imminence of the peril to the Imperial Valley justifies the cost of the Boulder Canyon dam even if only temporarily required for flood control purposes; or that the cost is justified, independently of storage, by the additional power that could thus be produced by a dam of the height proposed. In any event, some storage below the Virgin is desirable, if not necessary, even if Glen Canyon reservoir is constructed, in order to regulate the water at that point to meet immediate irrigation requirements farther down the river. Which reservoir should be built first and whether the full capacity of both is needed are questions about which there is considerable difference of opinion. I shall only say that there appears to be enough doubt to warrant a thorough study of the upper site before commitment is made to Boulder Canyon, and that in such study due consideration should be given to power developments in the middle section as well as to irrigation and flood control on the lower section. I have placed emphasis upon this question of the location of primary storage, whether at the head or at the foot of the middle section, because it is a factor of great importance in the problems of power development and may determine the entire course of such development upon the river.

Power Development Possibilities

The extent of the interest in the power possibilities of the Colorado River (see Figs. 4 and 5) may be judged from the fact that there are on file with the Federal Power Commission 20 applications affecting the Colorado River and its tributaries aggregating four and one-half million primary horse power and six million horse power of estimated installation. It is, however, quite apparent that no such amount of power will be developed in the near future simply because it could not be disposed of. The rate of power development on the Colorado is a question of markets. The sites at the headwaters will gradually be developed to supplement the existing Utah and Colorado power systems. When we turn to the middle or canyon section, however, we find that local demands for power in this part of the Colorado basin are hardly sufficient

to justify at the present time any large-scale development. The mining market of central Arizona probably would justify an initial development of some 100,000 horse power, but to justify large-scale development utilizing any such storage as proposed at either Boulder Canyon or Glen Canyon would require that primary markets be sought outside the basin, a situation involving long-distance high-tension transmission.

The only section which at present seems capable of furnishing the requisite demand, and the section which gives greatest promise of increasing its demand in the near future, is the southern half of the State of California. Notwithstanding the great power resources of that state, objection is already being raised against the diversion southward of the electric energy generated from the waters of the central and northern sections of the state. With the continued depletion of its oil reserves and with increasing industrial and agricultural development, the time appears not far distant when California, should it maintain its present growth of power demand, would be required to go outside its boundaries for new sources of power, even if economic considerations did not lead it to do so at a much earlier date.

The development of power in the basin of the Colorado for use outside will, however, be an advantage, not a disadvantage, to the people and the industries within the basin. The potential power available is more than the basin itself is ever likely to require. If power is developed on such a scale and at such a cost that it can be economically delivered in large quantities, hundreds of miles from the point of generation, it can be economically delivered near at hand in smaller quantities, and this fact, if the power is developed under proper auspices, would result in the extension

of facilities to existing local markets and in the development of new ones; for the most complete disposition of its products is the ultimate object of power development. The mining areas within the basin, the railroads which traverse it, the towns within it and along its margin, all would be sought out as users of power once development were made and the main transmission system established. Distribution of power throughout a sparsely settled area is, however, likely to be attempted only through extensions from a transmission network constructed primarily to serve other and more extensive markets elsewhere. The states within the Colorado basin would never have secured the railroad service they now possess had they not been on the main routes between the Mississippi Valley and the Pacific Coast. They will be in a similarly favorable position with respect to electric power service when trunk transmission lines are constructed across their territories.

The final factor which determines whether power sites can be utilized, the degree to which they may be developed, and the distance to which the power may be transmitted, is of course, the unit cost of energy delivered. To a considerable degree unit costs are less as quantities increase. Particularly on a stream like the Colorado where, irrespective of the size of the project, large preliminary expenses will be involved and long and expensive transmission lines will be required, large-scale development is likely to prove much cheaper in construction costs per unit of available output than small-scale development. The extent, therefore, to which the water powers of the Colorado are to be developed and the degree to which they will be made to serve the interests of the Colorado basin itself are likely to depend largely, if not primarily, upon whether the power is developed in isolated independent units or in a system of interconnected plants with a transmission network extending over the entire territory. If development proceeds by independent units, a few restricted areas will get the benefit of such part of the resources as are developed. If the other plan is followed the entire basin and all the adjacent territory may share in the benefits. Such a plan, however, can be carried out only by agencies whose authority is not circumscribed by state lines—agencies in whose own interest it will be to extend as widely as possible the territory which they serve. Such a plan does not necessarily imply either a single ownership, or Government ownership; but it does imply such an interrelationship, at least, as will insure the operation in one interconnected system of the power developments on the Colorado River.

Political and Economic Considerations

We come now to a brief consideration of what we have called the political relations of the problem. Under the provisions of The Federal Water Power Act, applicants for license must present evidence of having secured from the state, necessary rights for the diversion and use of water. It is the general rule of law within the Colorado basin that he who first puts the waters of a stream to use has a first right in their use. On this doctrine of priority of appropriation, extensive rights to the use of the waters of the Colorado have been acquired on the lower river, for it is that section of the river which is being the most rapidly developed. The fear has consequently arisen in the states in the upper section that, before the time when they can put what they believe is their share of the water to use, rights to such share will have been acquired on the lower river, particularly if power developments utilizing the full flow of the stream should be authorized on the middle or lower river. Because of this fear and in the hope that the matter might be settled without the endless interstate litigation that would otherwise be almost inevitable, a proposal was made that the several states affected enter into a treaty or compact by which they should mutually agree on the apportionment among themselves of the waters of the river. Under the provisions of the Constitution, such a compact or agreement between states requires the assent of Congress. This assent was given by Act of Congress of August 19, 1921, which authorized the creation of a commission to be composed of one representative from each of the seven interested states, who, together with a member appointed by the President, should form a Compact Commission, and should report their conclusions to Congress on or before January 1, 1923.

This Commission has been appointed with Secretary Hoover as the representative of the United States and chairman, has held several sessions, but has thus far come to no agreement. Under the terms of the Act creating the Commission, its authority is limited to the determination of an "equitable division and apportionment" of the waters of the river among the states. It has no authority to grant rights itself, and its powers do not conflict with those of the Federal Power Commission or other federal or state agencies. Since, however, its conclusions might affect or be affected by the approval of applications by the Federal Power Commission, action upon such applications has been suspended awaiting the conclusions of the Colorado River Commission.

There are also international relations involved. The Colorado River forms the boundary between the southwestern tip of Arizona and the Mexican State of Lower California. Below the Arizona line it separates Lower California from Sonora. Some 190,000 acres of land in Mexico are now being irrigated from the river, and it is estimated that 630,000 additional acres are irrigable, a total of 820,000 acres or 40 per cent of the irrigable area tributary to the river below Boulder Canyon. Under such circumstances it is manifest that international comity, if for no other reason, requires that this situation be taken fully into consideration in any plans of Colorado River develop-

ment. In its Preliminary Report on the Problems of Imperial Valley and Vicinity of January, 1921, the Reclamation Service recommended equitable participation by the Mexican Government in the cost of storage works, and arrangements with that Government for the construction and maintenance of flood protection works on Mexican soil. Such participation and arrangements could, of course, be brought about only by the concurrent action of the two Governments.

There is also the question of the degree to which the United States should itself take part in power or other developments along the river. It is argued, and with apparent justification, that the cost of flood and irrigation storage is greater than the irrigation interests alone can bear and that, therefore, the Government should itself construct the works and recoup itself by sale of power, some 600,000 horse power of which could be developed at Boulder Canyon. Whether this arrangement would or would not effect an equitable distribution of benefits among irrigators and power consumers, I am not prepared to say.

There are furthermore those who advocate development at Government expense of all the powers along the Colorado River, the distribution of such power by the Government at cost, and the prohibition of any development by private capital on the river. This is, of course merely an instance of the age-long contest, between advocates of public and of private ownership and operation. On account, however, of the probability that it may be found necessary that the Government participate in the development of the river at least to the extent of furnishing flood protection, general action is unlikely to be taken upon the applications before the Federal Power Commission until conclusions have been reached upon the extent, if any, to which the Government should thus participate.

Finally agreement among the several interested agencies should be reached on the general procedure and the general plan of development to be followed on the river, in order that whatever work is done or projects constructed may fit into a scheme for the fullest practicable utilization of the river for all uses to which its waters are adapted. There is an apparent existing need for additional power in certain sections within the basin. The several interested agencies should, therefore, reach their conclusions at the earliest practicable date so that the present order of suspension may be lifted.

Summary

The primary elements of a general plan for river development appear to be as follows: (1) Storage at the headwaters for irrigation in the upper section and for such power development in this section as can be accomplished without undue interference with irrigation; (2) storage below the San Juan of sufficient capacity to control floods and to regulate the water available at that point for power use in the middle section; and (3) storage below the Virgin sufficient, at, least, for regulation to meet irrigation requirements of the lower river and for such additional flood protection as may be necessary or desirable. If this or some similar plans can be agreed upon, and an equitable apportionment of the waters effected, the details of the immediate application of the waters of the river to their respective uses in the individual sections will be greatly simplified, and work may be started on the series of developments upon which the economic progress of the whole Southwest primarily depends.

Discussion

J. B. Fisken: One thought occurred to me when I read the paper and that is that we now have connection over the Idaho-Montana line through to Seattle, Tacoma, and I don't know just how far south, with a break between Tacoma and Portland, and some breaks in Oregon; and I don't think it takes any very great imagination to visualize the time when our plants in Eastern Washington will run in synchronism with plants on the Colorado River. It will not in any sense be transmission from Eastern Washington to Southern California, but it will be simply an interchange of current, our plants furnishing the load as required on the northern end and meeting the western Washington plants, the Oregon plants and so forth.

It is extremely interesting, and as far as I can see, extremely complicated. The question of ownership, of the lines, private, state or Federal, I think, is involved in this, and I am afraid that it is going to take a long time until development will finally take place.

220-Kv. Transmission

Southern California Edison Company System, and Some 220-Kv. Researches

BY R. J. C. WOOD

Associate, A. I. E. E.

Southern California Edison Company, Los Angeles, Cal.

Review of the Subject:—*The rapid growth in the demand for electric power and the increasing distances to which transmission is desirable, have constantly forced the use of higher transmission voltages.*

The Southern California Edison Company, having two single-circuit tower lines 241 miles long from its Big Creek hydroelectric plants to near Los Angeles, had the alternative of either duplicating these lines or of raising the voltage upon them. The latter procedure was found to be vastly the more economical. Other things being equal, the amount of power that can be transmitted varying with the square of the voltage, and the existing voltage being 150 kv., a doubling of capacity will result by raising the voltage to 220 kv.

To avoid the difficulties inherent in changing over generating and substations built for the lower voltage, and in which adequate clearances would be very difficult to obtain, it was decided to use auto-transformers at each such station, transforming between 150 and 220 kv. Additional sectionalizing switching stations will be built in the line, making six in all, so that the rebuilding of the line may be done without crippling service, and insulator testing can be done at any convenient time. An extension of the line 30 miles in length will be built so that the completed 220-kv. system will be 270 miles long.

Preparatory to the final design, a considerable amount of investigation and research was carried on. The best form of insulation that would fit existing towers had to be determined, standard suspension insulators being preferred over new untried designs. Laboratory high-voltage tests of insulation at oscillator frequencies of 30,000 and 50,000 cycles and at continuous 60 cycles were undertaken in order to get as much information as possible, all such tests being made in dummy towers so as to duplicate actual conditions as nearly as possible.

The next step was to equip 27 miles of one Big Creek line with additional insulators and shield rings and carry out field tests. This section of line was energized to 280 kv. for one month, and to 241 kv. for about five months, extending through the greater part of the rainy season. Considerable care was taken to obtain reliable measurements of voltage, current and corona losses.

The results of the laboratory and field tests lead to the firm belief that nothing extraordinary will happen with 220-kv. transmission. The difference between operation at this voltage and existing voltages will be only of degree. There seems to be no pressing need of new designs of insulator so that as new designs are developed they may be given the acid test of time on unimportant lines where their failure will be of small moment.

CONTENTS

THE imminent increase of transmission voltage from the existing maximum of 165 kv. to 220 kv. has been forced by the extremely rapid increase in the demand for electric power, which on the one hand in certain cases, rendered the acquisition of rights of way and building of new lines difficult to effect within the allowable time and upon the other, has led to the transmission of such large quantities of power over long distances, that the higher voltage was required to realize the lowest total cost per kilowatt-hour delivered.

The Southern California Edison Company was confronted with the problem of doubling the transmission capacity from the Big Creek hydroelectric plants to the territory surrounding Los Angeles. The solution depended upon the conversion of the two existing 150-kv. tower lines to permit of operation at 220 kv., together with such terminal changes as would allow existing plants to feed into the lines, substations to take power from them, and future extensions to be made.

The general plan decided upon was as follows:

Presented at the Pacific Coast Convention of the A. I. E. E., Vancouver, B. C., August 8-11, 1922.

Big Creek No. 1 and No. 2 plants of 32,000 (48,000 ultimate) and 48,000-kw. capacity respectively will remain unaltered, delivering power at 150 kv. to two 52,500-kv-a. auto-transformer banks installed close to each plant. Each auto-transformer bank will have sufficient capacity to convert the whole output of its respective plant to 220 kv., so that there will be full capacity in reserve units.

Big Creek plant No. 8, of 22,500-kw. capacity, was designed and built for 220-kv. operation, but is now operating upon 160-kv. taps of 220-kv. transformers. Upon completion of the 220-kv. system the transformers will be connected for the higher voltage and the plant will feed directly into the 220-kv. lines.

Big Creek No. 3, now under construction, is designed for 220-kv. operation.

The Vestal substation, the first tap off the lines—109 miles from Big Creek No. 1—will be fed through two 52,500-kv-a. auto-transformer banks. The present terminal substation at Eagle Rock, 241 miles from Big Creek No. 1, will have two 110,100-kv-a. auto-transformer banks just outside the station. These substations will continue to operate as before, being fed at 150 kv. from the auto-transformers.

All auto-transformers will be star-connected, solidly grounded, with tertiary windings of kilovolt-ampere capacity equal to the transformer rating of the auto-transformer itself, and with a tertiary reactance of from 10 to 13 per cent.

At present the only switching station in the lines is at Magunden, 140 miles from Big Creek No. 1 and 101 miles from Eagle Rock. Oil switches of 220 kv. will be installed here, also at Vestal, permitting sectionalizing, cross connecting, or paralleling the two lines at either or both stations. Four additional cross-over sectionalizing switching stations will be built, equipped with air-break switches not intended to break load or charging currents but to be used only in separating parallel lines.

It will thus be possible to test insulators without having to take out more than 43 miles of one line at any one time.

A 30-mile extension of the Big Creek lines will be built from Eagle Rock substation, or nearby, to a new substation which will lie east of Los Angeles and will deliver power to a rapidly developing industrial section of the city. Upon this line where no limitations of old construction exist, thirteen suspension units will be used.

In order to obtain better voltage distribution as

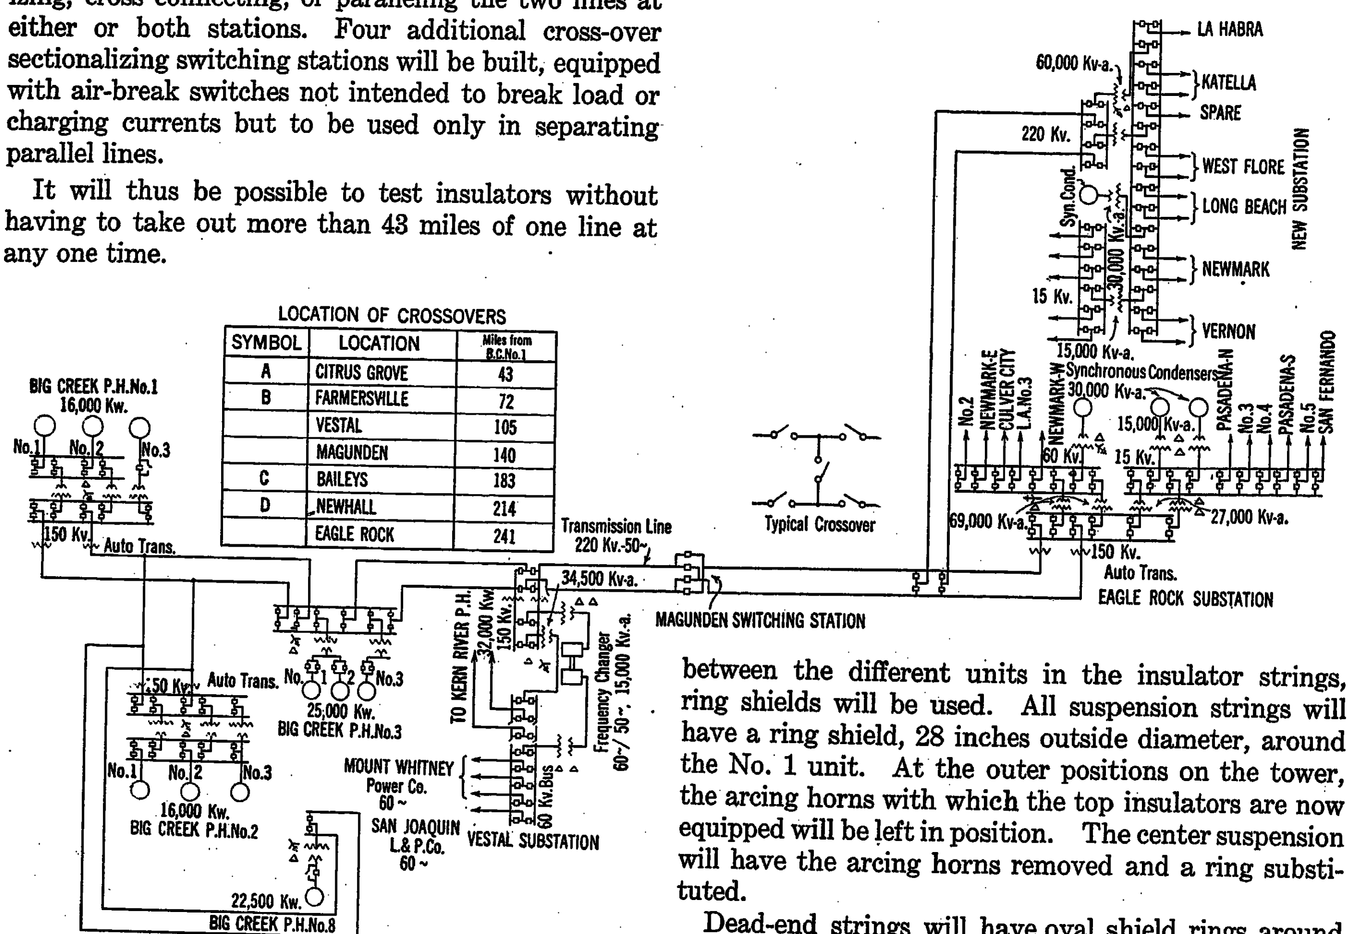

Fig. 1—Single Line Diagram—First Unit of 220-Kv. Transmission of Southern California Edison Company

This rather extreme amount of sectionalizing was considered advisable, as the number of insulators decided upon, viz. eleven to a suspension string, is about the minimum number that will afford satisfactory operation, and all the insulators on the lines will be meggered at least once a year and any accumulation of bad units forestalled.

Even had these considerations not prevailed, the sectionalizing was necessary for the reconstruction of the lines for 220 kv., as longer sections could not be taken out of service under the existing load conditions without undue drop in voltage.

It is planned to replace some of these air-break cross-over switches with oil switches in the future, with a view to automatic sectionalizing in cases of line trouble.

between the different units in the insulator strings, ring shields will be used. All suspension strings will have a ring shield, 28 inches outside diameter, around the No. 1 unit. At the outer positions on the tower, the arcing horns with which the top insulators are now equipped will be left in position. The center suspension will have the arcing horns removed and a ring substituted.

Dead-end strings will have oval shield rings around the No. 1 units of the two parallel strings of which they are composed. At the tower end the existing arcing horn will remain.

Tie-down strings will have a shield ring around the top No. 1 unit, the numbering convention being to count always from the conductor towards the grounded end. The shields used at the bottom of suspension top of tie-down and line end of dead-end strings will be made of cast aluminum alloy. The rings for the top of center suspension strings will be of galvanized tire iron. All rings are so supported that they will retain their normal position relative to the axis of the insulator string whatever the inclination to the vertical of the latter may be. This material will all be manufactured locally.

For the purposes of voltage regulation all generating plants are equipped with Tirrell regulators, maintaining constant voltage at the generator.

At Eagle Rock substation will be one 30,000-kv-a.

and two 15,000-kv-a. synchronous condensers which are now in operation. The new 220-kv. substation east of Los Angeles will initially have one 30,000-kv-a. condenser and will be so designed that in the future, extensions can be made to accommodate three or more additional condensers, all condensers regulating for constant voltage by Tirrell regulators.

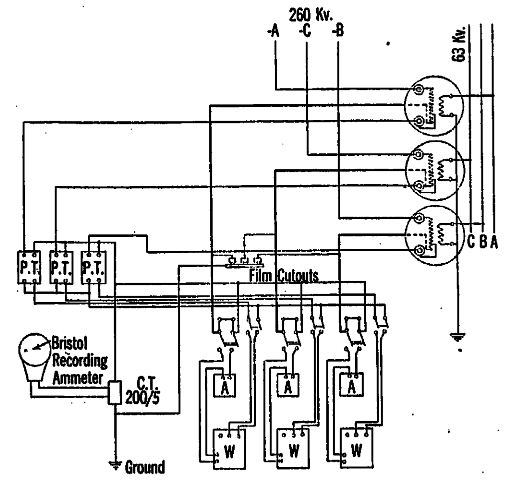

Fig. 2—Connections of Energizing Transformers and Meters Used on Field Tests

It is calculated that a total condenser capacity of 180,000 kv-a. will regulate for 240,000 kw. transmitted over two lines with zero regulation from generator to substation, the power factor of the load being taken at 0.85 lagging. While there are some theoretical considerations which render zero voltage regulation very attractive, it costs money, and there will be many cases where the marked increase in carrying capacity of the line, due to a slight drop in voltage from generator to substation, will be hard to overlook from an economical standpoint. This is a matter of distinguishing between feeder transmission lines and high-tension busbars and no general rules will apply.

Such calculations as have been made do not indicate the advisability of installing condensers at the middle point of the line, entirely satisfactory regulation and economy of transmission being effected by concentrating the condensers at the receiving end. It does not therefore seem necessary in this case to distribute condensers as has been done for several years past upon the Southern California Edison 60-kv. system, where, to describe one instance, in the transmission from Kern River No. 1 hydroelectric plant to Colton substation (a distance of 170 miles) synchronous condensers were installed at 110 and 143 miles from Kern River and at the end of the line, affording proper voltage regulation at intermediate points of the line and reducing line losses.

The 220-kv. oil switches will have a rupturing capacity of not less than 1,200,000 kv-a. Disconnecting switches for station use will be mounted upon separable post-type insulators. At Big Creek No. 8 these took the form of tripod posts, each leg composed of 14 standard 10-inch suspension disks connected by bolted flanges.

The general diagram of connections is shown in Fig. 1. This represents what may be called the first unit of 220-kv. transmission.

The existing clearance to ground upon the Big Creek lines is 25 ft. The reconstruction for 220-kv. entails the raising of a great percentage of the towers to afford a minimum clearance of 30 ft. to ground in all country susceptible of cultivation. In mountainous and the more inaccessible country, clearances will be established in accordance with rulings of the State Railroad Commission.

The towers will be raised bodily without interference with conductors or ground wire, and a structural steel, vertical sided extension frame bolted between them and their old foundation anchors, which will not be disturbed in any way. Among other advantages, the benefit of having old well settled foundations will be retained.

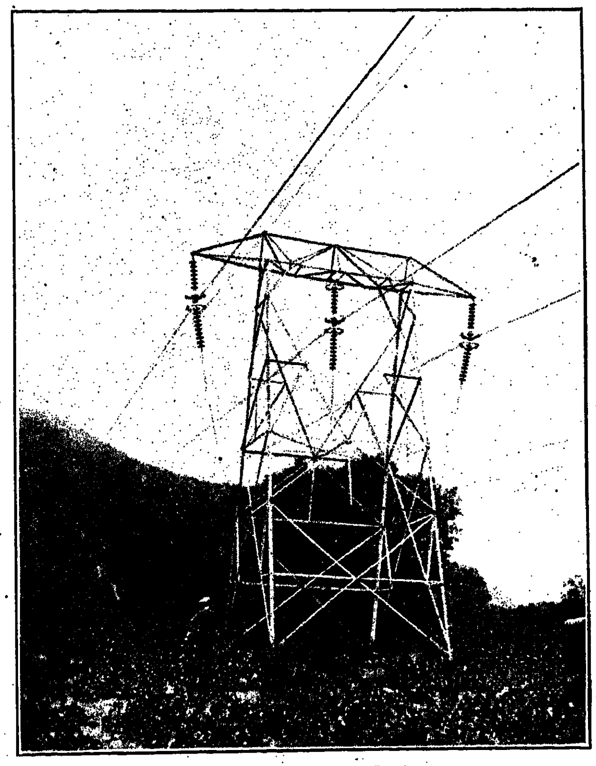

Fig. 3—Tie-Down Tower

The general appearance of the tower line with insulators equipped with shield rings is shown in Fig. 3 which illustrates a tie-down tower. A dead-end insulation is depicted in Fig. 4, both illustrations from the *Electrical World.* The rings that will be installed on the balance of the lines will differ from those illustrated in being only 2½ in. instead of 5 in. deep.

All this work is scheduled to be accomplished this year, so that actual operation at 220 kv. should be started quite early in 1923.

220-Kv. Investigations

When it was decided that investigations should be begun as to the best manner of making the change to 220 kv., a program was laid out which included:

1. The effect of shield rings, enlarged conductors, and other devices and expedients for improving voltage distribution over strings of suspension insulators.
2. The behavior of strings of various numbers of insulators under high-frequency, high-voltage oscillator discharges.
3. A duplication to a certain extent of the experiments made with the oscillator, and such other investigations as were desired, using 60-cycle high voltage.
4. Test under line conditions of the scheme of insulation which would be decided upon as a result of the laboratory experiments.
5. As extensive corona tests as were practicable, to determine definitely the sufficiency of the existing cables on the Big Creek lines.
6. To note such other matters of practical or academic interest as might arise or develop during the tests.
7. A complete study of line regulation, synchronous condenser capacities required, and the most economical size of conductor for new lines.
8. Tower design, single circuit vs. double circuit towers, most economical span, clearance to conductor.
9. Lightning arresters, ground wires and protective apparatus.

A committee was formed to carry on the investigations including members of the engineering, operating, construction and designing departments of the company. The various branches of the work were allocated to those especially capable of handling them, frequent meetings enabling all to keep in touch with the general progress.

The account which follows gives some of the results of the labors of this committee.

Before any laboratory tests or other investigations were begun, certain limitations of the insulation problem were felt to exist. Firstly, the selected insulation had to fit into existing towers which could of course be raised, and otherwise modified, but which it was extremely undesirable to weaken mechanically; this latter restriction practically preventing any increase of clearance between conductor and tower being obtained by modification of the tower structure. Secondly, it was felt that every effort should be made to utilize standard suspension insulators.

The modern 10-inch suspension insulator has reached a high perfection and can be bought of several manufacturers. Several years were required to bring this insulator up to its present excellence and to prove it. The insulator is an innocent looking little thing, but it is doubtful if the manufacturer, and still less the user, can always forsee the troubles that may arise from making even apparently minor changes in its shape. At all events the user cannot be sure that a new type will be satisfactory for his purpose until it has been tried out for several years. It therefore appeared logical and to be better business to use the standard insulator whose behavior and endurance are fairly well-known, predicated always upon satisfactory insulation being obtainable rather than to experiment with something new.

This point of view is not to be taken as indicating that no further advance in the art of insulator design is to be expected, far from it, but it is felt that new types should be tried out upon the less important lines. Deterioration from age can probably be just as well determined upon 60-kv. lines as upon those of 220-kv. It is also felt that the operating companies owe it to the advancement of the art to afford facilities for trying out new designs, but they cannot afford to jeopardize important trunk lines in so doing.

Laboratory Tests upon Insulation

Voltage Distribution. As is well-known, the several units of our unshielded suspension string of similar insulators do not divide the total voltage across the string equally between them. This may lead to a displacement current discharge across a heavily stressed

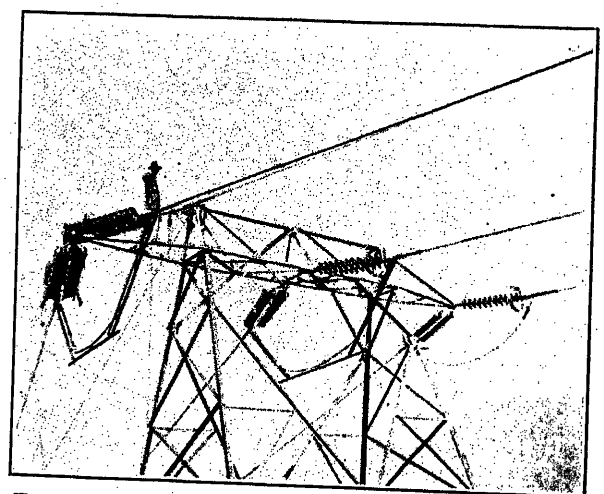

Fig. 4—Erecting Shield Rings on Dead-End Tower

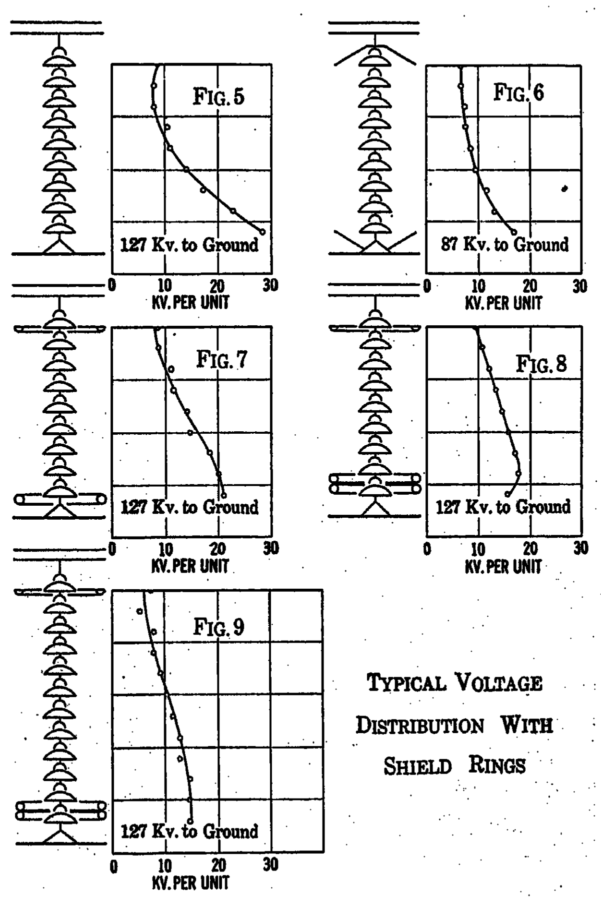
unit if the surface condition of the porcelain is poor from dirt and moisture; such a partial failure of the string may set up oscillations followed by a string flash-over. Whether any such action actually occurs in practise is open to question. Efforts to render the surface of a string of insulators conducting with salt solution have only given negative results in the sense that before a non-unit string, normally used at 87 kv. to ground, could be made to flash over at as low a voltage as double line potential, an amount of conducting material had to be deposited upon its surface that was many times that found upon insulators in ordinary service.

It seems advisable however to equalize this voltage to a certain degree as between units in a string. Through the kindness of Prof. Harris J. Ryan, a series of tests with the high-voltage potentiometer was made at Stanford in 1920 and 1921 to determine the quanti-

tative effect of shields of various proportions. Typical distribution curves are shown in Figs. 5, 6, 7, 8 and 9. Practically any desired distribution can be obtained, even with strings composed of insulators all of the same kind, and further variation and complication is obtainable by mixing units of different internal capacities.

With all similar units in the string it is difficult to obtain a uniform voltage distribution in long strings without using very large and expensive shields, and suffering an excessive reduction in the flash-over voltage of the whole string. Fortunately, as will be further discussed later, it is actually detrimental to have a close approach to uniform distribution and still worse to have an inverted distribution with less voltage across units near to the line than across others.

As a firm basis from which to start it was determined that the maximum voltage across any unit must not exceed that in the existing Big Creek line under normal operation at 150 kv. As shown in Fig. 6 this amounts to 16.8 kv. when all insulators are good and to 21.5 kv. with one bad unit in the string.



FIGS. 5 TO 9—VOLTAGE DISTRIBUTION WITH AND WITHOUT SHIELD RINGS
Tests at Stanford.

The design of ring finally adopted (See Fig. 10) gives a maximum of 17.0 kv. when all insulators are good and 20.8 kv. under the worse condition for one bad unit.

It was found that extension downward of the outer lip of the inverted U-shaped ring, making the ring twice its original depth, had no measurable effect upon the voltage distribution. Similar deepening of the inner lip had, however, a noticeable effect in reducing still further the voltage across the No. 1 unit.

The additional cost of deepening the ring in this way was considerable which the small effect produced did not justify.

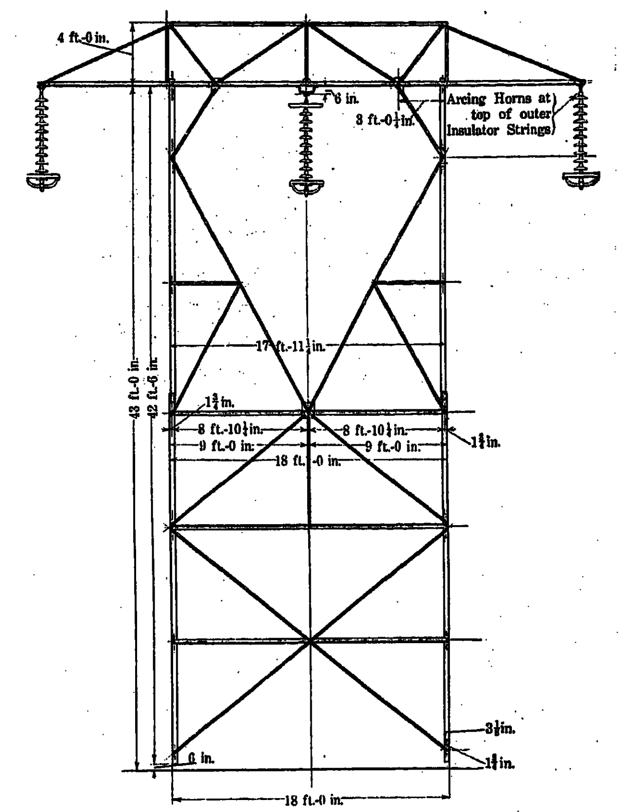


FIG. 10—STANDARD BIG CREEK TOWER WITH INSULATION AND SHIELD RINGS AS FINALLY ADOPTED

Arc-over. The most instructive test of an insulator is its behavior under high voltage up to the point of arc-over or flash-over.

Overstress of particular units and parts of units becomes apparent in the dark by the formation of corona, and the path taken by the discharge when flash-over occurs gives a valuable indication of the likelihood or otherwise of damage being done to porcelain by arc-overs on the line.

A great number of studies was made with Prof. Ryan with oscillator discharges at about 50,000 cycles, with Mr. A. O. Austin at 30,000 cycles, and with Mr. F. W. Peek, Jr. at 60 cycles. It was thus hoped to obtain information upon the behavior of high-frequency effects, which may or may not actually occur in the line, and also to determine the factor of safety to normal-frequency voltages.

These tests were all made with insulators suspended in dummy towers so that the flux distribution might be approximately the same as it would be on the line.

This precaution is necessary, and it may here be

emphasized that flash-over tests made under different conditions as to grounded insulator supports and energized conductors are not comparable for the same insulator arrangements.

The path of the discharge with oscillator frequencies and blue snappy flash discharges follows quite approximately the lines of flux distribution existing just before discharge occurs. With 60-cycle arc-overs this same general direction of the initial discharge is followed, the power arc which immediately follows is mobile, and flashes around with air currents and the reaction due to its own field.

FIG. 11—FLASH-OVER AT 50,000 CYCLES
Test at Stanford.

Fig. 11 shows oscillator discharges at 50,000 cycles, the top three units of a 12-unit string being short-circuited with fine wire. The discharges are seen to follow the lines of force in a general way.

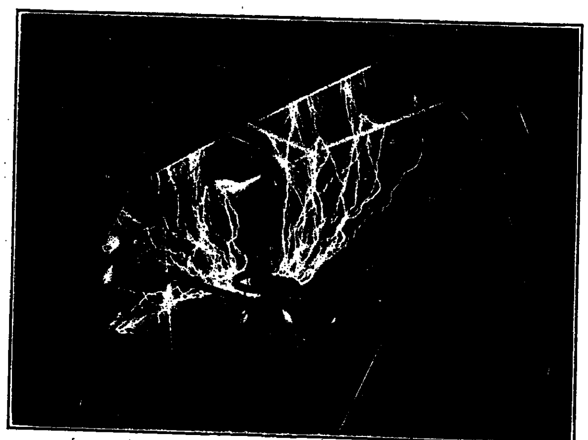

FIG 12—FLASH-OVER WITH INVERTED U-SHAPED RING
Test at Stanford.

Figs. 12 and 13 show arrangements identical except as to the cross-sectional shape of the shield ring. In Fig. 12 the ring has a ∩ section, and in Fig. 13 the ring is made of round pipe. It will be noticed that the discharges start from the outer lower edge of the ring in Fig. 12 and are directed further outward from the insulator string than in Fig. 13, where one discharge cascaded the top three units. These illustrations represent 30 closings of the switch in the oscillator circuit. At each closing, lasting perhaps one second, the discharge would usually take place along only one of the flashes shown, although occasionally a flash-over would split between two or three directions.

FIG. 13—FLASH-OVER WITH RING OF CIRCULAR CROSS-SECTION
Test at Stanford.

Fig. 14 shows a 30,000-cycle oscillator discharge under artificial rain upon an 11-unit string, the voltage, as measured by sphere gap, being 451 kv. It may be noted that there is no evidence of corona or streamers on the insulators.

In Fig. 15 attention is called to the spark discharge to the top of the string following the tubes of force.

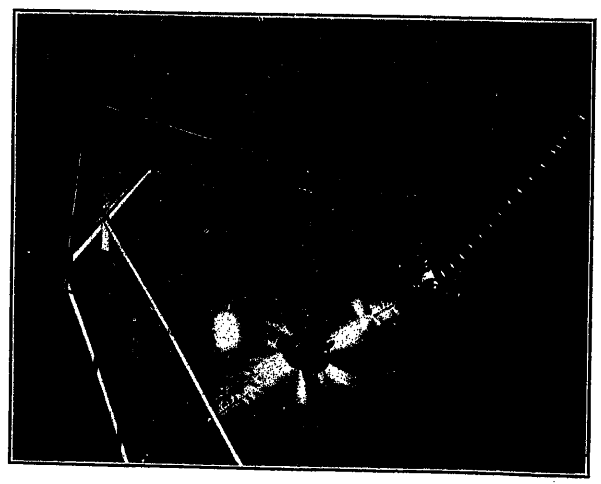

FIG. 14—FLASH-OVER IN ARTIFICIAL RAIN AT 30,000 CYCLES
Test at Barberton.

The insulator string is so long, 13 units, that the majority of the discharges goes to the tower braces. The absence of corona on the insulators may again be noted.

Figs. 16 and 17 illustrate the effect of the shield ring in directing the arc outward from the insulators in the case of flash-overs under rain. There is not any

lowering of the flash-over value although the arcing distance is reduced four inches by the ring.

Fig. 18 shows a flash over a dead-end string equipped with shield ring and arcing horn such as will be used on the line.

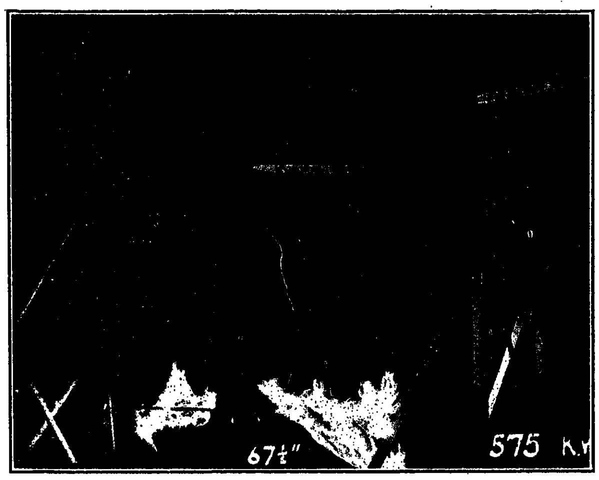

Fig. 15—Arc-Over, 13 Insulators with Deep Shield Ring
Test at Pittsfield.

With both oscillator and 60-cycle discharges there is cascading of the string, or some portion of it, at those parts where flux reenters the string, or expressed differently, where the slope of the voltage distribution

Fig. 16—Arc-Over in Artificial Rain, with Deep Shield Ring
Test at Pittsfield.

curve changes sign as in Fig. 19. The oscillator seems to cause rather more cascading than does 60-cycle voltage.

In Figs. 20 and 21 is summarized a number of arc-over tests at 60 cycles with different numbers of units in the string. These tests were made with different kinds of shield rings placed at various heights above the conductor, thus giving different arc-over values for the same length of string. Points shown as full circles indicate tests where cascading occurred. Clear circles are for tests where the arc-over was clear

Fig. 17—Arc-Over in Artificial Rain—Lower Arcing Horns Only
Test At Pittsfield.

of the string. Some tests were made with one or more units short-circuited with fine wire to represent bad units; in such cases the test is plotted on the chart for the number of good units. There is a fairly well

Fig. 18—Arc Over Dead-End String
Test at Pittsfield.

defined line of demarkation between the regions of cascading and of clear arc-over, which is interpreted as indicating that, for the particular tower arrangement used, a certain length of string, or number of units, can be forced up to a certain maximum arc-over voltage without cascading, but that if, by lowering the shield

ring for instance, the flash-over voltage is increased, then cascading will occur. The two curves show the extent to which the clear arc-over voltage is affected by the tower structure surrounding the center conductor, as compared with the outer conductor.

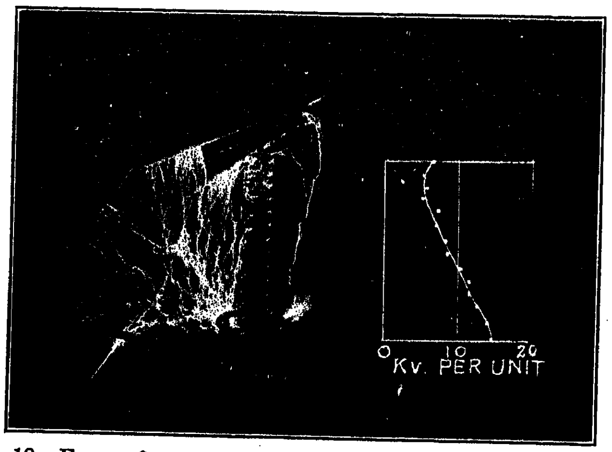

FIG. 19—FLASH-OVER AT 50,000 CYCLES SHOWING CASCADING IN RELATION TO VOLTAGE DISTRIBUTION
Test at Stanford.

The relation between the arcing distance, measured in a straight line and not along the path of the discharge, and voltage is shown in Fig. 22 with, for comparison, the ordinary spark gap curve for points.

Arc-over under rain conditions will start as a cascade string and flare out away from it, at all events in those cases where a gradual diminution in unit voltage duty obtains along the string. No quantitative evidence has been obtained as to how great a part is borne by the outward flux from the string in forcing out the arc from a wet string, but the tendency is in the right direction and should be taken advantage of. Such arcs over wet strings are shown in Figs. 16 and 17; the initial discharge is plainly marked, the whole mass of flame not existing all at one time but being a superimposed record of the wanderings of the arc.

To settle the question as to whether dirt or moderate roughness of the surface of the ring would materially affect the flash-over value the experiment was tried of attaching a pointed piece of wire one-half inch long to the ring, the wire sticking out normal to the ring surface. No difference in flash-over value could be detected whether the point was in position or not. It was concluded that the ordinary roughness of commercially manufactured articles would be immaterial.

It has appeared from these studies that in order to prevent damage to a string of insulators subjected to accidental flash-over, the following points of design should be adhered to:

1. The voltage gradient along the string from conductor to grounded support should gradually decrease.

2. A shield ring should surround the No. 1 unit so proportioned that even under rain conditions discharge will start from it rather than from the hardware of the first unit. The ring should be complete so as to permit an arc to travel round it without crossing into the string.

3. The cross-sectional shape of the ring should be such that an arc-over produced by sufficiently high voltage will start from a part of the ring where the field of force, or flux, is strongly divergent from the insulator string, thus forcing the arc well out and away from the insulators. The point of origin of the arc-over

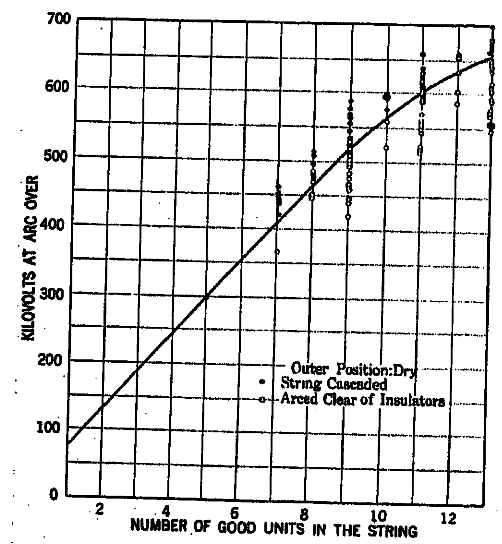

FIG. 20

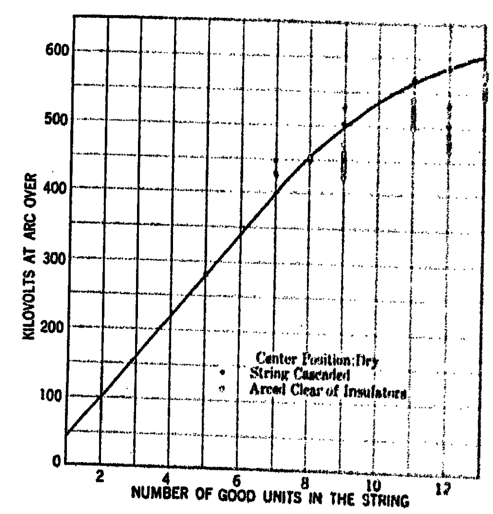

FIG. 21

FIG. 20 AND 21—SUMMARY OF ARC-OVER TESTS AT 60 CYCLES OF SUSPENSION STRINGS WITH AND WITHOUT SHIELDS
Characteristic cascading curves—Locke No. 5996 insulator in Big Creek tower.
Tests at Pittsfield.

but by a proper proportioning of the shield ring the first three or four units can be prevented from cascading, the initial discharge taking place from the ring to the cap of No. 3 or No. 4 unit and then cascading the rest of the string. With sufficient power behind the arc, it will almost instantly leave the insulator

is controlled by the radius of curvature of the cross-section of the ring in its various parts.

4. A top shield ring is advisable both to prevent an increase in voltage gradient over the upper third of the string and also to allow of the arc traveling around clear of the porcelain.

Field Tests

After the conclusion of the laboratory tests a portion of the West Big Creek line, 27 miles in length, was cut out of regular service, and equipped for high-voltage testing on a scale approximating more to actual service conditions than could be obtained in any laboratory. Some account of the results has appeared in the *Electrical World* of February 11th, 1922, with a corrected table of coefficients in the May 6th number.

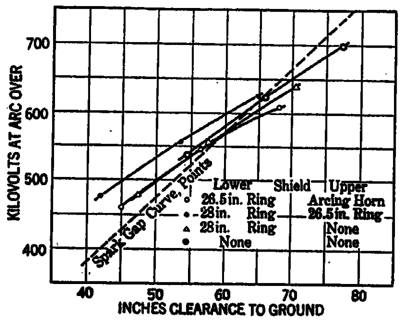

Fig. 22—Relation between Clearance to Ground and Arc-Over Voltage at 60 Cycles

For the sake of convenience and easier reference some of the substance of the article will be included here.

The purpose of the tests was to obtain:

1. Measurements of corona loss under such atmospheric conditions as might occur, and the determination therefrom of constants for weathered aluminum cables of large size.
2. A determination of the charging current of a line equipped with shielding devices and a comparison with calculated values.
3. A study of insulation.
4. Miscellaneous data.

The physical constants of the line are:

Conductors: Steel core aluminum, core 7-strand 78,500 cir. mils; aluminum strand 605,000 cir. mils; diameter 0.96 in.; horizontal construction, spacing 17 ft. 3 in.; average height above ground 33 ft.

Ground Wire: ½-in. steel 7-strand cable.

Towers: Structural steel.

Insulators: Cap and pin standard 10-in. suspension.

Transpositions: None.

At first two insulators were added only to those suspension strings where not less than normal clearance to ground would remain after so doing, this resulted in there being:

249 Suspension strings of 9 units.
42 Suspension strings of 11 units.
348 Dead-end strings of double 13 units.
48 Tie-down strings of one more unit than the corresponding suspension.

The shield ring was of a slightly different design from the one that will be used for the conversion of the complete lines but had practically the same electrical characteristics.

It had developed in laboratory tests that an arc-over in the central position of the tower would most frequently ignore the arcing horns at the top of the insulator string and go to the cap of the top unit. It was feared that this would endanger this unit and possibly some below it, so a lighter type of shield ring was installed around the top unit of all center position strings. In the outer positions the tower structure does not so effectively shield the arcing horns, and flash-overs go to them. No upper ring was put there and the arcing horns were left in position.

The lower end of all suspensions had shield rings, as had the line ends of dead-end strings, horns being left at the tower ends of these latter.

Tie-down strings had rings around their top units, the rings being similar to those used at the top of center suspensions.

The line was energized from three 4500-kv-a. 150,000/72,000-volt transformers, having various taps, connected in star on the high side with neutral grounded. For the first tests the low side was connected in star on the 36,000-volt tap and fed from the 64,000-volt (nominal) bus at Eagle Rock substation.

Corona Loss. Realizing that for the results to have any value, fairly accurate measurements of voltage and power would be necessary, some care was taken in the selection and calibration of instruments.

For the measurement of voltage, taps were brought out from the high-tension winding of each transformer near the grounded end and the ratio determined of the voltage from tap to ground compared with the voltage across the whole high-tension winding. This was found to be 7.1 kv. to 150 kv. The tap voltage was measured in service through 200-watt, 11,000/110-volt potential transformers whose only other load was the potential coils of Weston wattmeters.

The voltage between phases was found to be well balanced so that ordinarily the voltage from only one conductor to ground was read and recorded.

The load upon the energizing bank of transformers not exceeding 7 per cent in kilowatts of their rated capacity and being practically constant in kilovolt-amperes, voltage readings were taken off the low side of the transformers through potential transformers for many of the tests, the proper ratio being determined by comparison with readings on the voltage tap on the high side. The rise of voltage along the line was calculated not to exceed 0.3 kv. and was neglected.

Readings were taken regularly by the switchboard attendants to the nearest 0.5 volt on the meter, corresponding to 1.25 kv. on the line. This lack of precision was to some extent compensated for by the number of readings, a reading being taken every two hours except in rainy weather when hourly records were kept.

Power delivered to the line was measured by three Weston laboratory wattmeters calibrated, down to a power factor of 0.04 leading, against standards in the laboratory of the Southern California Edison Company, these standards having been previously checked by the Bureau of Standards. Checks were also made against oscillograph records as detailed later.

When tests were first planned it was hoped that the losses on each conductor would be determined separately; the effect of the different capacities between pairs of conductors due to the three conductors being in a horizontal plane and conductors and ground, there being no transpositions in the line, was overlooked. The effect of these capacities is illustrated in Fig. 23 where *A G*, *B G*, *C G* are the conductor voltages to ground and *A B*, *B C*, *C A*, *B A*, *B C*, *A C* are voltages, between conductors representing the relative times at which the first letter becomes a positive maximum to the second.

Assume first that there are no losses. Consider the conductor *A* one of the outer conductors; its charging current, considered as a condenser to ground is I_{AG}. There is also the condenser formed by conductors *A* and *B* and and *A* and *C* respectively, *C* being the center conductor. These have charging currents I_{AB} and I_{AC} the resultant line charging current being I_A. On account of the capacity *A C* exceeding that of *A B* the current I_A is displaced more than 90 degrees ahead of the voltage *A G*. The wattmeter fed by *A G* and I_A therefore reads backward when connected normally. For similar reasons wattmeter *B* reads forward and wattmeter *C* reads zero, with a circuit symmetrical about conductor *C* the sum of the wattmeter readings is zero.

The effect of losses in the circuits is to reduce the negative reading of wattmeter *A* finally rendering it positive in increasing degree as the loss increases. Both *B* and *C* wattmeters read positive with increase of losses, the sum of the three readings being the total power. Some considerable knowledge of the various circuit capacities is therefore required before the losses upon individual conductors can be determined. In the present case, including as it does three conductors and a ground wire on the one tower line and a similar adjacent line, the currents and voltages in the two lines having various phase displacements, and the capacities varying to some extent with the corona, the mathematical solution becomes complicated.

As a further check upon instrumental and systemic errors the instrument potential transformers were interchanged, wattmeters were interchanged, phase rotation upon the low side of the energizing transformers was changed, each of these changes being made singly at a time, no readable change in losses was effected by interchange of wattmeters or potential transformers.

The effect of changing rotation is given in Table I.

TABLE I
Effect of Phase Rotation upon Wattmeter Readings

Conductor Phase	West *C*	Center *B*	East *A*	Sum of wattmeters
Wattmeter reading..........	− 6.0	+ 0.5	+ 6.5	1.0
Phase......................	*A*	*B*	*C*	
Wattmeter reading..........	+ 6.0	0	− 6.0	0.0

The positive and negative readings interchange with the phase interchange in accordance with the vector diagram Fig. 23. The difference of 1.0 in the sum of the readings is equivalent to 0.33 kw. per mile of conductor; the readings were necessarily taken some hours apart.

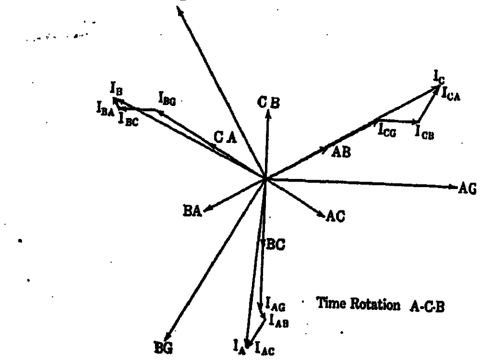

FIG. 23—VECTOR DIAGRAM OF CURRENTS AND VOLTAGES WHEN METERING CORONA LOSSES

The magnitude of the effect of induction from the parallel line was determined roughly by energizing the test line from a separate generator, at a slightly lower frequency than obtained on the paralleling lines. As the phase relation between the two lines changed, the wattmeter readings oscillated between minimum and maximum readings. The extent of the oscillation is given in Table II as follows:

TABLE II
Test for Induction from Parallel Line

Phase	*C* Watt-meter reading	Am-peres	*B* Watt-meter reading	Am-peres	*A* Watt-meter reading	Am-peres	*A* Kv. to neutral
Min.....	− 4.2	15.5	− 0.2	16.9	3.0	15.0	124.6
Max.....	− 5.0	15.6	+ 0.2	17.2	6.0	15.8	124.6
Min.....	− 5.2	17.1	− 0.4	18.8	4.2	16.8	137.3
Max.....	− 5.9	17.2	+ 0.2	19.0	7.2	17.4	137.3

The larger swings of the *A* wattmeter are due to its being undamped. Both *C* and *B* wattmeters had well damped movements. The period of the swings was of the order of one or two per second. The maximum and minimum readings were not simultaneous in the three meters and it is felt that the effect of the parallel circuit upon the sum of the three readings was very small.

The practical requirement was to determine the total losses and this is given correctly by the sum of the three wattmeter readings.

The sensitiveness of the wattmeters was such that the sum of the three scale division readings multiplied by 26.4 gave the total loss in kilowatts; the routine readings were taken to the nearest half a scale division.

The relative readings of the three wattmeters is shown in Figs. 24 and 25, which indicate that the variations are according to the theory of the vector diagram Fig. 23.

As a still further check upon the wattmeters, though it was only a rough one, oscillograph records of voltage and current were taken simultaneously with wattmeter readings and the curves analyzed, by the eighteen-ordinate method, the results being as follows:

Phase A

Voltage in kv.:

$200.3 \sin (P t - 359° 43') + 1.31 \sin (3 P t - 168° 13')$
$+ 3.12 \sin (5 P t - 177° 59') + 0.16 \sin (7 P t - 135° 0 0')$
$+ 0.27 \sin (9 P t - 68° 10') + 0.38 \sin (11 P t - 123° 40')$
$+ 0.16 \sin (13 P t - 71° 33') + 0.27 \sin (15 P t - 101° 19')$
$+ 0.11 \sin (17 P t - 63° 25')$

Current in amperes:

$24.82 \sin (P t - 274° 29') + 0.19 \sin (3 P t - 339° 27')$
$+ 2.44 \sin (5 P t - 86° 59') + 0.38 \sin (7 P t - 99° 17')$
$+ 0.01 \sin (9 P t - 89° 57') + 0.14 \sin (11 P t - 351° 02')$
$+ 0.04 \sin (13 P t - 231° 20') + 0.04 \sin (15 P t - 101° 19')$
$+ 0.04 \sin (17 P t - 189° 28')$

Power calculated from the above ....206.3 kw.
Power measured 7.3 × 26.4 .... =192.7 kw.

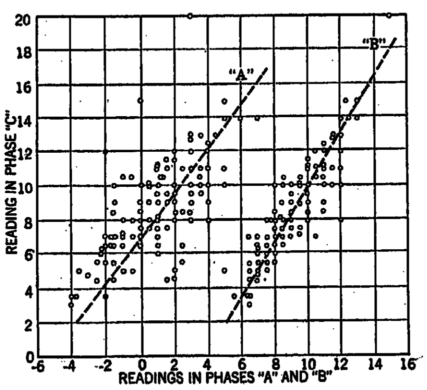

FIG. 24—RELATION OF THREE WATTMETER READINGS, 19.5-MILE TEST AT 161 KV. TO NEUTRAL

This is considered a satisfactory agreement when the difficulty of measuring oscillograph curves and the smallness of the wattmeter reading are taken into account.

$I^2 R$ losses in the transformer high-tension windings and line conductors were calculated.

From Peek's formula, after substituting the physical constants of the line; the logarithmic mean of the three conductor spacings being used:

$$P = \frac{0.01263}{\delta} (e - e_0)^2, \quad \text{also}$$

$$e_0 = 162.2\, \delta\, M_0 \quad ; \text{ whence}$$

$$M_0 = \frac{e - \sqrt{\dfrac{P\,\delta}{0.01263}}}{162.2\,\delta}$$

where M_0 = Surface irregularity factor and used here to include weather effects including storm

e = Voltage to neutral in kv.

P = Average kw. loss per mile per conductor

δ = Air density coefficient.

By the above formula each hourly and two-hourly observation was calculated and the corresponding value of M_0 found that would satisfy the quadratic equation of loss.

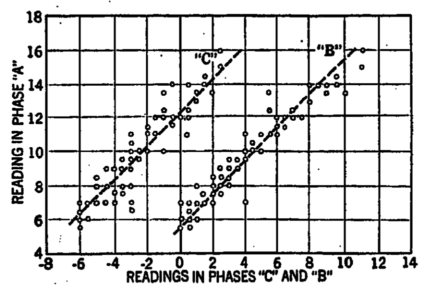

FIG. 25—RELATION OF THREE WATTMETER READINGS, 27-MILE TEST AT 141 KV. TO NEUTRAL

The line was energized at around 161 kv. to neutral from Sept. 16th, 1921, to Oct. 15th, 1921, when it was decided to lower the voltage to about 140 kv. to neutral. This was done for two reasons; the noise of the line at 161 kv. to neutral was annoying to property holders, and it was felt that data should be collected at a voltage

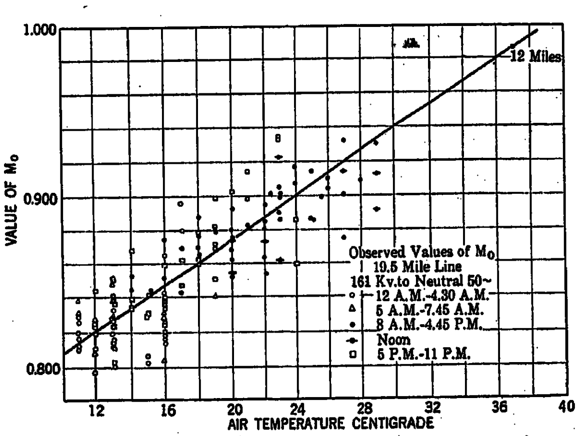

FIG. 26—VALUES OF IRREGULARITY FACTOR CALCULATED FROM OBSERVATIONS IN RAINLESS WEATHER

nearer that at which commercial operation was going to be undertaken.

The selection of 140 kv. was made because its excess above the critical disruptive voltage on the test line was approximately the same as would exist with commercial 127 kv. to neutral at the points of highest altitude of the whole line. Data from the test line, at an average elevation of 1500 feet, would therefore correspond to commercial conditions at 220 kv. between conductors at between 4000 and 5000 feet. At 140 kv. to neutral the line was almost noiseless so that that voltage was suitable in all respects.

TABLE III
Daily Average Storm Losses at 141 kv. to Neutral

Date	No. of hours	Loss Kw-hr.	P Loss per conductor per mile	Temp. deg. cent.	Bar. cm.	$e - e_0$	Kv. to neutral e	Critical voltage e_0	Factor M_0

Average			1.853				140.8	128.9	

The results for the test upon 19½ miles of line at about 161 kv. to neutral are plotted in Fig. 26, including one observation upon 12 miles of line at a high temperature.

It will be noted that there is apparently a relation between M_0, and consequently the loss in the line, and temperature, which is not accounted for by the Peek formula. Observations taken during different periods

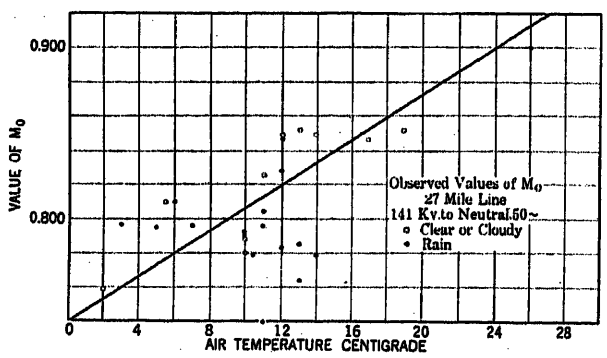

FIG. 27—VALUES OF IRREGULARITY FACTOR CALCULATED FROM OBSERVATIONS IN RAINY WEATHER

of the day are distinguished in the chart with the object of determining whether variations of load in the adjacent power-carrying line were responsible for the variations in M_0 apparently however they are not.

These observations were made during all kinds of weather with the exception of rain or snow, but include clear, cloudy, heavy fog, and misty conditions.

The value of M_0 does not seem to depend much upon such conditions but varies mainly with temperature, and for the particular conductor experimented upon is given by

$$M_0 = 0.00667\ (t + 111)$$

Where t = deg. cent.

In clear weather no loss was measurable at 140 kv. to neutral, the voltage was quite close to the critical point as a loss of some few tenths of a kilowatt per mile per conductor occurred in cool cloudy weather.

Storm losses are given in Table III as average quantities taken over each day, the relation these bear to the annual average can be gaged by the total precipitation during the period registered at Los Angeles which was 12.60 inches as compared with the annual average of 15.6 inches.

The plot of M_0 with temperature is in Fig. 27, the drawn line being the line of Fig. 26 produced.

The lowest values of M_0 observed occurred during the storms of Dec. 19, 1921 and Jan. 29, 1922. On Dec. 19th a total precipitation of 3.28 inches for the twenty-four hours was recorded at the Weather Bureau's station at San Fernando, close to the line, and not far from the middle of its length, and otherwise having climatic conditions averaging those along the length of the line.

Hourly readings for this day are given in Table IV and indicate the value of M_0 to be expected under heavy precipitation.

During the storm of January 29, 1922, a snow storm covered part of the line for a short time at noon, the precipitation recorded in Los Angeles for the hours 11 a. m. to noon being 0.52 inch. The losses and constants for the four hours of heaviest loss are given in Table V.

TABLE IV

Hourly Storm Losses Dec. 19, 1921 at 141 Kv. to Neutral

Time a. m.	Loss per conductor per mile P	Temp. deg. cent.	Bar. cm.	$e - e_0$	Kv. to neutral e	Critical voltage e_0	Factor M_0

1:00	6.26	6	71.2	22.3	139.4	117.1	0.722	Rain

Of interest is the effect upon losses of suddenly energizing an idle line during stormy weather. This was done during a rain storm, the line having been dead for an hour. The readings, which were of only relative value, were taken on the switchboard indicating wattmeter measuring total input to the low side of the energizing transformers and the following readings obtained:

TABLE VI

Initial Loss on Energizing Line

Time after closing switch	Wattmeter reading kw.
0	1150
15 seconds	700
30 "	500
45 "	400
1 minute	350
2 "	300

Upon another occasion a reading as high as 2500 kw. was obtained on first energizing the line after it had been idle for an hour in a rain storm, it being remembered that transformer losses are included.

It is not known where the extreme loss occurs but most probably it is over insulator surfaces.

The rapid decrease of loss with time shows to what extent the line and insulators dry themselves under the influence of leakage current. The quickness of the drying—a 50 per cent reduction of loss in 30 seconds—would indicate that there is not much to fear from strange voltage distribution effects upon insulators due to ordinary rain storms, as the effect of leakage current is to remedy the trouble; furthermore, the effect of wet surfaces is to increase the capacity of the insulators and produce a more even voltage distribution between them. The wave shape of the impressed voltage upon

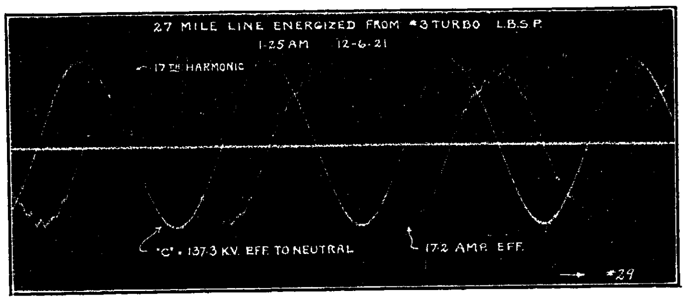

FIG. 28—CHARGING CURRENT OF EXPERIMENTAL LINE

the line for the two series of routine tests was approximately as follows:

Series at	161 kv.	140 kv.
Fundamental amplitude......	100.00	100.00
Third harmonic............	0.66	0.65
Fifth "	3.62	1.56
Seventh "	0.99	0.08
9th to 17th "	Less than 0.4	Less than 0.2

In addition to the continuous routine tests at approximately constant voltages a test on variable voltage was run on Oct. 12, 1921.

The line was energized over connections separate from the general system from a 15,000-kv-a. Curtis steam turbo-generator. The voltage wave shape was extremely close to a sine as evidenced by the wave shape of charging current of the line which showed only ripples of the 17th harmonic, see Fig. 28.

TABLE VII

Corona Test of 19½ Mile Line

			Temperature 11° C			Bar. 72.0 cm.		
Time a. m.	Kv. to neutral	Kw. total loss	Kw. $I^2 R$	Corona loss kw.	Loss per conductor per mile	$- e_0$	e_0	M_0
12:50	124.6	26.4	8.8	17.6	0.301	4.9	119.7	0.743
1:05	116.2	0	7.3	..	..	..	..	..
1:20	133.1	13.2	10.1	3.1	0.053	2.04	131.0	0.813
1:30	139.4	66.0	11.4	54.6	0.934	8.57	130.8	0.812
1:43	147.9	118.8	12.5	106.3	1.818	11.97	135.9	0.844
1:55	155.5	264.0	14.0	250.0	4.275	18.34	137.2	0.851
2:05	158.5	356.3	14.8	341.5	5.840	21.45	137.1	0.850

The results are given in Table VII. Visual corona in the span between towers was not in evidence at 139.4 kv. but was plainly noticeable at 147.9 kv. The visual corona point is somewhere between these two values.

The value of M_0 calculated from this test is higher than would be in accord with the data of Fig. 26 at a temperature of 11 deg. cent. This is to be expected from the better wave shape of voltage used in the test

of Oct. 12th. Assuming 146 kv. to be the critical visual point, the value of M_v, the visual irregularity factor can be calculated from Peek's formula.

$$e_v = 21.1\, M_v\, \delta\, r \left(1 + \frac{0.301}{\sqrt{\delta\, r}}\right) \log_e s/r$$

whence for the constant of the line
$M_v = 0.713$

TABLE VIII
Single-Phase and Three-Phase Corona Test
Date Jan. 3, 1922

Time a. m.	Kv. to neutral	Loss kw.	Charging current amperes	Circuit arrangement
8:10	140.5	26.4	18.1	Average Three-phase
11:00	142.0	13.2	18.5	Single-phase with idle conductor insulated.
11:22	141.2	13.2	18.5	
11:40	141.6	2.6	18.4	Single-phase with idle conductor grounded.
12:10	139.5	5.2	18.35	
12:15	141.2	10.4	18.5	
5:00 p. m.	142.6	0	18.0	Three-phase

Different observers' ideas upon visual corona differ so that this value may be considered in good accord with Peek's value of 0.72 for local corona.

To substantiate the form of the formula, which makes the corona loss dependent upon the voltage to neutral and not upon voltage between conductors, two of the energizing transformers were reconnected, with low sides in parallel on the same phases and high sides in series, middle point grounded, single and three-phase losses could be then compared, there being the same voltage to neutral in each case, as follows in Table VIII:

TABLE IX

In both three-phase and single-phase tests the voltage to neutral was only slightly above the critical disruptive point with only negligible losses in consequence. Had the voltage between conductors been the determining factor the single-phase loss with 283 kv. would have greatly exceeded the three-phase loss at 245 kv.

Corona Losses on Line at 220 Kv.

From the various data accumulated it has been possible to estimate what the average annual loss from corona will be upon the two complete lines. There

TABLE X
Annual Kw-hr. Corona Losses at 127 Kv. to Neutral

Altitude feet	Precipitation inches	Annual loss per conductor per mile Kw-hr.
2000	20	10
3000	25	1114
4000	30	2898
5000	35	7805

being considerable variations in altitude above sea level, losses have been calculated for different elevations at average temperatures for fair weather, heavy storm and average storm. The values of M_0 assumed for different weathers and temperatures are believed to be conservative. The resulting loss P in kw. per conductor per mile are given in Table IX.

The kw-hr. loss per annum involves not only the magnitude of storm losses but the duration of the same.

For want of a better method it has been assumed that these losses will be directly proportional to the annual precipitation in any locality. This is based primarily upon the observed data on the test line where

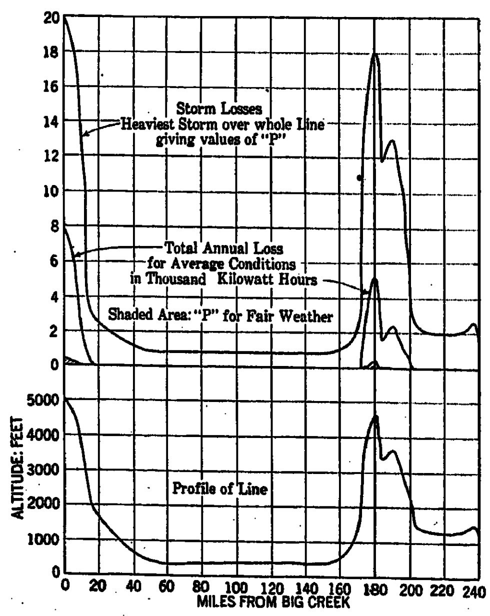

Fig. 29—Profile of Big Creek Line and Corona Losses

a total loss of approximately 74,600 kw-hr. occurred upon 81 miles of single conductor during an average precipitation upon the line of 15.47 inches, or at the rate of 4820 kw-hr. per inch. From Table III it is seen that this rate of loss corresponded to an average loss per conductor per mile of $P = 1.85$.

Expressing the annual kw-hr. loss per conductor per mile = P_a then

$$P_a = \frac{74{,}600 \times P \times P}{81 \times 15.47 \times 1.85} = 32.2\, P \times p$$

P is the average storm loss at any altitude as given in Table IX. p = Annual precipitation in inches.

Applying appropriate precipitation data, Table X is obtained, giving annual kw-hr. losses at different altitudes.

Fig. 29 gives an approximate profile of the Big Creek lines together with the constants of Tables IX and X applied to it.

Fair weather losses occur only at 4000 ft. and above and are entirely negligible. The heaviest storm losses are plotted assuming the whole length of the line to be simultaneously involved which is practically impossible. However, under this extreme assumption the maximum loss, obtained by integrating the loss curve amounts only to 5000 kw. total for both lines; 2.08 per cent of their rated carrying capacity.

TABLE XI
Charging Current of Line Equipped with Shield Rings
Line Energized from System

Length of line miles	Voltage to neutral kv.	Changing current amperes				Calculated	Measured in per cent of calculated
		A	C	B	Avg.		
7	157.1	5.0	5.8	5.2	5.33	4.865	109.5
12	158.65	8.8	9.7	9.0	9.17	8.425	108.8
19.5	160.7	15.0	16.0	14.6	15.20	13.87	109.6
27	140.9	17.98	18.92	17.59	18.16	16.84	107.8
27	141.0	17.96	18.94	17.75	18.21	16.85	108.1

The annual loss shown by another curve in the same figure totals 780,000 kw-hr. At a 50 per cent load factor the load transmitted over the lines will be of the order 1,000,000,000 kw-hr. per annum. The average corona loss is therefore about 0.08 of 1 per cent and at higher load factors becomes correspondingly less.

Practically all of this loss will occur in a distance of 44 miles. Moderate enlargement of the conductor from a diameter of 0.96 in. to 1.05 in. and 1.10 in. according to elevation would eliminate this small loss.

Charging Currents

The charging current of the line was measured by Weston ammeters having 25-ampere scales. The meters were connected directly in the grounded end of the transformer high-tension windings. They were correct to within less than 0.1 ampere.

The calculated current is based upon the logarithmic mean spacing of the conductors and exact hyperbolic formula, inductance being

$$L = 0.741 \log \frac{S}{r} + 0.304 \text{ millihenries per mile to neutral}$$

and capacity given by

$$C = \frac{0.0388}{\log \dfrac{S - r}{r}} \text{ microfarad per mile.}$$

In the 7- 12- and 19.5-mile tests $Y\,Y$ connected transformers energized the line and the voltage wave shape is responsible for about 2 per cent increase in current, leaving on an average 7.3 per cent increase over the calculated. In the 27-mile test with delta-star transformers the wave shape was more nearly sinusoidal and but 0.8 per cent increase is due to harmonics leaving a final increase of 7.1 per cent. The average for the test upon a separate turbine with practically pure sine wave of voltage gives 7.6 per cent more than the calculated current.

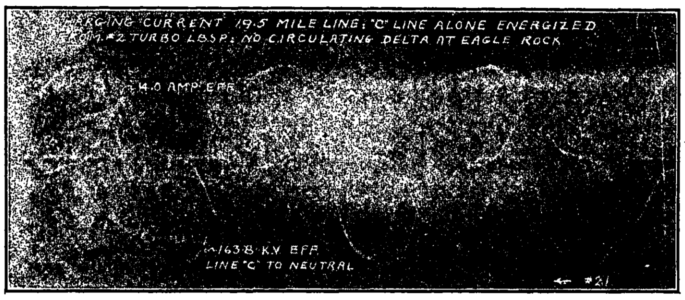

Fig. 30—Charging Current of a Single Conductor

It can therefore safely be said that the shield rings that will be used, together with the effect of other hardware, insulators, ground wire and adjacent parallel line, will cause an increase in charging current of about 7½ per cent above values calculated from the mean logarithmic spacing of the conductors by the above noted formulas.

TABLE XII
Charging Currents at 159.5 Kv. to Ground
19.5 miles of line

Phase	A	C	B
Three-Phase	14.80	15.50	15.10
Two Conductors	14.44	Out	13.6
	Out	14.20	14.30
	13.94	14.69	Out
One Conductor	13.78	Out	Out
	Out	14.40	Out
	Out	Out	14.08

A comparison of the charging current with either one, two or three conductors energized, the idle conductors being insulated from ground, is as follows, the voltage to neutral being the same in each case:

These values of charging current are not directly comparable with each other due to wave distortion when only one and two conductors are energized. They have a practical bearing upon what happens when switch contacts fail to operate simultaneously. Oscillogram Fig. 30 shows the distortion.

Residual Current to Ground

The residual current to ground from the neutral connection of the transformers increases with the volt-

age. With delta connections such as will be provided by auto-transformer tertiaries the residual will be chiefly a fifth harmonic superimposed upon a fundamental of induction from the parallel second circuit.

The fundamental can be greatly reduced by having the proper phase relation between the two circuits, the best relation giving only approximately one-half the current, that will flow when the relative phase relations are most unsuitable.

Neither the test line nor the paralleling power line was transposed; transpositions will greatly reduce residuals and will be put in both lines before operating at 220 kv.

Peek has showed that grounding the line through transformer neutrals at several points along its length also reduces the residual. The Big Creek lines will be grounded at both ends and the middle, and no trouble from ground currents is expected to arise.

Insulation

As the work of installing shields upon the line progressed additional sections were energized.

Sept. 16, 1921	7	miles	of line	were	energized	at	275 kv.
Sept. 27, 1921	12	"	"	"	"	"	277 "
Sept. 30, 1921	19.5	"	"	"	"	"	280 "
Oct. 20, 1921	27	"	"	"	"	"	241 "

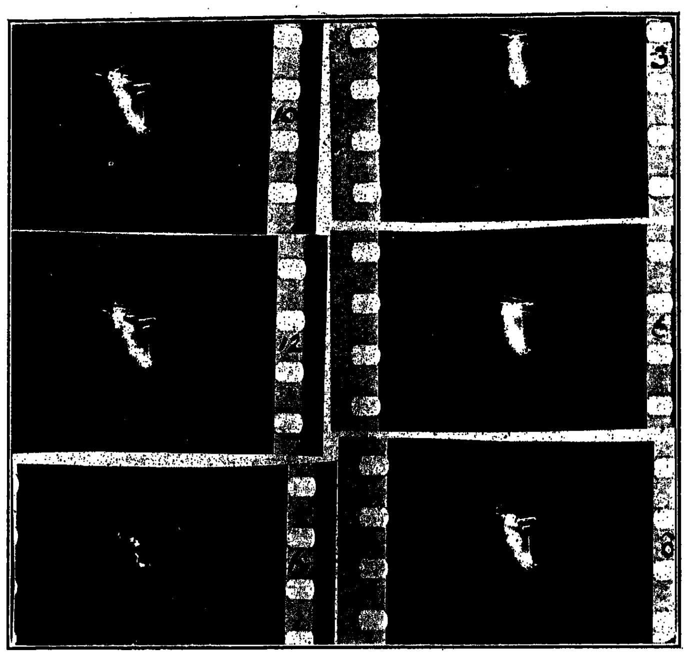
During the above time and up to Nov. 25th, 85.6 per cent of the suspension strings had 9 units, the remainder 11 units each, standard 10-in. suspension disks of cap and pin type being used throughout.

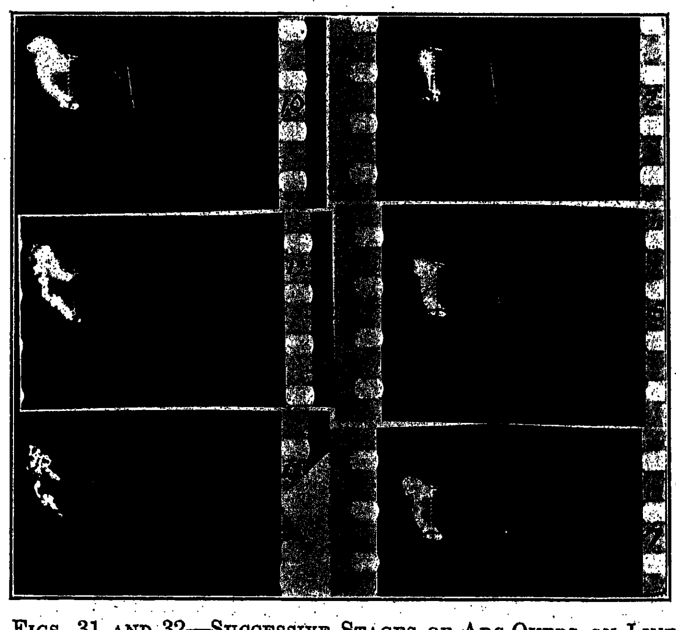
From Nov. 25, 1921 to Dec. 4, 1921 the line was out of service while additional insulators were installed, bringing all suspension strings up to eleven units each.

The line remained energized until Feb. 16, 1922 when the test had to be discontinued as the energizing transformers could no longer be spared for the purpose.

The first rain of the season came Sept 30, 1921, starting with gentle showers and mist and continuing thus intermittently throughout the day. At 8.52 p. m. the relays upon the 65-kv. side of the transformers cut the line out of service. The line was not put back into service until noon of the following day when it was switched onto the system at full voltage during the rain. No further trouble developed, but two or three days later, the cause of the trouble on the 30th was found by the patrolman to be a nine-unit suspension string which had arced over under about 161 kv. to ground. The arc-over was typical, having followed an identical path to that observed in laboratory flash-overs under artificial rain. It originated on the lower shield ring, then jumped to the cap of the No. 3 unit, then to No. 4, then jumped clear to No. 7 cap and cascaded both No. 8 and No. 9. The porcelain of the top No. 9 unit was cracked off on one side. This string with eight good remaining units went back into service in the rain and stood up until changed some days later. This was the only failure of insulation while the line was energized at 280 kv. It occurred under the most trying climatic conditions of the first rains, upon insulators covered with the accumulated dirt and dust of the whole preceding dry season.

During operation at 245 kv. the line kicked out on Nov. 6, 1921 and Jan. 18, 1922 without apparent reason in clear weather. The line was most carefully patrolled





Figs. 31 and 32—Successive Stages of Arc-Overs on Line

but no evidences of flash-over discovered. Later after the test was all over and the transformers were being put into normal service at 150 kv. one of them broke down and upon opening up the coils it was found that surface discharges across insulating barriers had taken place under the oil. There is no proof that this was the cause of the unexplained cutting out of the line but it seems probable.

With a view to observing the action of the insulation with its shields under arc-over, with more energy in the arc than was obtainable in the laboratory, intentional arc-overs were made by pulling a No. 40 copper wire across the insulator. Both still and motion pictures were taken of the arc which behaved entirely similarly to laboratory arcs with the exception that the light was vastly greater.

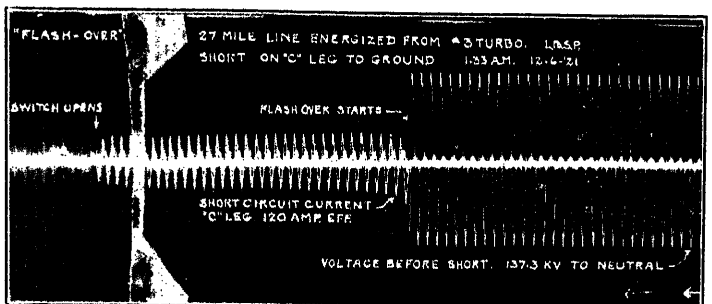


Fig. 33—Current During Arc-Over on Tower

For these flash-overs the line was fed from a 25,000-kv-a. steam turbine. The current in the arc was approximately 120 amperes. Fig. 31 shows progressive stages of an arc in the center position of the tower and Fig. 32 shows similar stages of an arc in the outer position. It is interesting to note the dying out of the arc in patches of incandescent vapor. These arcs lasted about 32 cycles, the relay then opening the circuit. No damage was done to porcelain or hardware. Fig. 33 gives the oscillogram of the performance; gradual decrease in the current is noticeable as the arc lengthens.

Air-Break Switch

Some experimental work was done toward developing an inexpensive air-break switch for line sectionalizing. To settle the question as to whether such a switch would be able to break the charging current of a 27-mile length of line, one was set up in the line and opened.

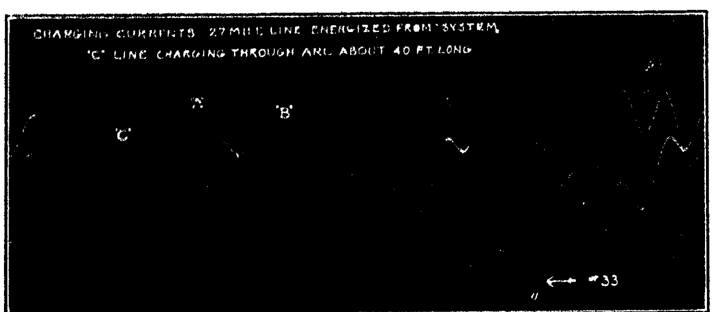

Fig. 34—Charging Current of Line through Long Open-Air Arc

The arc held on for about six seconds, in quiet air, rising continually higher until it broke. The total length measured along the arc reached a maximum of from 60 to 70 ft. with a 23-ampere arc. Such an arc increases the charging current to the line due to wave distortion as shown in Fig. 34.

In view of the extremely long arc and the liability of its being blown into adjacent conductors it was decided to abandon the idea of breaking charging current upon air-break switches but to operate the sectionalizing switch stations so that the air-break switches would be used only for separating parallel lines.

Tower Design

Comparative studies were made of the cost of single- and double-circuit towers as follows: Clearances from insulator shield to tower of four five and six feet; conductors of 605,000, 1,000,000 and 1,500,000 circular mils of aluminum with steel core and copper conductors of resistance equivalent to the two larger sizes of aluminum; flexible and rigid towers, all towers to stand the unbalanced pull of any two conductors being broken and anchor towers to stand all conductors being broken on one side.

The combinations and permutations of these variables are many.

The final decision was for single-circuit towers, as costing no more per circuit than double-circuit construction.

Steel-core aluminum was preferred above copper, and the extra cost of obtaining six ft. clearance over that for four ft. was so insignificant that the minimum of six ft. was adopted.

The only condition under which double-circuit towers would seem advisable would be where it was extremely difficult to get rights of way. It also appeared somewhat hazardous to tie up such quantities of power as 240,000 kw. upon a single-tower line, at all events with the size of the whole system such as it will be for some few years to come.

Protective Devices

The 150-kv. lightning arresters now in service at Big Creek generating plants, Vestal and Eagle Rock substations, will remain in operation, but it is not intended to install any arresters on the 220-kv. lines.

The two existing Big Creek tower lines have one ground wire on each and these will of course remain. They are of service in distributing ground current over several towers in the case of insulator arc-over. They are also felt to be of some slight mechanical advantage, although with rigid towers this would only be effective after a tower member buckled or a tower foundation washed out or gave way.

Mention has been made of the possibility of automatic sectionalizing of the line; this would be effected by balanced relays.

The method now used of breaking arc-overs is to lower the fields of generators and synchronous condensers until the arc breaks, and upon building up the field once more the generators pull into step, if they have fallen out of synchronism, and service is resumed in about one minute on an average.

Plans are under way to make this operation automatic which should result in a great saving of time.

Conclusions

Transmission at 220 kv. has been invested with a certain glamour, and the further investigation has been carried the more certain it appears that transmission at this voltage will only differ in degree from transmission at lower voltages, with which we are familiar. No new or startling effects are expected or appear probable.

The unequal voltage distribution over long insulator strings can be eliminated to the degree where individual units will be stressed less than they now are on lines in commercial operation. This is effected by shield rings which at the same time can be so designed as to keep any accidental arc well away from the insulators. Corona upon insulators and hardware is also prevented.

Standard suspension insulators can be used, so that 220-kv. transmission need not wait upon the design and trial of new types of insulator.

Transformers and switches are already developed, and have been built by more than one manufacturer.

The corona constants of large cables are known within rather narrow limits so that lines can be confidently designed to have definite known losses.

The charging current of commercial lines is also sufficiently well determined so that calculations of voltage regulation will be accurate.

There are therefore no apparent obstacles in the way of 220-kv. transmission, the only requirement being that the amount of power to be transmitted shall be sufficiently large, and the distance great enough to warrant the cost of 220-kv. equipment. The increased carrying capacity of the transmission lines then more than offsets the equipment cost and 220-kv. transmission becomes more economical than at any lower voltage.

Discussion

W. A. Hillebrand: Concerning the experiments on the disconnector switch, with regard to characteristic flash-over and the opening distance and clearance from the ground necessary to prevent the arc from shooting across the gap. Was any effort made to control the direction of flash-over by means of screens or guards which would reduce the gradient between the blade and the clip on the opposite side?

R. J. C. Wood: The only attachment to the switch is a vertical piece of pipe on the clip end which, when the switch was opened, formed, with the switch blade, a horn gap. This pipe was within three or four inches of the clip. The arc would very often hold onto this clip and pay no attention to the horn at all. There was no other attempt to influence the arc. The arc hung on for five or six seconds. We were satisfied that the arc was too long and that we had better not attempt to use such a switch for breaking charging currents.

W. A. Hillebrand: I think you misunderstood me, Mr. Wood, it is not in connection with the switch or breaking charge.

R. J. C. Wood: That was the charging current?

W. A. Hillebrand: Yes, but as I understood you to say, your disconnecting switches in the substation being 220, are mounted on the tripod that you had the nine-inch gap—linear gap necessary—a nine foot gap with regard to the striking distance to the ground, to prevent the possibility of an arc shooting across the open gap into the substation wire.

R. J. C. Wood: We had a big shield around the top of these posts, the circular disk to which the legs were attached was in the neighborhood of twenty inches in diameter, and formed a shield for the insulators distributing voltage in the same way that the shield on the transmission line does, it also prevented corona from the switch clip; but we did not try anything such as Mr. Hillebrand suggests. We were rather skeptical of any of these high-frequency effects existing at all. But we thought we had better make sure and arrange this side-gap so that if any of these unknown things did come in then we would be safe. In making the test we duplicated the set-up of the station, the walls, columns, etc., so that the field surrounding the switch would be the same in the test as it would be in the power house. Does that answer your question?

W. A. Hillebrand: Yes. One other thing which had better perhaps be discussed, that may be of extreme interest, and is of unquestioned importance, that is, the charging current of the line, the kv-a., its relation to the generator, the capacities available, the methods of energizing—of excitation, and finally of switch synchronizing. That is, you have to energize the line with presumably a very considerable potential difference between the open end of your line and the system at Eagle Rock, which you will have to parallel.

R. J. C. Wood: First of all as to the charging kv-a. on the line, that will be 50,000 kv-a. for one line, the whole distance. After once getting started, there will be no difficulty, the line can be cut up into sections. If we have to, when we first start we can energize a section at a time adding generators as required. Also, we will have synchronous condensers at the load end. It is quite possible to put a condenser on the line and with a generator on the other end, bring the whole system up together from standstill, having the condenser on the end reduces the kv-a. required from the generator. One way of looking at it, part of the required 50,000 kv-a. comes out of the generator, part of it out of the synchronous condenser.

Apart from the magnitude, I do not see why operating problems are going to be any different from what they are now. With lines paralleled at the generating end only, one has a higher voltage than the other at the load end, when one is carrying the load, the other is not carrying the load.

Upon paralleling at the load end, loads and voltages in the two lines will equalize. There will be surges of course but so far we have been unable to record higher than an 80 per cent voltage rise when cutting in or out a 100-mile section of line and if the line is not good for that it is not good for anything.

With regard to determining what these high voltages—surges—on the line actually are going to be, all that can be obtained is an estimate based upon what we actually have now on the 150-kv-line; we have been working for some time to determine what voltage rise—surges—occur on that line in normal operation. We have had a lot of experience trying to make a surge recorder. We finally rigged up a device comprising substantially six points, which formed six air gaps of different lengths, varying from about the 64th of an inch to one eighth of an inch. These points are opposite a metal plate, and a kodak film moves along in the gaps. We have arranged to use an ordinary standard kodak film, load and unload it in daylight, the substation man or anybody else can handle it.

But we have had records on the surge recorder of as much as something less than 100 per cent rise of voltage. Of course there is nothing very precise about it. The first gap is set to discharge at slightly above the line voltage—possibly 10 per cent; the second gap at 25 per cent above voltage, the third at 50, the fourth at 100, and the fifth at 200 per cent above normal voltage. The highest surges that we have any record of so far, occur when we kill the bus in the station where we have this recorder installed. We have records of surges which occur when oil switches are opened at the far end of the line. The recorder, by the way, is on the bus at Eagle Rock substation, and we get records of

switching operations at Big Creek, on the other extreme end of the line, but so far we have no records of anything like 200 or 300 per cent above normal voltage, which voltage would still be insufficient to flash-over an ordinary string of insulators.

We have been troubled with unexplained flash-overs on the Big Creek line. This has occurred at times when operation is apparently entirely normal. No switching is going on, fair weather, apparently no reason at all, the first thing we know there is a flash-over and the voltage is down and we are in trouble —which does not last very long, about from one to two minutes; but at the same time the larger the system becomes and the greater amount of power that is going over the line, the more serious, even what we call a momentary interruption, becomes. We are bending all energies now to try to determine what is actually going on in the present line, and we feel that until we get the answer to that we will not have the answer to the flash-over.

J. Mini, Jr.: Through the courtesy of Mr. Wood I had the opportunity of visiting and seeing the tests made on his system during the time they had on the high voltage, and I feel that there have been very few tests ever made—probably none ever made, of a line of such high voltage and that length on an actual transmission line. When the line was operating somewhere around 280,000 volts it was noisy and visible at night. The fact that the line was alive was easy to detect while it was operated with above voltage, but when the voltage was brought down to 220,000 volts you would have to be told that the lower voltage was on or you would not be aware of it.

There are one or two points in connection with Mr. Wood's paper where he tells you that the transmission line source is from star-grounded transformers and the receiving end connected to delta-delta transformers. He also tells you that they break these flash-overs by lowering the voltage. I believe that when we come to connect both ends of the transmission system star-grounded, that is the receiving end and the sending end, it will not be so easy to break the flash-over as it is under their present system where the receiving end is connected delta. I speak from our experience of 110,000-volt transmission lines where the receiving end is connected star-grounded as well as the sending end, and it is only in the case where we have one generator on the line and the energy is small that a flash-over can be broken, that is, the arc can be broken by lowering the voltage at the generator's end. The flashover arc is fed from both ends, whereas in Mr. Wood's system at the present time the real energy current in the flash-over arc to ground comes from the sending end.

We have found that the best method of getting rid of these flashovers, when they happen, (of course this can only be done when you have duplicate transmission lines operating in parallel) is by having one relay that is set very light for ground trouble, and three other relays set heavy so far as trouble between phases goes, you can have this line severed from the system at the receiving end and sending end in ample time before any damage is done.

Before we put in this system of residual relays which trip a line out with a moderately light ground, a flash-over to ground on our lines burned them down invariably. It was practically impossible, with hand operation for the operator to disconnect a line in time, before the wire had not been so severely damaged by burning that it subsequently pulled in two.

There is just one other point that comes to mind in regard to operating these lines at very high voltage and long mileage, and that is, if you have duplicate lines, and say one line is fully loaded and you want to switch in a second line, there will probably be a very large phase angle at the receiving end between the loaded and empty line voltage which will cause a severe disturbance of the voltage while equalizing the load by throwing them together. It has occurred to me that it might be possible in this case to close the line at the receiving end first and back voltage to the power house; then put on a separate generator and pull up some of the load and finally parallel the lines at the power house after the load was more equally divided over the two lines.

F. W. Peek, Jr., (by letter): Mr. Wood gives some very interesting and important data on the various factors affecting transmission at 220 kv. Mr. Wood's conclusions are not based on laboratory work alone but also upon the several years operating experience of the Southern California Edison Co. at a 30 per cent lower voltage. No radical changes in types of apparatus have been found necessary.

Standard ten-inch disk insulators will be used. The use of a simple metal ring shield will reduce the maximum unit stresses below those on present successful lines operating at lower voltages. The ring shield also serves as a very efficient arcing ring. Tests at 280 kv. on a thirty-mile section of line indicated that the line insulation will be quite satisfactory. There was only one arc-over. This occurred on a nine-unit string at 280 kv. during the first rains after the insulators had had a chance to accumulate dust for a full season. This is probably the worst condition to contend with in California. In connection with the arc-over of wet and dirty strings I wish to point out that unless the power supply is large, laboratory tests are of little value as an indication of arc-over voltages in practise. This follows because when the power is limited by the generator or transformer the heavy current flowing over the conducting surfaces lowers the voltage before an arc develops. The arc-over voltage thus appears much higher than would actually be the case on a large system.

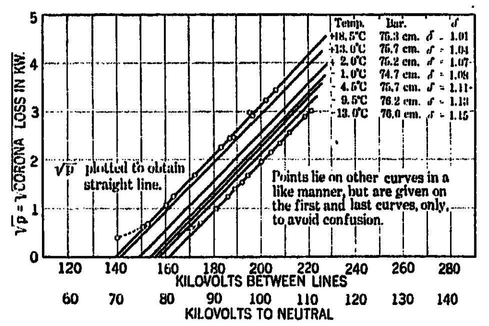

FIG. 1—CORONA LOSS MEASUREMENT AT VARIOUS TEMPERATURES

3/0 Seven Strand Cable. $r = 0.59$ cm. $S = 310$ cm. Single phase 60 cycles—1.09 km. Total Conductor Fair Weather.

The neutral of the system will be thoroughly grounded and thus eliminate dangerous oscillations and high voltages in case of an accidental ground on one or more lines. The permanent grounding of the neutral at the transformer also makes possible a much safer and better transformer. In fact, all creepage surfaces in the transformer are eliminated.

I am particularly interested in the corona measurements, because these measurements check so well with my own made on an outdoor experimental line in Schenectady in 1910 and discussed in the TRANSACTIONS.

It is interesting to make a comparison. In the Schenectady work it was also found that when a line had been idle and had become wet or dirty the loss was quite large on the first application of voltage. It was at first thought that this was due to leakage over the insulators. Tests were then made with a great many insulators bunched together so as to practically eliminate the line. It was found that the insulator loss was negligible under the above conditions and also in very heavy rain and snow storms. The excess loss was found to be due to the wet or dirty conductor surface. A study in the dark showed that water was sprayed from the conductor with a considerable increase in corona which extended out a great distance from the conductor surface. When there was fog, rain, snow or sleet this condition was found to be continuous.

In the formula for the disruptive critical voltage there is a

factor, m_0, called the irregularity factor. This factor is used as a measure of the effect of roughness or irregularities of the conductor surface in lowering the critical voltage. It is unity for a smooth cylinder and less for cables. It is, therefore, not much affected by temperature and is constant for any weathered conductor. In fact, we found m_0 constant over a range of hot summer temperatures to below zero temperatures of winter, (See Fig. 1). Fog, rain and other conditions lower the critical voltage in the same way.

The weather factor, which may be called m_s, is variable. An average value of m_s for storms is 0.8. Mr. Wood has combined m_s and m_0 in one factor and denoted it by capital M_0.

Thus $M_0 = m_0\, m_s$

I rather think it undesirable to do this because small m_0 is a constant which applies to a given weathered conductor anywhere,

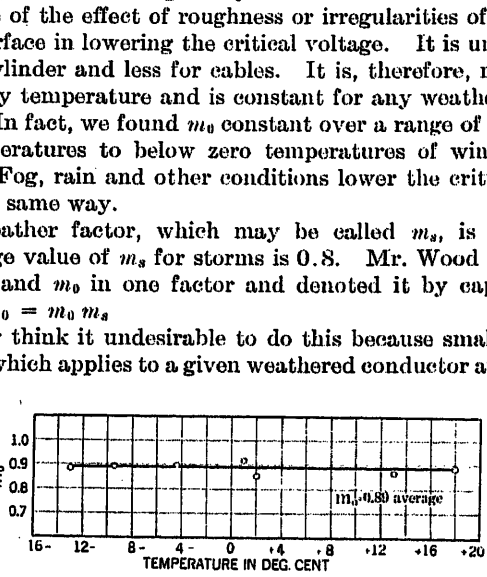

FIG. 2—3/0, 7-STRAND CABLE $r = 0.59$ CM. $S = 310$ CM. SINGLE PHASE—60 CYCLES—FAIR WEATHER

while m_s will vary with the location and the season. Mr. Wood shows an apparent variation of capital M_0 with temperature in Fig. 27. Upon examination it is found that the stormy weather points occur at the lower temperatures. I am inclined to believe that the apparent reduction is not due to the lower temperature but mostly to the storms or fog that occurred at the lower temperature. It will be noted that the fair weather points in Fig. 27 can be equally well represented by a line parallel to the temperature axis at 0.85 and the stormy weather points by a line parallel to the temperature ended at 0.80 (See Fig. 3).

Then Fair Weather $M_0 = m_0 = 0.85$

Stormy Weather $M_0 = m_0\, m_s = 0.80$

The average storm factor for the particular tests is therefore:

$$m_s = \frac{0.80}{0.85} = 0.94$$

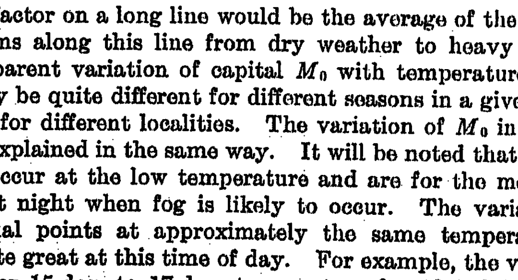

FIG. 3—BAD WEATHER AND CLEAR WEATHER POINTS DATA FROM FIG. 27

This factor on a long line would be the average of the various conditions along this line from dry weather to heavy storms. The apparent variation of capital M_0 with temperature would probably be quite different for different seasons in a given locality and for different localities. The variation of M_0 in Fig. 26 can be explained in the same way. It will be noted that the low points occur at the low temperature and are for the most part taken at night when fog is likely to occur. The variation of individual points at approximately the same temperature is also quite great at this time of day. For example, the variation of M_0 for 15 deg. to 17 deg. temperature for 12 A. M. to 4:30 A. M. is from 0.80 to 0.90. The shot gun effect of these diagrams should be expected for a long line where all of the variables are not under control or known. The starting voltages vary along the line and the meters record an average condition. Part of the individual variation is also due to the fact that the values were obtained at the lower or unstable part of the curve.

The above discussion is given as a possible explanation of the apparent variation of M_0 with temperature which Mr. Wood has found. It is not intended as a criticism of the value of the data. Such measurements on operating lines are of great value and the industry is greatly indebted to Mr. Wood.

Referring now to the m_0 factor as originally employed, it is desirable to obtain conductors in which this is as nearly unity as possible. It is necessary to give this factor greater consideration as the voltages are increased. A smooth cylinder would be a desirable conductor. Since in present practise cables are employed it is of great importance that the individual strands be regularly placed and free from burrs and points and other irregularities of manufacture. The loss near the critical voltage on a new cable will often be higher than on a cable that has "weathered" under the action of voltage when there is a tendency for the burrs to disappear by oxidation at the over-stressed points. In making measurements on new cables of different stranding we have found high losses near the critical voltage where strands had been mutilated in manufacture.

It may be of interest to point out further possible irregularities in manufacture that will affect M_0. The Southern California Edison conductor which is highly satisfactory for 220 kv. is made up of individual strands about one-tenth of an inch in diameter. A single strand would have corona at very low voltage. In the cable each strand is placed around the surface as its neighbor is placed. Corona starts at a very high voltage because each strand shields its neighbor and the stress is divided equally

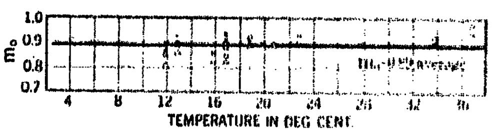

FIG. 4—M_0 VALUES—IRREGULARITY FACTOR OF THE CABLE SURFACE

Data taken from Table I—*Electrical World*, May 6th, 1922, also included Fig. 26.

Points indicated by x are bad weather points divided by an assumed average bad weather factor, $m_s = 0.95$ to reduce to m_0.

Points indicated by o are fair weather points calculated from data given in the table.

Points indicated by △ are points calculated by Mr. Wood where they do not agree with the x or o points.

x Storm points in table divided by $m_s = 0.95$.

o Fair weather points from data in table. $m_0 = \dfrac{m_s\, m_0}{m_s}$

△ Given when Mr. Wood's calculations do not agree.

between them. If, in the process of manufacture, one strand becomes squeezed out so that it stood above its neighbors it would take more than its share of the stress and local loss would occur at a lower voltage.

In conclusion I wish to again express my appreciation of this paper and to point out that it further confirms our belief in the success of 220-kv. transmission.

R. J. C. Wood: Mr. Peek's criticism of the use of the symbol capital M_0 to include the combined effect of surface roughness and weather conditions is well taken. It should be remembered however that the whole investigation was primarily undertaken to determine the constants of a definite line already built in a definite location, and that for this purpose the single factor answered the purpose. Sufficient data are given so that those interested may further split up this factor as desired.

There seems to have been some misunderstanding of Fig. 26 and 27. Fig. 26 gives the results obtained experimentally while operating at 161 kv. to neutral. The observations were taken every two hours, and from the measured loss, the physical constants of the line, and the atmospheric data, that value of M_0 was determined which would in each case satisfy the other

conditions. A casual glance at the plot of M_0 against temperature shows that the two increase and decrease together, although the air density factor has already been allowed for in the calculation of M_0. The diagram is somewhat of the shot gun variety, and had average values of M_0 for each degree Centrigrade been plotted a much better looking result would have been obtained but at a sacrifice of sincerity. In Fig. 27 values of M_0 are plotted after having been determined from observations taken in both clear and rainy weather while operating at 141 kv. to neutral. No claim is intended that these values of M_0 bear any relation to temperature in fact the diverse weather

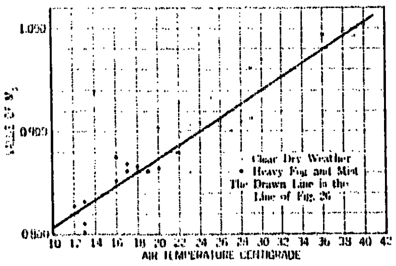

FIG. 5—OBSERVED VALUES OF M_0. 19.5 AND 12 MILES OF LINE, 161 AND 156 KV. TO NEUTRAL, 50 CYCLES

conditions would preclude such an idea at once, but; for comparison, the line of Fig. 26 is extended through Fig. 27 as an indication of what might be expected to be the values of M_0 *in clear weather* at the lower temperatures, and to show the extent of the deviation from the fine weather line, caused by rain.

In Mr. Peek's replot of Fig. 27 in his chart No. 3 he has compressed the vertical scale so that a direct visual comparison of the two charts is difficult to make. His suggestion that the low temperature observations in his Fig. 3 are probably due to moisture is I believe not tenable as in this country such temperatures as 2 deg. cent. are only obtained with clear skies and unimpeded radiation.

Since reading Mr. Peek's discussion I have gone over the original data very carefully, together with U. S. Weather Bureau reports, and have selected a number of observations about which there is apparently no doubt as to absence of fog and including readings upon 12 miles of line taken at high temperatures. These are plotted in the accompanying Fig. 5 as clear circles. In the same figure are plotted a number of observations taken in heavy fog and mist but not rain, these showing in full circles. Apparently there is no discontinuity between the fair and foggy weather data and this would indicate that it is temperature and not fog that determines the variations of M_0 for this line.

In most of the published data upon corona loss measurements a suitable value of M_0 has been chosen and the loss, as calculated assuming this M_0 to be constant, shown in the familiar parabolic curve, observed losses have then been plotted lying more or less along the curve. The value of M_0 is chosen so as to place the calculated line well through the observed points in the upper part of the curve at high voltages, and the lack of agreement at below the visual corona point assigned to the dark realms of probability.

From a practical standpoint it is precisely the sub-visual region that is the most interesting. A transmission line cannot be expected to have a corona loss in accordance with the quadratic law until there is sufficient corona upon it to smooth out its roughnesses and this seems to be at about the visual point. This is illustrated in Fig. 6 in which is shown the observed losses of the test of Oct. 12, the data being in Table VII. The drawn lines show calculated losses, first assuming the whole line to have an irregularity $M_0 = 0.85$ which agrees well with the observed data above the visual point, and secondly assuming three tenths of the length of the line to be in corona with a factor $M_0 = 0.78$ which agrees with the observed losses below the visual point.

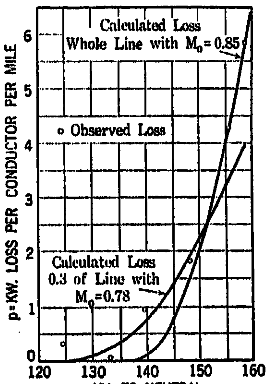

FIG. 6—CORONA TEST, 19.5-MILE LINE, 11 DEG. CENT., BAR. 72 CM. 50 CYCLES, OCT. 12/21

It seems logical to conceive of the line as having certain portions rougher than others and consequently having a lower value of M_0.

It should be remembered that in all the calculations of this paper the mean logarithmic spacing of the conductors has been used equal to 1.26 times the spacing between adjacent conductors. If on the contrary the spacing between adjacent conductors be used in the calculations, larger calculated values of charging current and higher values of M_0 in the corona formula will result.

An Overpotential Test for Insulators

BY G. W. LAPP
Associate, A. I. E. E.
Chief Engineer, Lapp Insulator Company, Inc., Le Roy, N. Y.

Some of the factors met in the design of insulators and characteristics of routine electrical tests are discussed in this paper.

A new overpotential test is described with its application and effects. Results of this test make possible a higher standard of practise in the manufacture and use of transmission line insulators.

Ever increasing responsibility is being placed upon transmission line insulators. To establish by specific tests that each insulator put into service has a liberal initial factor of safety and further to be assured that the insulator will be proof against deterioration in service is the ideal toward which we are working.

Factors in Design

PERMANENT high dielectric strength in an insulator is the fundamental requirement, but this is not an independent factor in the determination of sound insulators. Along with dielectric strength we must consider the flash-over voltage of the insulator, its shell thickness and its impulse ratio. If these three be high the dielectric strength should be correspondingly higher.

The ratio of puncture voltage to the product of flash-over voltage times impulse ratio may be taken as the electrical factor of safety in service. This factor of safety may be increased by higher dielectric strength and by lower flash-over voltage, while the impulse ratio is rarely utilized as an independent variable in designing insulators. Higher dielectric strength in turn is a function of thickness as well as dielectric strength per unit thickness. Thickness is a matter of design while unit dielectric strength in the case of porcelain insulators, is contributed by effective solution of the ceramic problem. These two factors may appear to be independent but they are, as a matter of fact, strictly interdependent. Thicker insulators have replaced the thin sections of former days, but unless this increase in thickness is accompanied by better porcelain, the sought-for increase in dielectric strength is but temporary. The thicker the porcelain, the more necessary it is to prove its soundness.

Thicker shells of good material are better. They are stronger mechanically and more quiet electrically. But what shall tell us that they are not of a quality whose inferiority is hidden by the thickness of the shell? The electrical test is the only practical means of proving each insulator.

Routine Electrical Tests

The routine electrical test is depended upon to weed out poor material. The potential of this test as usually applied, is flash-over voltage. The potential required to puncture a piece of good quality may run twice the voltage of flash-over. Some insulators fail on flash-over test. Those that pass the test, range in dielectric strength between flash-over and the puncture strength of sound porcelain. Some insulators that pass this flash-over test have inherent weakness that would cause them to fail if the potential difference were higher or applied for a longer time. Application of voltage longer than a few minutes produces but few additional punctures so that attention has been devoted to increasing the voltage of test.

The most obvious possibility of applying higher potentials is to immerse the insulator in oil as in puncture testing. This has never become a routine test on insulators for service because of its many disadvantages. On account of the presence of this medium of low dielectric constant and high dielectric strength the application of full potential is limited to areas actually in intimate contact with the conducting terminals. This restriction localizes and intensifies the dielectric flux to such an extent that damage may be done to perfectly good insulators. Aside from this, the immersed oil test is expensive to apply.

Two other tests that have had commercial application in routine testing of suspension insulators, secure a slight excess of voltage above 60-cycle flash-over by utilizing the impulse ratio or the time lag of the insulator. They are known as the high-frequency test and the impact test.

The High-Frequency Test

This test employs damped wave trains of the order of 100,000 to 200,000 cycles a second applied for a few seconds. The vigor and time with which this test can be applied are somewhat limited by the tendency of the flash-over streamers to become localized and then to start digesting the porcelain by local heating. The detection of a small percentage of unsound material that the 60-cycle open flash-over test would have allowed to pass has heretofore justified the use of this test. It cannot be relied upon for the detection of the greater part of material that is improperly fired nor for many checks that escape visual inspection.

The Impact Test

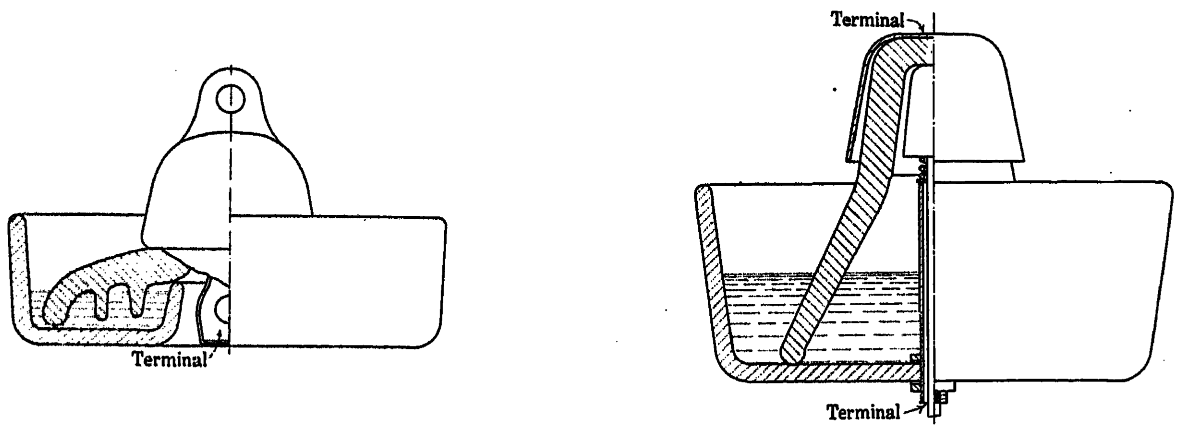
In the electrical impact test a spark gap in series with the test causes a slight amplitude of damped high frequency to be superimposed upon the low-frequency wave.

A condenser across the line adds to the slight surge of high-frequency energy when flash-over of the auxiliary gap occurs. The intensity of this test varies with the energy available from the source and from the

Presented at the Pacific Coast Convention of the A. I. E. E., Vancouver, B. C., August 8-11, 1922.

condenser and depends upon a nice proportioning of the electrostatic capacity of the auxiliary gap to the capacity of the insulator, and is further affected by the resistances in the circuit. If the capacity of the gap is too low the insulator charging current leaks across the gap too early to cause much high-frequency amplitude to remain on the crest of the 60-cycle wave. If the capacity in parallel with the auxiliary gap is too high, the insulator flash-over starts at normal frequency and the impact effect is lost again. The impact effect is greatest with an auxiliary sphere gap discharging just before the low-frequency voltage wave reaches maximum value. As the possibility of utilizing the impulse ratio of the insulator in commercial routine testing depends upon the electrical constants of the circuit, a standardized test of this nature is not readily attained and verified.

At best, either the high-frequency or the impulse test adds but a few per cent to the voltage available to test the dielectric strength of the insulator. It must be assumed that voltage surges in service will equal in intensity any test voltage depending for its added effectiveness upon the steepness of its wave and the time lag of flash-over. Such tests cannot raise the minimum factor of safety above unity, much less establish a definite margin of safety or weed out insulators that may deteriorate in service.



Figs. 1 and 2—Arrangement for Overpotential Test

The Overpotential Test

To make it possible to test insulators at any definite voltage desired from flash-over to high puncture, the following overpotential test has been devised and used for commercial testing. In this test (Figs. 1 and 2) the insulator is placed in an insulating dish which holds a sufficient depth of oil to form an electrical flash-over seal at the rim of the insulator at the same time leaving the head and center part of the shell exposed to the air. The inside terminal is connected with a conductor passing up through the center of the dish. In effect the dish becomes part of the insulator which temporarily, for testing purposes, acquires an extended flash-over distance, sufficiently long to prevent flash-over at the chosen testing voltage.

Application of the Test. With the above simple arrangement many possibilities at once appear. On account of the presence of air inside and outside, the vital center of the insulator is bathed in active corona (Fig. 3) which diffuses the potential without concentration and without local heating and injury to the insulator; although covered with this ionized air the temperature of the insulator at the end of test is not hot. The area exposed to active potential may be limited as desired by raising the oil level.

On account of absence of flash-over (see spark gap, Fig. 4), the specified test voltage can be maintained at a constant value by holding a fixed voltmeter reading showing potential impressed upon the primary of the

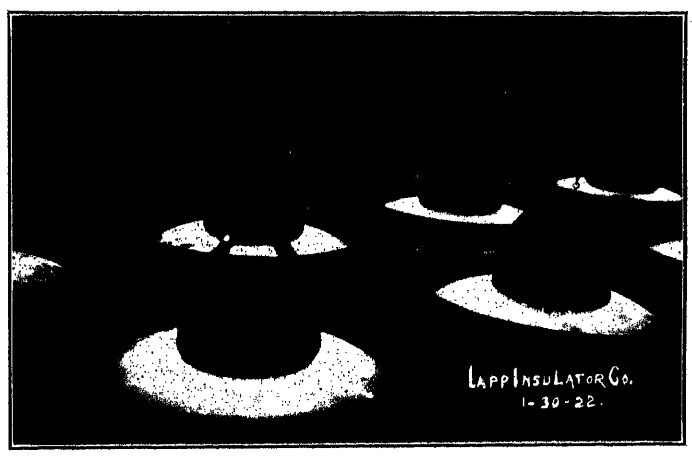


Fig. 3—Overpotential Test—Center of Insulator Bathed in Active Corona

testing transformer. This value can be verified accurately at intervals by checking against the spark gap without the disturbing surges that accompany calibration with parallel flash-over. Either the sphere gap or needle gap can thus be used to calibrate the test without the discrepancies that usually attend the determination of flash-over voltage by means of these two

gaps. Not only will the surge from a flash-over test cause the gap to discharge and vice versa, but the sphere gap is more sensitive than the needle gap and usually more sensitive than the test to this voltage kick because of differences in impulse ratios. By eliminating flash-over we eliminate the indeterminate effects noted and make it possible to apply to the insulator an accurately

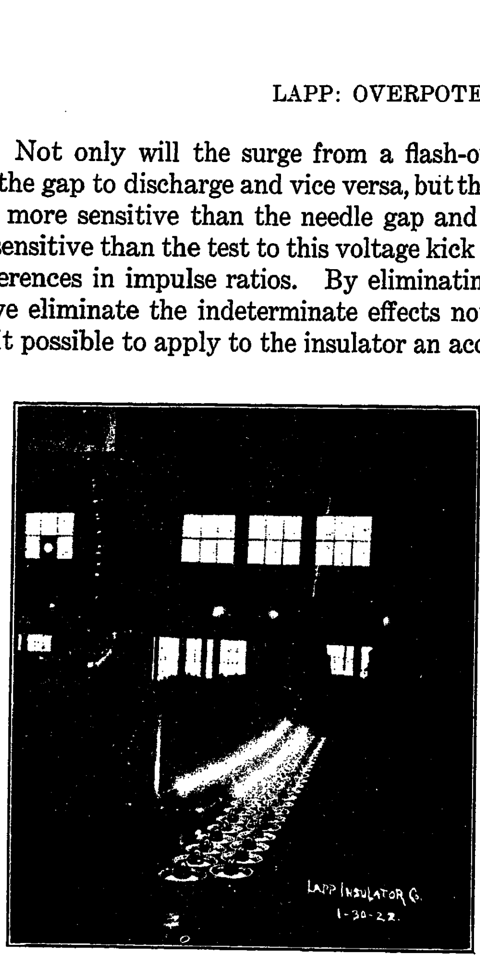

FIG. 4—OVERPOTENTIAL TEST—SPARK GAP

determined voltage of approximately sine wave. The importance of applying low frequency may be gained from an observation of the effects of the "high-frequency" test. It appears that the surface digestion of the porcelain is due to a lack of penetration of the dielectric stress deep enough to cause a uniform potential gradient throughout the thickness of the dielectric. It appears that the energy per half cycle of the damped high-frequency wave is not sufficient to supply the energy required by dielectric hysteresis and to overcome the counter electromotive force due to time lag of the dielectric in giving up charge except for the surface of the insulator which is immediately in contact with the rapidly reversing potential. The fact that continuous waves of the same order of frequency heat the dielectric many times more rapidly than this damped wave train test, indicates the degree to which the energy is curtailed. This phenomenon may be compared with the skin effects in a solid electric conductor which make the body relatively impenetrable to high-frequency electromagnetic induction.

By confining the high-frequency energy to the surface of the dielectric, destruction proceeds piecemeal through thermal expansion and spalling of the affected region, rapidly taking advantage of the initial local or superficial difference in dielectric strength and accomplishing a puncture only by a process of progressive destruction. This type of failure requiring several thousand successive cycles for its completion, does not appear to correspond to the line failures caused by surges or by lightning as these latter seldom show evidence of progressive digestion of the porcelain. Such line failures are probably completed by a few cycles of high energy which shatter the dielectric by applying a fairly uniform potential gradient to insulators of weakened dielectric strength.

Results of the Test. The fact that the punctures produced by this overpotential applied in a smooth sine wave of low frequency are of marked suddenness and violence, would indicate that this test eliminates fairly material that would be likely to puncture in service due to low dielectric strength of the total path of puncture.

In the overpotential test, involving as it does a higher intensity of applied potential, it is a matter of first importance to know that insulators which have safely passed the test have not been weakened because of the test so as to sacrifice part of their useful life. Two points of information are available in this condition. The first is the dielectric strength as actually determined by puncturing under oil insulators that have passed the overpotential test. The curve of distribution of punctures as obtained on the test itself provides the second source of information. (Fig. 5.)

From records of puncture under oil of 1 per cent of several thousand suspension insulators, representative of six months' production, minimum and average puncture values were increased about 20 per cent and 15 per cent respectively, above previous values on similar units tested by liberal flash-over with impact.

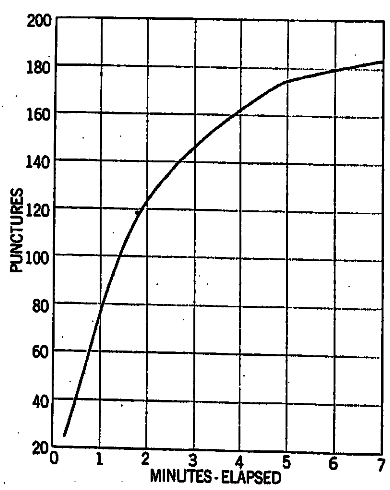

FIG. 5—TIME DISTRIBUTION OF PUNCTURES—OVERPOTENTIAL TEST

10-in. suspension insulators. Potential applied 125 per cent of flash-over. Time of test, 5 min.—2 min. after last puncture.

Maximum values of puncture were fully as high after applying the overpotential test. In no case was an oil puncture value below the overpotential used on the test.

The curve (Fig. 5) giving distribution of punctures throughout the five minutes of test shows that two-thirds of the failures occurred in the first and second minutes

of test and failures diminished in succeeding minutes, indicating that at the voltage of test no evidence of dielectric fatigue had appeared. If the time of application were to cause increasing loss this curve would show a tendency to rise again. For the purpose of securing further data on the effects of time and intensity of voltage application, a few units were left through successive tests, a total of about twelve hours, without puncture.

Specification Limits. When standard 10-in. uncemented suspension shells are given a vigorous flash-over test for several minutes as is usual, and then tested after assembly, the final 60-cycle flash-over and the "high frequency" together puncture a certain small percentage. When the overpotential test is applied instead of the above final tests, it eliminates about four times as many units and thereby removes the units that would be most likely to fail in service. This margin of dielectric strength or test voltage may be fixed at as high a value as experience proves necessary to weed out material not reliable as a dielectric. The exact value to which it may prove economical to limit the test voltage will be determined by a balance between the cost of failures in service and the cost of insulators of the grade specified. That point can be worked out and a definite standard of dielectric strength established on as sound a basis as engineers are accustomed to use in the purchase of steel for example. The point is that this overpotential test makes possible a definite specification and a means of fulfillment. With a knowledge of the kind of material that goes up on the line, we have a definite starting point for service records.

Design versus Material

It may be objected that the foregoing lays too much stress on dielectric strength and overlooks matters of design and structural details that have undoubtedly been the cause of some failures of insulators. While this problem of design is important, specific information is available for its solution. Physical failures other than dielectric may be classified as to type and definite provisions made in the insulator structure to correct the trouble. Given a porcelain insulator of tested high dielectric strength, the permanence of its electrical and mechanical characteristics is also assured by the same test. For such porcelain coefficients of elasticity and thermal expansion become stable. Design tests for mechanical strength run fairly uniform and liberal factors of mechanical safety can be employed. Few purely mechanical failures are experienced on account of external loading. Insulators of stable dielectric material, with adequate provision for differential thermal expansion and contraction, do not fail in service.

Differentials within individual shells as well as between the shells and the metal and cement composing the structure, should be considered in compensating for temperature variations. Stresses within the insulator can be kept well within the strength of the porcelain with a good margin of resistance to meet external service loads. When porcelain is fairly treated in design with due regard to its known characteristics, it attains a high order of reliability.

Porcelain as a Material for Insulators

Some of the facts about porcelain may be recalled with interest. Within its strength it is three times as flexible as steel since its elastic coefficient is about ten million. Its yield point is also its ultimate strength. There is no permanent elongation. In this particular it compares very favorably with the metals in reliability. When the metals approach the condition for zero ductility they become very unreliable. Steel when alloyed or treated to such a degree that the elastic limit approaches the ultimate strength, becomes impossible to handle without cracking. Reliability is in proportion to ductility of the metal. Porcelain in this respect is of superior toughness because of its thorough anneal and its flexibility.

By taking advantage of its characteristics, the very limitations of porcelain may become a source of strength. A rod of porcelain is a case in point. Values of modulus of rupture in bending for moderate-size rods are observed to be twice as high as values of ultimate strength in tension. This is about the same ratio as found in cast iron and is due to analogous causes. In both cases segregation of density occurs to some degree in the forming process. Skin friction in the die from which the clay is extruded and in the mold through which the iron flows, slightly differentiates the surface from the interior material. In the subsequent shrinkage of the cast iron when it solidifies and in the shrinkage of the clay as it dries, and later as the clay is fired, and further as it is cooled, all of the changes progress from the outside to the inside, accentuating the initial differentials and leaving the rod with a shell under compressive stress and the center volume in tension in all directions. It is now readily seen that when such a rod is stressed in tension, a value lower than the true strength is obtained because part of its strength is cancelled internally. When stressed by bending, the initial compression in the side opposite the load, reverses to a tension stress only after the load has caused flexure, and at the instant of rupture the greater part of the area of cross-section is under tension while the neutral axis is shifted to the compression side. As porcelain is many times as strong in compression as it is in tension, this means favorable loading and an unduly high value of modulus of rupture is found.

The above case of the rod is discussed at some length to illustrate in a quantitative way, the cause and effect of internal stresses. This simple case may give some idea of the value of careful design and indicate why some designs must fail. The hazards accompanying increase in thickness may be appreciated to some degree

by this analogy between porcelain and cast iron. Sound cast iron is made and relied upon; sound porcelain can be made and relied upon in designs that respect its properties.

Porcelain now has this advantage, its soundness as a dielectric and to a great extent, the permanency of all its qualities can be tested by the application of a sufficiently high potential and this can be accomplished without deterioration of what strength it may possess.

Conclusion

Meeting the increasing demands for reliability in transmission of power, a test has been developed which applies to an insulator a definite chosen potential in excess of its highest normal flash-over voltage.

By the elimination of doubtful material, the minimum factor of safety of the insulators can be raised to a point where sound dielectrics are assured.

This test gives to the purchaser a definite basis for specifications and a means of attaining a higher duty insulator.

It gives the operating engineer a knowledge of what grade of insulators he puts on his line—a basis for service records that will mean something.

In this test the manufacturer will find a spur to progress and a proof of quality.

Discussion

C. E. Skinner: Porcelain is essentially in effect a conglomerate of spar, flint and kaolin. Each individual piece has its own personal history. A very large number of factors inevitably enter in, to affect it for good or ill in its making. Much can be done by the ceramist and by the porcelain factory to insure uniformity, but the day will never dawn when lots of porcelain insulators can be tested by sample as we test steel and many other materials. We must always test each piece to see that that piece does not have accidental defects and weaknesses that would unfit it for its intended service. What is required is a test that will search out such defects and weaknesses and which will leave the piece uninjured by the test itself. It is up to the porcelain manufacturer to so operate his plant that he secures the maximum of uniformity, and the test should eliminate all pieces which fall below an agreed standard. The agreed standard should be that which gives satisfactory service under the prescribed conditions. As no test can duplicate service conditions—in fact probably no series of tests can duplicate service conditions—the combined experience of manufacturing, testing and service will finally show what balance should be struck between severity of test and service. We can so test that we destroy every insulator, then we have none for service. The most careful manufacturer cannot hope to so fabricate that no test is required, so there must be an economic balance between test and service. We all welcome any test that will help to show us whether design and material are right, and any test that will eliminate insulators which would not give service.

Mr. Lapp's test is one which should aid designers and manufacturers in determining whether design and material are right, and possibly may be justified in certain cases for a routine test where conditions are unusually severe. I very much doubt, however, if this test will entirely eliminate insulators which would develop flaws or faults in service, and particularly those which may be due to mechanical stresses.

I think the test is one that we should all welcome and give a thorough trial. It will not be an easy test to carry out on large numbers of insulators.

C. L. Fortescue: Mr. Lapp seems to have made out a very good case for the method of testing insulators which he advocates. However, he falls into some errors in his anxiety to make a case for this type of over-potential test. In high-frequency tests for example, the applied frequency as he says, is damped trains of the order of 100,000 to 200,000 cycles a second, but the actual frequency of the test to which the insulator is subjected may be many more times this frequency for the reason that flashover of the insulator sets up another train of damped oscillations which are superimposed on the impressed train. The severity of the high-frequency test is due to the fact that for each half cycle of the 60-cycle current supplying the high-frequency set many more damped oscillations of the natural period of the insulator occur than in the case of the 60-cycle flashover test. However, there is, as Mr. Lapp remarks, a question if such a test may not cause damage by the heating due to the high frequency localized stresses, which are incidental to such tests, and therefore, it becomes necessary to limit such tests to a comparatively short period, as compared to the 60-cycle routine test.

In the 60-cycle routine test the actual 60-cycle applied voltage is not the time test voltage, but the flash-over of the insulators superimposes a highly damped train of oscillation at every half cycle which raises the potential to a value considerably above its normal 60-cycle flashover of the insulator. In order to obtain the best results with this test the impedance of the transformer should be at the proper relation to the capacity of the low and the applied frequency. When this condition is approximated this method appears to be a very reliable routine test for insulators.

The overpotential attainable is, as Mr. Lapp states, limited by the impulse ratio of the insulator, but so too is the impulsive stress to which the insulator is subject under operating conditions Indeed, if we would make a true comparison we would find that, if anything, the potentials to which the insulator is subjected under routine test are several times more severe than any surge they are likely to get in service.

Puncture tests under oil indicate that the 60-cycle routine test, when properly carried, weeds out all the insulators which are likely to be a hazard under operating conditions.

The impact test is a very useful test on insulators also. In this test a large condenser is shunted by the insulator or insulators it is desired to test in series with a sphere gap. The latter is set to a setting somewhat greater than the flashover setting for the potential it is desired to impress on the insulator. The condenser terminals are connected to the terminals of the 60-cycle transformer and the voltage across it is raised until the sphere gap breaks over. It is essential in this case that the capacity of the sphere gap be small compared to that of the insulator, otherwise the initial flashover may take place across the insulator. There is, however no difficulty in obtaining proper operating conditions. The main difficulty is in determining the value of the impulse to which the insulator has been subjected. There is also, in this test the same danger which Mr. Lapp mentions of the arc localizing along a certain path, and melting the porcelain.

Mr. Lapp is, I think, in error in his assumption that the voltage surges to which an insulator is subject in service will equal in intensity the values obtained on test. It is quite possible to obtain conditions on test many times more severe than any that can be obtained in service.

Regarding the test recommended by Mr. Lapp, it has many good points in its favor. One is that the insulators are not flashed over and the testing equipment will not have as severe service as in the case of flashover. Another is the absence of the deafening noise accompanying flashover test, and the presence of large amounts of ozone which tend to produce headache.

A good feature of the method is that the value at which the test is made is under control. In the general run of suspension insulators, a certain test value may be found economic. For

special requirements, a higher value may be necessary and for such cases, the batch may be taken from the standard batch by eliminating those insulators which fall below the test requirements. So far this is very good, provided that the purchaser of the special insulators agrees to pay a special price for his selected insulators. Otherwise, the purchaser of the standard insulator will have to bear part of the cost of the losses sustained in selecting insulators for more exacting service.

I think it very doubtful if this method of testing will be of any advantage for any other type of insulator than the suspension type. There are certain features in this method which make it very good when applied on a small scale, but on a large scale, there would be many disadvantages. The handling of large amounts of oil in vessels exposed to the air is, to say the least, unpleasant and may be hazardous unless the testing is done in an isolated fire proof building. Altogether, I feel that while electrically the method presents some good aspects, it should be carefully investigated before it is adopted.

It should be understood by all concerned that more severe requirements will most assuredly lead to more costly insulators. This may, of course, be economically justified, but it is well to point a warning so that the purchaser will realize that he is not going to get something for nothing.

Mr. Lapp knows that equally as good elimination up to a certain point may be obtained by methods in vogue. Whether a higher elimination will be justified is a question which depends on the worth of the increase in reliability to the user, because such elimination will certainly increase the cost of the insulator to the purchaser.

Lastly, there is some unpleasantness associated with the use of oil in testing insulators which, while not of paramount importance, makes it desirable to find something more convenient to use.

E. E. F. Creighton: Some of those present may not know that I started the oscillator test some years ago, and I have been waiting a long while for people to take it up. Now there are good reasons for that, the principal reason being that the main trouble with insulators could not be corrected by any of the electrical tests that we had in mind. The main trouble—ninety-nine per cent you might say, or maybe it is ninety per cent of the troubles—came from moisture in the porcelain. The moisture I should say in the cement causing a deterioration in the porcelain, and most of that deterioration was due to the absorption of the moisture.

That perhaps is not the major trouble, but the expansion of the cement itself. Cement has a property of expanding, as civil engineers have shown us, continually, if it is moistened and dried. Every time it is moistened it expands, every time it is dried it contracts; every time it is moistened again it expands a little bit farther, so that each time it gets thicker and thicker, until finally it so fills the space between the pin say and the porcelain, or between one porcelain shield and the other, that the natural temperature expansion will cause a crack in the porcelain.

Now as a matter of fact part of the trouble in recent years has been due to this expansion effect. Naturally, the test will not show that. There is a perfectly good porcelain insulator, when it leaves the factory, that has been broken by temperature effects. That fact, however, does not detract in any way from the desirability that Mr. Lapp has emphasized here of an over potential test. When we get rid of the large number of the troubles due to expansion of cement, then it seems to me it becomes necessary to make refinements of over-potential tests.

As Mr. Skinner has pointed out, any sort of test is going to eliminate—any sort of severity in test is going to eliminate more porcelain, and it has to be paid for; but I think it is a very good investment. The whole question, which has been under discussion for years, is what is a reasonable, proper test. The nearest we can come to it in my estimation is to say what are the strains put on an insulator in practise. The principal dielectric strain comes from lightning. Lightning may be of low frequency, but it is more liable to be of high frequency, therefore some transient test, or some continuous test with the higher arc-over value should be applied—some continuous test which is equivalent to a transient test.

The nearest I could see to the proper test was to apply a very sudden test, either by the oscillator or by the impulse test, which would be equivalent to lightning. There has been discussed many times the question of whether it does not damage the porcelain. Just to conclude the matter, compare this situation, an insulator that is tested equal to arc-over value, that porcelain, at the instant that the test ceased, may be at the point of puncture. It has been damaged, it would have punctured, say if the test had been continued a few seconds longer; therefore, there is a piece of porcelain that is damaged and put on the line. Now consider the over potential test, a test at say twenty per cent above arc-over values. That insulator may also be just ready to puncture when the test is stopped, but you have that factor of safety, enough to protect the insulator from lightning.

It seems to me therefore, that, finally, the standard test will be some form—and it does not make any difference to me personally—of over potential test as a perfectly proper test to put on the insulator.

C. P. Osborne: This matter of insulators to the operating men reminds me of the small boy who didn't know which school he wanted to go to. We will have four or five different salesmen come into our office and each of them will tell you the advantages and disadvantages of his insulator. One will tell you that porcelain must be thick, the next one will tell you it is in design, the next one will tell you that the curve is not just right—and the operating man is up in the air. I have been attending these conventions for about ten years, and as yet I don't believe the manufacturers agree on types of insulators. Of course, each manufacturer has his own ideas of these things, and each is the best according to his own ideas.

I have had considerable experience with insulators in a country where we have no salt air, but we have great differences in atmospheric conditions—a great deal of rain, then sunshine, then fog (of course it only rains once in a while in Oregon); but we have had considerable trouble with different types of insulators in our operation, and it seems to me that manufacturers and operating engineers are not close enough together. It is a serious problem. Right now we are endeavoring to build a line, and the economic question in building the line is what type and form of insulator to use. We have to calculate the cost from many angles to arrive at the economic figure for this. You can go to an expense which would be prohibitive. The operating man has to keep his expense down. The manufacturer must manufacture something that the operating man can afford to use, but the manufacturer must charge a price at which he can deliver an insulator that will give the operating man service. Service is the first thing we must get. Public service corporations are simply the tools of the public; you cannot give the public an excuse for a shutdown. They are educated to the point where you must give them continuous service, and when an insulator breaks down it is the least of their troubles. We can say, well the manufacturer thought he had insulators that would not break down. Of course, several reasons might cause the insulator to break down. The boys might shoot it, for instance; and sometimes small checks in the enamel will occur which allow moisture to get into the porcelain. These checks may not be visible to the eye without a magnifying glass. The reason for this I do not know. I don't want to place the blame on any one manufacturer; I find it on most any insulator we have, and we have several different makes.

I do feel that there is not enough cooperation between the operating man and the manufacturer. Somehow it seems to me that a change ought to be brought about through closer study of operating conditions. It is the same thing in operation as it is

in manufacture. It may be that no two operating men will agree on the same subject; but we are vitally interested in this insulator game. I do feel great strides have been made in the manufacture of insulators in the last few years, and I am beginning to feel the weak spots in our system are not so much on the line as formally.

R. J. C. Wood: If it can be proved that we are going to get better insulators for the money, the proposed method of testing will be justified.

I agree with Mr. Fortescue as to the statement of Mr. Lapp that we will get surges in practise more severe than the highest test we would ordinarily put upon an insulator. If such a condition existed I would consider the line to be under insulated.

The whole matter is a question of economics. We will pay extra money for good insulators just so long as we get our money's worth and no longer. We have had some small experience with this testing device of Mr. Lapp's. They sent us out some of the porcelain to test and we tested a number of insulators. Many of the punctures that we got with this method of test were some little distance out from the cap, approximately half way between the cap and the outer diameter of the porcelain. Presumably, as Mr. Lapp suggests, the insulator was not designed for this particular form of test, and to meet the more severe condition imposed by this test the porcelain would have to be thickened out towards the edge of the insulator. Whether that would actually be required to take care of the stress that occurred normally on the line, I rather doubt. It might be putting material in a place where it was not necessary on account of line stress in order to make it pass this particular, special test. However, another few ounces of clay in the insulator does not amount to anything in the matter of cost. There has been a good deal of talk in the past as to the possibility of damaging an insulator by subjecting it to excess electrical tests—and presumably a feeling that an insulator can be tested with a certain potential of less than puncture value with resulting damage. Perhaps some of those present can tell us the nature of that damage, what it is that happens in the porcelain that takes some time to come to fruition.

On the Big Creek lines we have got quite a number of insulators—there are some 7000 towers, suspension towers with twenty-seven dead-end towers with one hundred and thirty-two insulators on each; and there is a great percentage of those dead-end towers, so there are a great many disks on the line. We have kept records of every individual insulator that is meggered and its location in the string on each line, each phase, *a*, *b*, and *c* on each tower, and the date and a few other things. All these data were taken for the last three years and punched on cards; then run through the machine and the information segregated in any desired manner.

The analysis of insulators that show low on the megger shows that in the suspension strings a vastly greater percentage of the top units proved bad, the ones nearest the tower. The first thought was, that in Southern California the sun which shines there has been shining on these top units on and off every day of course, and expanding and contracting them, and that is the reason why they have failed so much more than any others in the string. But we found that in the dead-end insulators which lie in a horizontal plane and all get the sun alike and the same thing is true, it was the one nearest the point of suspension at the tower which proved bad in the greater percentage. The one showing the next highest percentage was the one next to the conductor. Of the others there was nothing to pick, they all showed about an equal percentage of failures.

This at once began to have the ear marks of a mechanical failure. There is a good deal of vibration on these lines, and it was a sort of crack the whip performance; the one nearest the tower took the brunt of the shock. It seems that there is a great deal of room for research on the strength of porcelain and insulators under repeated alternating stresses. We are starting some work on this latter phase of the question and rigging up a small span about twenty-five feet long with a dead-end insulator at one end similar to the insulators on the Big Creek line, with a tension arrangement on the other end, so that this twenty-five feet of cable may be stressed to the same amount as the actual line. A motor driving an eccentric connected to the centre of the span will keep it in violent vibration back and forth. We hope to discover whether such a vibration has any effect upon any insulator, and whether it picks out the ones nearest the point of support in the same way that often happens on the line. If so, we will have started on the road to discovery of some of the causes of most of these failures.

There is need of an insulator of greater mechanical strength so that we can increase the size of our conductors. The amounts of power now transmitted are becoming so large that the corona limit is not going to be the determining factor in the size of a conductor but we will go above the corona limit of size in order to cut down line loss. And this all ties in with the question I raised before, as to whether it is not a mechanical weakness that is responsible for the greater part of these insulator failures.

Alan W. Eshelby: Mr. Wood has asked the question "What happens during the flashover?" I don't pretend to stand here and tell you what happens, but I would like to suggest a possible means of finding out what happens during the flashover. To the best of my knowledge, the method I will describe, is not in use commercially at the present time.

I have been interested for a number of years in photography and it occurred to me that the use of quartz in the camera in place of the glass lens might be of some advantage in photographing incipient corona. I therefore had such a lens ground and equipped my camera with it, but as I was not in a position to make standard laboratory tests I had to be content with taking photographs of flashovers on generators in actual service. I made these photographs using two cameras. One camera equipped with a standard Jena glass lens, the other equipped with a lens ground from natural rock crystal. Both shutters being arranged to operate simultaneously. In practically every instance there was no similarity in the photographs.

Quartz as you know, is transparent to the ultra violet end of the spectrum, while glass is absolutely opaque. The photographic emulsion is more keenly sensitive to the ultra violet end than the visible end. In fact the ordinary photographic emulsion is sensitive from approx. 3250 Å to 6000 Å and certain special emulsions have even a greater range.

The Westinghouse Company has developed for use in special tests, a high-speed camera which takes a series of photographs rapidly succeeding each other (not a motion picture camera) all exposures being made on one plate, unfortunately Mr. Legge, who designed the camera, has used a very cheap achromatic lens in this camera and I feel that here is a case where the quartz lens would tell an entirely different story. To those who are interested and wish to experiment along those lines let me suggest that they use natural rock crystal and not synthetic quartz, remembering that the speed of quartz is approx. seven times that of glass.

W. D. A. Peaslee: There are several points in Mr. Lapp's paper with which I believe it is necessary to take issue. The first sentence of his second paragraph is a little bit misleading, as he has not specified the frequency of flash-over voltage, or the frequency at which the impulse ratio is taken; obviously it would not be correct to use a flash-over and impulse ratio, taken at different frequencies in this way.

The last sentence of this second paragraph I agree with most heartily and believe that it cannot be too strongly impressed upon the manufacturers and users of porcelain insulators.

In regard to his remarks about the effect of immersing the insulator in oil for testing, I believe he has omitted the most important result of such an immersion; that is that the different dielectric constant of the oil distorts the flux, the dielectric flux

producing an entirely different distribution over that encountered in air. On page 492 he makes the statement that the high-frequency test adds but a few per cent to the voltage available to test the dielectric strength of the insulator. I believe this statement is entirely unwarranted, as my experience in a good many years testing in this particular field, indicate that an increase in the neighborhood of 30 per cent can be so secured under constantly stable conditions.

The overpotential test discussed by Mr. Lapp is not at all new and while I do not know who originated it, I do know that it has been known to advanced workers in this field for ten years or more and has been abandoned by some of them for rather definite reasons, most important of which are that it protects the petticoats of the insulator from the searching effect of a high-frequency test and that it distorts the field around the insulator, making the test not at all representative of the conditions under which the insulator will be forced to operate on the line. I believe it is fundamentally wrong to run a routine test on any apparatus that is radically different in conditions from those which it will encounter in practical operation.

I am very much amazed at his statement that the insulator does not get hot under this test; as my experience of this test a good many years ago indicated a rather decided rise in temperature of the samples under test.

I am also very much astonished at the claim that the surface digestion of porcelain is due to a lack of penetration of the dielectric stress. I believe that it can be conclusively demonstrated that this digestion is entirely a temperature effect and is due to the extremely high temperature of the corona streamers. I cannot conceive of any lag in the establishment of the dielectric field of an order of magnitude necessary to make this claim substantially correct and I believe that the heat absorbed on sustained high-frequency stress, is entirely an energy function, due to the characteristics of the porcelain as a conductor of the third class wherein the current voltage characteristic changes from a positive to a negative value at some particular current density. I do not believe the data available warrant the assumption that this phenomenon mentioned can be compared with the skin effect in a solid electric conductor. In regard to his specified limits, he states that when the overpotential test is applied instead of the above final tests, it removes the units most likely to fail in service, I would like to ask if he has submitted the units that have received these overpotential tests, to a subsequent high-frequency test, and if so what results were obtained.

I believe that fundamentally there is no such material as a true dielectric of dimensions greater than atomic distances. I can conceive of dielectrics such as a chain of hydrocarbon linkages wherein the displacement of electrons from their attending nuclei within the atom, could be transmitted over the space occupied by several atoms, but as the range of atomic forces is of the order of one Engstrom unit, I cannot conceive of a substance consisting of isolated atoms or molecules functioning as a true dielectric. It seems much more tenable that these insulating materials are conductors having a variable current voltage characteristic, which changes at some point from positive to negative and that their destruction, instead of being a dielectric rupture, is merely due to the fact that the current density has passed the critical voltage point and a further increase of current can result without an increase of applied voltage, or even with an attendant decrease in the voltage drop across the conducting path.

I believe if this theory is applied to the behavior of our insulating materials, a great many of the seeming discrepancies we are accumulating, will be explained and we can appreciate more exactly the fundamental mechanisms of failure of insulating materials under applied voltages.

G. W. Lapp: It is gratifying to hear a note of acceptance of the overpotential test, in principle at least, by most of those who have contributed to this discussion.

Practical economic considerations may set a limit to ones enthusiasm in actually applying such a test to his product but the demand for continuity of electric service should justify higher standards among users of insulators.

Definite improvements in the quality of insulators in the last few years have made it possible now to adopt this overpotential test as a routine test at a slight difference in price.

Among the various points brought out in the discussion no fundamental objection to the overpotential test has appeared.

Mr. Fortescue has noted some of the phenomena of the high-frequency and 60-cycle flashover tests and seems to be impressed with their severity but mentions the difficulty of obtaining values for the impulse effects. Admittedly the deafening and stupefying effects accompanying these flashover tests are extremely spectacular compared to the quiet intensity of a full wave overpotential test but it takes more than noise and ozone to puncture questionable porcelain. It is quite possible to take the units from those spectacular tests and knock out four to six times as many more by applying 120 per cent overpotential.

When flashover occurs on the rise of the 60-cycle voltage wave the heated path of the spark partly lets down the voltage for the remainder of the half cycle. The higher frequency oscillations are superimposed on a lowered base and the few fine peaks that rise from the damped train seem to have small power to puncture porcelain.

In assuming that the insulator in service may be subjected to a condition as severe as flashover test I had in mind a string of insulators with some of the units punctured. Lightning would then cascade the sound units subjecting them to full impulse flashover voltage. Mr. Fortescue has small respect for nature when he conceives that the flashover test is "many times more severe" than such a cascading impact.

Professor Creighton's estimate that over 90 per cent of the troubles in insulators are due to absorption of moisture by the porcelain is in harmony with the conclusion of the excellent paper by Farr and Philpott which is open for discussion. The porosity of porcelain may be due to improper materials, to underfiring or to overfiring and is by far the most subtle factor in insulator manufacture. Porous porcelain may be sufficiently low in dielectric strength to increase the losses by puncture even on the usual flashover test.

The most important function performed by the overpotential test is to eliminate most of this porous material before it is put on the line. As an ultimate safeguard against absorption we glaze our porcelain all over.

The evidence of destruction of insulators because of expansion of Portland cement in the joints is not conclusive. In fact the existence of numerous regularly spaced vertical cracks around the cement joint of pin type insulators appears to give direct evidence of shrinkage of the cement. From an examination of many old insulators including some unbroken glass insulators, through which these shrinkage cracks could be clearly seen, one would conclude that shrinkage of the cement rather than expansion is typical.

One of the insulators examined for these cracks was broken apart exposing the flat top of the second shell the surface of which was pitted because portions of the porcelain had been crumbled off and were found adhered firmly to the adjacent cement. This was an extreme case of disintegration evidently due to absorption of moisture and freezing. It gives some idea of the internal forces that may be present in porous porcelain which help the force of thermal expansion or contraction to crack the piece.

The crazing of the glaze on single fired bodies such as insulators is unusual, when crazing does occur as on dishes it is of a coarse pattern easily seen. It would seem that Mr. Osborne has detected a microscopic form of crazing that has hitherto escaped observation. Even devitrification would not be expected to occur in the type of glass used for insulator glazes.

When Mr. Peaslee comes to witness this test he will be dis-

mayed to see the pittiless manner in which it punctures defects in petticoats and shells as mentioned by Mr. Wood. In fact it is preferable to seal the outer lips of the shell only to save the petticoats from puncturing. It might save years of misdirected effort if some of the advanced workers known to Mr. Peaslee would publish results of their tests.

The very moderate temperature rise exhibited by hard fired disks after several minutes application of 120 per cent of flash-over voltage must be due to low losses both within the dielectric and in the corona enveloping the surface. For porcelain having an appreciable power factor the heat due to internal losses on this test is rapidly cumulative to quick puncture because there is no cooling medium as in the immerzed oil test to prevent a rise of temperature. The low temperature of the corona appears to be due to its intensity which causes a high degree of uniform ionization and high conductivity of the air. As the current traversing this low resistance corona is only the small charging current required by the dielectric the ohmic loss is probably very small. By preventing the hot concentrated flashover streamers the major source of heat is eliminated.

A number of units that had passed the over potential test were given the high-frequency test with maximum severity of application without puncturing any of them. The greater number of punctures caused by the overpotential test doubtless includes the same insulators as would be punctured by the 60-cycle and high-frequency tests.

Failure of Disk Insulators on High-Tension Transmission Lines

BY HARRISON D. PANTON
Associate, A. I. E. E.
Yadkin River, Power Company, Rockingham, N. C.

THE writing of this article is prompted by the fact, brought out at several Institute meetings at which papers dealing with disk insulators were discussed, that although much successful research laboratory work has recently been done to determine the electrical and mechanical characteristics of insulators of this type, there is available practically no accurate information showing the actual operating performance of such insulators during a period of years. Having recently compiled certain information of this kind I take pleasure in making it available to the profession in the hope that those members who are engaged in the field of ceramic research may find it of interest and possibly of some assistance to them in their work, from which I hope will soon be developed a disk insulator possessing greater mechanical and electrical strength than any such insulator at present available.

The laboratory results of several well known investigators, among whom are Prof. H. J. Ryan of Stanford University, and Mr. F. W. Peek, Jr. of the General Electric Company, have definitely determined the voltage gradient curves and electrical stresses existing in disk insulator assemblies consisting of a number of disks of the same type. Their results show that in an unshielded assembly of seven cap-and-pin type disk insulators with a voltage to ground of 61,000 volts, the voltage gradient curve will be as given in Fig. 1. From this curve we see that the potential drop across the various disks ranges from a maximum of 14,000 volts across the disk nearest the conductor to a minimum of 6500 volts across the third disk from the tower or grounded end of the assembly. Investigation has also shown that the voltage gradient for the third of the assembly nearest the conductor is greater than the gradient for the surrounding air that of the middle third of the assembly is approximately the same as for the air, and that of the top third of the assembly is less than that for the air. As a result of this condition there is a leakage of current from the disks of the lower third of the assembly to the air, and from the air to those of the upper third.

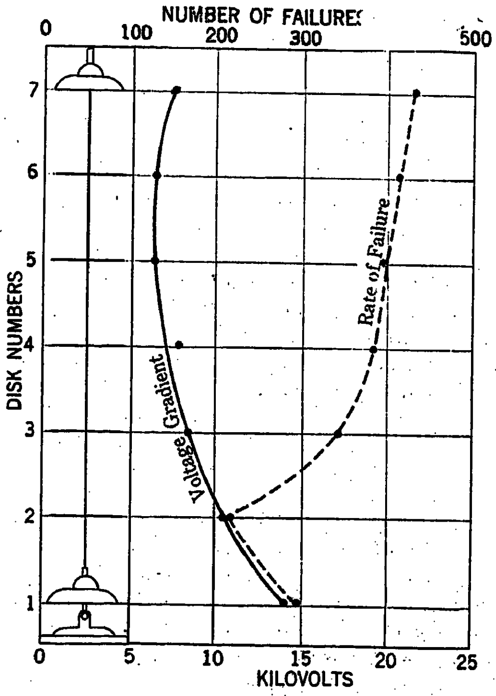

FIG. 1—VOLTAGE GRADIENT AND RATE OF FAILURE CURVES FOR SEVEN-DISK ASSEMBLY, UNSHIELDED
Line Voltage 105,000
Voltage to Ground 61,000

Now consideration of the facts that the leakage resistance is not uniformly distributed along the assembly, and that the various units and the surrounding air are subjected to unequal electrical stresses,

Presented at the Pacific Coast Convention of the A.I.E.E., Vancouver, B. C., August 8-11, 1922.

resulting from the unequal potential drop across the various disks, would lead us to believe that the disk adjacent to the conductor should fail most frequently and that the rate of failure of each of the seven disks in the assembly should bear a definite relation to the intensity of the electrical stresses to which that particular disk is subjected. However, an inspection of the tabulated results given in Table I, II and III, covering nine years of actual operating experience, shows no such relation existing between the rate of failure and the electrical stresses to which the disk are subjected as determined in the laboratory. Indeed these tables show that with the exception of disk No. 2, disk No. 1, the disk nearest the conductor, has the lowest rate of failure in the assembly, and that with the exception of No. 2 disk this rate increases with the position away from the conductor until the highest rate of failure is found for the No. 7 disk this being the one attached to the tower. I would very much like to have someone more familiar than myself with insulator research and high-voltage phenomena furnish a theoretical explanation of the observed results as embodied in Tables I, II and III.

The tabulated results given in the three tables are based on the operation of a 100-kv. double-circuit steel-tower line 97 miles long during the period from March 1912 to October 1921.

The principal physical features of this transmission line are: Double-circuit steel towers 73 feet high, supporting two three-phase circuits of No. 1/0, six-strand copper wire; The three conductors of each circuit are on the same side of the tower, the vertical spacing between these conductors is nine feet; the horizontal spacing of the two circuits is 15 feet for the bottom and the top conductors, and 21 feet for the

middle conductors; as originally built the horizontal spacing of the two circuits was the same for a'l three conductors but so much trouble was experienced with the wires whipping together when snow or sleet fell off the line, that in 1916 the spacing between the middle conductors was increased to 21 feet by putting a three-foot extension on each end of the middle crossarm. The average span length is 680 feet. The disk insulators used are of the cap and pin type manufactured in 1911, and these insulators are consequently a

Cap and pin seven-disk assembly

product of the early days of disk insulator manufacture. When the line was built, six of these disks were used on suspension assemblies and seven on tension or dead end assemblies. However, so much trouble was experienced with these insulators failing on tension assemblies that in 1915 all cap and pin disks used in tension assemblies were replaced with tension assemblies made up of eight Hewlett disks, and the number of cap and pin disks used in all suspension assemblies was increased from six to seven; this insulation is used at present, although as seen from Table III, the rate of failure of the cap and pin disks is rapidly increasing.

Tables I, II and III refer only to the cap and pin disks used on suspension assemblies, there being on this line a total of 4452 such assemblies consisting of a total of 31,164 disks. The failures shown are only those located on our annual insulator test; failures causing cases of line trouble, which are invariably due to lightning, are not included as very often in such cases when three or four disks show signs of having been punctured the entire assembly is replaced. The information contained in Tables I and II is similar but it was necessary to separate it into two parts as the seventh disk added in 1915 was put in the position nearest the wire; the former No. 1 disc then becoming No. 2, No. 6 becoming No. 7 and so on. The small number of failures found in 1913, 1914 and 1915 is due somewhat to the fact that the tests made during these years were not as thorough as those that have been made in subsequent years.

Note: 1921 Figures not included in Table III.

From Tables I, II and III we find that the rate of failure for the position of the disk in the assembly instead of being greatest for No. 1 disk and then in the order Nos. 2, 3, 7, 4, 6, 5, which theoretical considerations as deduced from the voltage gradient curve in Fig. 1 would cause us to believe should be the case; actually occurs in the order Nos. 7, 6, 5, 4, 3, 1, 2. This would indicate that the longest life is to be expected from the disks nearest the conductor and the shortest from those at the tower or grounded end of the assembly. These results are exactly contradictory of the conclusions deduced by the writers of several recent articles based on their research work in connection with disk insulator assemblies.

Should further investigation and experience of operating companies show that the results embodied in Tables I, II and III are typical of the performance of disk insulators in service on high-voltage transmission lines over a period of a number of years, then it would appear that the present experimental efforts being made to distribute uniformly the leakage res'stance among the disks of the assembly, by us'ng shields grading the disks in the lower third of the assembly, or by other means, are misdirected energy and that the essential thing to be done is to devise some means which will increase the life of the disks in the top third of the assembly and particularly that of the disk attached to the tower.

As previously stated, the cap and pin disks on whose operating pe formance the figures given in the tables are based were manufactured in 1911, and are there ore, undoubtedly inferior to the disks manufactured today, since the porcelains now produced are superior to those of ten years ago. However, this has no bearing upon the relative rates of failure of the various units in the assembly; since the only requisite for a fair comparison of these rates is that the disks used in the assembly shall be of uniform quality, and as all of the disks were manufactured by the same concern at the same period this should be the case.

In closing it may be of interest to state that in 1915 this company reinsulated several of its transmission lines, replacing the cap and pin disks with Hewlett type disks; and that the cap and pin disks removed were used to add an additional disk on some of the other lines, among them being the line concerning which the data given in the tables included in this article were collected. From this it will be seen that the disks added on this line in 1915 were not new disks but ones which had seen previous service. Before being installed in their new position these disks were given a thorough test, the General Electric oscillator being used to make this test. Out of about 5000 disks so tested over 700 failed, and in 90 per cent of these the failure was found to result from the puncture of the porcelain inside of the cap, or just at the edge of the cap. In these disks the cap is cemented on and the pin into the porcelain with neat cement, and as the coefficients of expansion of the metal cap and pin, of the cement, and of the porcelain are all different, it is my opinion that the so called aging and ultimate failure of these disks is primarily, a mechanical failure due to the gradual crushing of the porcelain inside of the metal cap by the varying compressive stresses to which it is subjected, these resulting from sudden temperature changes such as occur when a heavy shower falls on a hot summer day. Our experience with these cap-and-pin type disk insulators is that they deteriorate just as fast in storage exposed to the weather as when they are in service on the transmission lines.

Discussion

R. J. C. Wood: There is a very interesting thing in Table 3. In the early years we find that the No. 1 disk is the one which is failing to the greater extent, in 1913, 1914, 1915, 1916; and then in 1917 No. 7, which is the one nearest the point of support, usurps first place and keeps approximately that position, so that on the whole in these latter years it is the one nearest the point of support which shows the greatest number of failures. Now we all know that in the years 1913, 1914, the kind of insulator we were getting was very different from the insulators we get today; and that raised the question in my mind as to whether those early failures may not have been due to one cause—perhaps soft, porous porcelain, which was to be had in plenty; and the failures of the later years, when it is to be presumed that most of that poor stuff had been weeded out, have been caused by prolonged mechanical vibration.

W. A. Hillebrand: Experience with insulators on this line has been extremely interesting. There are several points worthy of note. One is the extremely low rate of failure of insulators in the suspension position over a period of seven years. It is one of the very best that I know of, as you will see from Table 3, very much better than the records of many comparative insulators over the same period. The second is a comparatively high rate of failure of insulators in the dead-end position, so much so that I think after three years they were all removed in favor of another type.

Now, I think within a year after the construction of this line, it was subjected to a heavy sleet loading such that over one section there was about one conductor break per mile, with about twenty conductor breaks all told. This meant that the dead-end insulators were practically all over-stressed, which may have influenced their high rate of failure. This is particularly likely to be true, if as is my belief, many types of suspension insulators are operated under a false mechanical factor of safety, that is, the actual unit stresses are very often considerably higher than what is calculated.

In the matter of vibration there is one case at least on record of an insulator having been practically pulverized from this cause. In another case of a transposition tower, insulators, which were subjected to practically no weight whatsoever, were failing at such a rapid rate that it was necessary to add a very considerable weight simply to damp out the vibration stress.

The question has been raised as to the reason for the peculiar shape of the curve shown in Fig. 1, that is the higher rate of failure of the insulator next to the conductor than that of the one above. It is to be noted that this paper is probably a record of insulators removed from all causes, as a result of line testing and of actual failure in operation.

Porcelain is a heterogeneous, conglomerate material consisting of an aggregate and a binder. The mechanism of its failure is probably that of a slowly developing crack similar to the well known depreciation of tableware. As the bottom unit of a suspension insulator string has an operating potential considerably higher than that of any other unit it is conceivable that a deteriorating insulator would at last be weakened to the point where it would be punctured by the operating voltage. For an equal rate of depreciation this would occur more frequently in the case of the bottom units than with the others.

Porcelain is never completely annealed. Due to daily temperature changes it is subject to working stresses within the body of the material itself, independent of any which may be imposed by cemented hardware. These facts incline me to a belief in a gradual deterioration of the manner stated. Furthermore, so far as I am aware, there is nothing in all ceramic experience to indicate that a large percentage of insulators now being manufactured will not deteriorate at a slow rate.

E. E. F. Creighton: I want to take up that point that Mr. Wood asked, I think, and which bears directly on the subject, deterioration. In order to find out what was the matter I made two different kinds of tests; one I will mention at the present time.

Hundreds of insulators were punctured. After each one was punctured the process was to take some red dye and with the vacuum on the opposite side of the punctured hole send the dye through the hole, then set the insulator aside to dry. It took a day or so usually—if you want to have it done thoroughly. Then I take up the insulator and find what sort of puncture hole takes place.

We found from those tests that nearly all the punctures were due to folds or defects in the porcelain. As soon as you break it to pieces you will find that the dye has run in little flat streaks in there so that the porcelain actually opened up and there was a big flat place in there. If a porcelain punctures because of porosity you will find the puncture takes the shortest path through the porcelain, that is, if the porcelain is three-quarters of an inch thick it will go straight through the three-quarters of an inch. In general, however, the path of the discharge is very much longer than the thickness of the porcelain, showing that there was a definite defect.

The three ingredients, clay and feldspar and the flint in proportion, usually about five, three and two, are mixed with water in a large vat, and then it is necessary to get enough water out so as to get the clay in plastic form; that means going through a filter press, and the filter press takes out perhaps a little bit too much water. At any rate, these filter cases, about two inches thick, about two feet square are piled up one on top of the other and hammered down, and they are mixed as much as possible and hammered down in the pile and left for several days for the moisture to equalize, then they are put through a machine and thoroughly mixed up. Now during that process there are these little air pockets that may be in there, most of them to be sure eliminated or we would not have got good porcelain at all, but these little pockets do from time to time continue through all that process, and those are the little incidental conditions which make porcelain unreliable.

Now those of us who have worked with porcelain realize that a perfect piece of porcelain is an accident. It is a craft and it is only a question of how great those holes are.

Now, does porcelain deteriorate, is there any chance that we will ever get to a place where we can count on the porcelain for an indefinitely long time? In order to get some data on that subject I made up a large wheel that I have described elsewhere, called the Ferris wheel. It would not pass in here—it would turn in this room. On the outside of that wheel insulators were placed, standard insulators. At the bottom we used a special cooling means to get the temperature down to twenty degrees below zero, Fahrenheit. At the top we put in heating units and resisters so that we could raise the temperature any desired amount. In between we had a cooling space of air. With that apparatus we could change the temperature of the insulator over a range far greater than it would have in practise.

Now we put an insulator through that process, and assuming that twice around was equivalent to one year, we carried the insulators through dozens and dozens of years of life. The test was perhaps a little more severe than they would get in practise.

We have no very good way of determining whether there was deterioration there, but this much we can say that after they had passed through those many temperature changes, running it in and out continuously we could detect no deterioration of the porcelain. That gives hope that the porcelain does not deteriorate, in fact to the contrary, for the well-known methods of manufacture of porcelain it is my feeling that there is no deterioration of porcelain itself. The deterioration, as has well been pointed out by Mr. Wood, is mechanical.

Ivar Herlitz: In the years 1914 and 1915, a large number of suspension insulators were installed on the 70-kv. transmission lines operated by the Swedish Board of Waterfalls. The design of these insulators was preceded by considerable research work. An account of the principles brought out by this research work, and of the operating results with the insulators, was recently published in the Swedish technical literature (*Teknisk Tidskrift,* Jan. 1922). A brief summary of some aspects of this paper may be of interest in this connection.

The essential principles for the design of these insulators were as follows:

1. The porcelain was, as far as possible, relieved of tensile and shearing stresses; the possibilities for concentrations of the electrical field were reduced by avoiding all sharp corners.

2. Cap, pin, and porcelain were cemented together in such a way as to allow the metal to expand and contract freely in the axial direction under temperature variations; stresses on account of radial expansion of porcelain, cement, and metal were eliminated by means of elastic cushions between the various parts.

3. Certain experiments having indicated that electrical phenomena in the cement might have a detrimental effect, it was decided to short-circuit the cement by means of a conducting film on the porcelain, which film was connected to the cap and pin respectively.

More than 70,000 insulators of this design have been in operation for 7 years without showing any aging phenomena. Some 20 units have been exchanged, but only on account of damage from arcs.

Experience has indicated that the short-circuiting of the cement is of little importance, but the demand for this feature accidentally gave rise to an interesting experience. On the first insulators the conducting film was made of graphite, but on a later delivery, of which 8000 were put into operation, lead had been used. Of these insulators, 15 per cent failed in a few years. An investigation showed that this was entirely due to the fact that the lead became oxidized and thereby greatly expanded. This seems to furnish a strong argument for the importance of taking care of the stresses caused by expanding cement.

H. D. Panton: In reply to Mr. Wood I will say that we have never purchased any of the cap and pin disk insulators in question since 1911; replacements up to the present time having been made with disks removed from other lines when reinsulated with other disks. Disks so removed are tested with the G. E. oscillator, and those found good have been used for making replacements on the line under discussion in my paper. It is very probable that Mr. Wood's conjectures with regard to the cause of failure of No. 1 disks in the years 1913 to 1916 are correct; that such failures were due to defective porcelain. However, it must be borne in mind that the tests made in 1913-14-15 were not as thorough as those which have been made in subsequent years.

Referring to Mr. Hillebrand's remarks the average failure of suspension disks in ten years including 1922 has been only 1.5 per cent per year. With regard to the high rate of failure of insulators in dead-end assemblies, these were so high, that by the end of 1914, when the line had been in operation for a little over two years, it was necessary to decide on a replacement of all these insulators used in dead-end assemblies with insulators of another type.

The sleet storm referred to by Mr. Hillebrand occurred on April 1st-2nd, 1915, when this line had been in service for three years and we had already experienced so much trouble with these dead-end assemblies that we were preparing to replace them with Hewlett disks prior to the time when this sleet storm occurred. This storm caused the line to go down in over 40 places in a section forty-six miles long, practically all breaks being due to conductors breaking under the load of snow and ice; the snow and ice on the line was so heavy that a piece of No. 6 telephone wire measured in the storm area was found to be 9-in. in circumference, that is inclosed in an ice and snow sheath nearly three inches in diameter. Comparatively few insulators were found to be defective after this storm when a routine test of all insulators of this line was made. On suspension assemblies only 0.4 per cent of the disks were found defective. Figures are not available but I do not believe we found any large number of strain insulators which had failed due to the stresses put upon them by this storm.

With regard to Mr. Creighton's "ferris wheel test" I do not feel that two trips around his wheel produces stresses in the insulators equal to those experienced during a year of service on the transmission line. I consider the most severe stresses experienced by insulators in this section due to temperature changes, to be those produced when a cold shower falls on a hot summer day. The temperature of the porcelain in the sun is around 120 deg. Fahr. or higher and that of the rain in the neighborhood of 60 deg. Such an experience as this will happen to all of our insulators at least 25 or 30 times each summer. The top disk is most exposed to an experience of this kind and we have thought that this was possibly the cause why disks in this position failed with the greatest frequency. It is to be noted that the disks in discussion have no elastic cushion of any kind between the porcelain, the cement, and the metal. The cement being in direct contact with both the porcelain and the metal. Certain compressive stresses are obliged to be set up due to temperature changes; whether these stresses are of sufficient intensity to rupture the porcelain, I am not in a position to state.

Test and Investigations on Extra High-Tension Insulators

From a Purchasing Engineer's Point of View, with Special Reference to Methods of Test for Acceptance, Tests for Porosity and Deterioration.

BY C. COLERIDGE FARR and HENRY E. R. PHILPOTT

Prof. of Physics, Canterbury College, University of N. Z.

Associate, A. I. E. E.
Testing Engineer, Lake Coleridge Electric Power Supply, Christchurch, N. Z.

Review of the Subject:—Owing to repeated failures (the number of which increased as time went on) of 66,000-volt transmission line insulators (pin type) of the first Hydroelectric undertaking, carried out by the New Zealand Government, in 1914, and having in mind that Hydroelectrical Power was to be developed to the utmost of the Dominion's power resources—of which there are many—the investigations contained herein were commenced at the suggestion of Mr. E. Parry, B.Sc. M. I. E. E. late Chief Electrical Engineer to New Zealand Government, and has been continued for the past five years with the sanction and support of Mr. L. Birks, B. Sc. M. I. E. E. Chief Electrical Engineer to New Zealand Government, with a view to ascertaining the cause of such failures.

It is the purpose of the paper to show

1. To what extent deterioration has set in on the 66,000-volt line referred to.

2. That the cause is due to the fact that the insulators were initially porous.

3. That tests at present in vogue with regard to ascertaining the porosity of insulator porcelain are totally inadequate, as the authors consider, immersion of the complete unbroken insulator under a pressure ranging from 1500 to 2000 lb. and the total amounting to 250,000 to 300,000 lb-hours the least that will give reliable results.

4. That non-porous insulators can be made that will remain good in service for an indefinite period and withstand perfectly the tests for porosity as recommended.

5. That individual testing with high frequency seems to be the only reliable method for testing for dielectric strength.

6. That a percentage test of each batch of insulators by the maker is unsatisfactory, because unless each shell of each insulator, in the case of pin insulators, and each dish in the case of suspension insulators, is definitely flashed over before being put to service, then breakdown trouble seems bound to ensue.

7. There is room for more cooperation between the insulator manufacturer and the purchasing engineer in regard to acceptance tests and the handling and maintaining of the insulator in service. If manufacturers will not agree to the tests as recommended by the authors, being made in the factory, then in countries such as this (New Zealand) which is situated so many thousands of miles from the point of manufacture, a public testing bureau should be established where undertakings could be arranged for, such tests to be made as described herein, when the cost of replacing the failures should be borne by the manufacturers.

8. That it has been found in New Zealand we have the necessary materials from which insulators can be and are being made, that will withstand the tests described equal to the imported wares.

CONTENTS

IN this paper we propose to give an account of some investigations which we have carried out in conjunction with the Public Works Department of New Zealand, with a view to obtaining some definite information regarding the causes of insulator deterioration in connection with the Lake Coleridge electric power supply system. It is hoped that this may be of some service to those interested in the insulation of extra-high-tension transmission lines, which are to play such an important part in the hydroelectric development of this Dominion in the future.

It is the experience not only in New Zealand but in other undertakings abroad, that the problem of producing an insulator that will successfully withstand both electrical and mechanical stresses for an indefinite period, without deterioration or destruction, is one of the most difficult in connection with the transmission and distribution of electrical energy at extra high tension.

It is proposed to describe in detail the tests and the results of these tests, on several types and makes of insulators, including those of British, American (U. S. A. and Canadian), New Zealand, Australian, and German manufacture.

It is desirable to state briefly how the authors came to deal with such a variety of makes.

Considerable experience has been obtained with insulator failures on the Lake Coleridge electric power

Presented at the Pacific Coast Convention of the A. I. E. E., Vancouver, B. C., August 8-11, 1922.

transmission line in this country, and at one time during the late war the position due to repeated failures became so acute that it was found necessary to purchase any makes available, having in mind that these investigations were about to be made. It was hoped that a careful investigation would demonstrate the best type and quality of insulator to withstand the requirements of the heavy duty called for, involving dielectric strength, mechanical strength and durability.

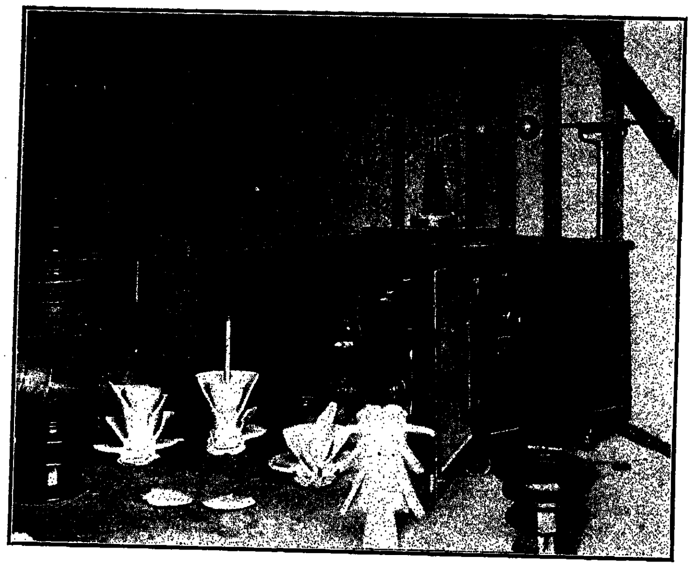

Fig. 1—Showing High-Frequency Oscillator and Samples of Punctured Insulators

The apparatus employed consisted of:

(1) A 1000-volt 2000-megohm megger set.

(2) A 20-kv-a. 100,000-volt 50-cycle single-phase testing transformer with a double-scale 100,000-volt and 50,000-volt Kelvin electrostatic voltmeter.

(3) A General Electric Co. high-frequency oscillator set, capable of impressing 175,000 volts with spark gap for voltage measurements (See Fig. 1.).

(4) In the hydrostatic pressure tests for porosity, a steel testing vessel with cast iron ends capable of containing a complete insulator of the largest size, and of withstanding a pressure of 2500 lb. per sq. inch, with a high-pressure compressor capable of working up to this pressure (Fig. 2).

The electrical tests were carried out at the Public Works Department test room at Addington, Christchurch, and the porosity tests at the Physical Laboratory, Canterbury College, Christchurch. For the latter purpose the special high-pressure vessel mentioned above was provided from a research grant received from the New Zealand Institute, the assistance of which is hereby acknowledged.

A detailed account of the vessel may be given, as it was eminently successful. After pumping up to a pressure of, say, 2200 lb. per square inch, it would frequently retain the pressure so well that it had not fallen below 1500 lb. per sq. inch in four days, although no further pumping had been done in the meantime.

A hollow piece of cast steel 15 inches in internal diameter, 19 inches in external diameter and 20 inches long, was turned at both ends, and a narrow spigot was left about ¼ inch from the inner edge and running round each end. This spigot was 3/8 inch high and about 3/16 inch wide. The spigot fitted with a corresponding groove in the covers which was ½ inch deep. The groove and spigot were of such a width that a piece of leather sewing machine belting fitted the groove exactly in width. When the end pieces were screwed down, the spigot was seated upon the leather belting and made a satisfactory joint. The end pieces or covers were of good cast iron eight inches thick, and held on by 12 bolts each 2 inches diameter. When the pressure was first applied at about 800 lb. per sq. inch, it was seen that moisture was "weeping" through the bottom cover, but this righted itself probably by internal corrosion and no further trouble was experienced. An illustration of this testing vessel is shown in Fig. 2.

Under this test the amount of penetration is apparently proportional both to the hydrostatic pressure attained, measured in lb. per sq. inch and to the time of immersion. The authors, therefore, propose to measure the intensity of the test by the product of these two factors or by the "pound-hours" to which a square inch of the insulator has been subjected.

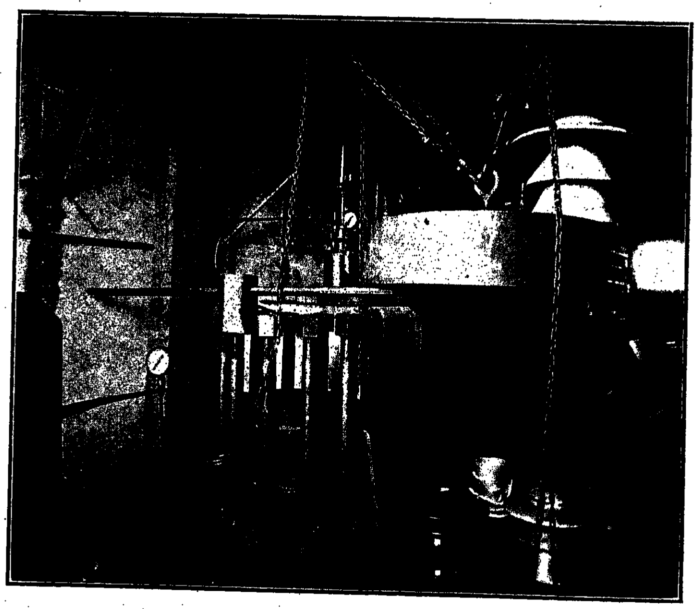

Fig. 2—Showing Large Porosity Vessel used for the Tests Described Herein, also the Small Vessel in Right Corner used for the Earlier Tests

The usual test adopted was at a pressure of 1500 to 2000 lb. per sq. inch applied for a period of seven days, *i. e.* for 250,000 to 300,000 pound-hours. We wish to insist strongly that the intensity of the porosity test to be of any value should be of this order. One important firm claims credit for its insulators because they will withstand a porosity test at a pressure of 200 lb. for 24 hours—*i. e.* 4800 pound-hours! In view of the prolonged exposure to the weather to which the

insulators are subjected in service, although only at atmospheric pressure, we consider that such a test is totally inadequate, in fact that any porosity test of less than 200,000 pound-hours is comparatively useless.

With regard to the efficiency of testing with high-frequency oscillations as compared with low or working frequency, the former gives, in the authors' opinion, much the more searching and reliable results.

After the Lake Coleridge 66,000-volt transmission line had been in service about two years, the insulator failures became so frequent that it was decided to test each insulator of the remaining stock of 500 individually, so as to insure that those used to replace the failures were reliable and good, and for this purpose the high-frequency oscillator was used.

The original consignment of insulators was imported in 1913 and this stock of 500 replace insulators was obtained in 1915 and stored in the open. They had of course withstood the makers' factory tests, but on being retested two years after delivery, during which they had been exposed to the weather in the works yard, no less than 43 or 8.5 per cent were found by individual tests to be defective. In several cases these insulators were of porous material, and had absorbed moisture during the period they had been in stock, as was proved subsequently.

Each of these replace insulators as it was tested, was numbered and its position on the lines when put into service was recorded, and although over five years have elapsed since these precautions were commenced, and over 200 breakdowns due to insulator failures have occurred, and over 500 insulators have been replaced, not one of the tested insulators has yet given trouble, which shows the efficacy of the method of testing individual insulators after they have been exposed to the weather in stock for a couple of years, thus weeding out porous ones. The main cause of deterioration of the insulators that did fail was apparently absorption of moisture, and if porous insulators are detected and excluded, insulator deterioration will largely diminish.

It seems to be the practise of some makers to test insulators with a set pressure at working frequency, from head to pin, and from these results to pass the batch or otherwise. We consider that this method is unsatisfactory, inasmuch as the faulty shells will not betray themselves (being protected by the good ones) unless each shell is individually flashed.

Further, this flashing should be done by high-frequency pressure, for the authors' experience has been that, where insulators have been guaranteed by the makers, as tested at a certain pressure, at low or working frequency, they have failed decisively when tested with the high-frequency oscillator at many thousands of volts below the guarantee. Others have withstood the pressures named by the makers *from head to pin* on both high and low frequency; but on individual testing of the shells, some were apparently mechanically perfect, but electrically were almost conductors, as will be seen later in the description of tests.

Methods of Test

The following program of tests was adopted:

(1) Measure insulation resistance of each shell with 1000 volt megger;

(2) Subject each shell separately to bare flash-over pressure at 50 cycles (working frequency) for 15 seconds;

(3) Subject each shell separately to bare flash-over pressure at high frequency for 15 seconds (Fig. 1);

(4) The complete unbroken insulator was placed in the porosity testing vessel and covered with a strong aqueous solution of fuchsin (Fig. 2). A hydrostatic pressure of 2000 lb. per sq. inch was then put on the vessel, and the insulator remained immersed in the fuchsin solution under a pressure ranging from 1500 to 2000 lb. per square inch for about a week, that is, until the number of pound-hours had reached 250,000 or 300,000.

As soon as convenient after removal from the porosity vessel the electrical tests were repeated, after which the insulator was broken up for signs of penetration. If the samples submitted withstood this complete set of tests without breakdown or signs of penetration, the batch was considered satisfactory.

It is worthy of note that of twelve makes tested, samples of seven failed to pass the tests, which shows the necessity for special acceptance tests in all cases.

It was impossible with the apparatus at our disposal to subject more than a very few individual insulators of any make to the hydrostatic pressure test for porosity. Some of the insulators so tested have been chosen to ascertain the cause of certain weaknesses previously known to exist; and the weaknesses have generally been found to be due to, or at least associated with, a band of porous material in the body of the porcelain. We consider, therefore, that if any of the few insulators in any batch that may be submitted for test are found to be porous, the whole of the batch should be rejected, and the maker informed that a repetition of such an experience would seriously jeopardize his chance of securing future contracts.

Megger Tests

While the megger test has its limitations, yet it seems to be advantageous in connection with the hydrostatic pressure tests; in that, after the insulator has been under the hydrostatic pressure, it is possible to obtain with the megger definite indication of the condition of the shells; but the greatest care must be taken when testing with the megger, for not only the humidity of the atmosphere, but even the handling of the insulator or the megger leads, will often tend to lead to wrong conclusions.

When testing insulators with the megger—dry as received—it has been noted with a dry contact, however thorough, that results are by no means consistent, as it is

almost impossible to "wipe" the whole of the surface of the joints between shells with the contact lead, and if any portion is missed, a puncture path or porous spot may also have been missed owing to the high resistance of dry cement.

It has therefore been found essential to cover the cement joints to a depth of about 1/16th of an inch with weak acid, which gives a sure contact over the whole area of the cemented joint, and more consistent results are obtained. But if high-frequency tests are to follow, the results of the high-frequency tests are likely to be misleading, unless the joints are thoroughly cleaned, because the oscillator cannot supply the C^2R losses due to dampness without undue voltage drop and probably the voltage would not reach flash-over owing to the poor regulation of the oscillator.

Humidity of the air, and human handling, are important factors when testing insulators with the

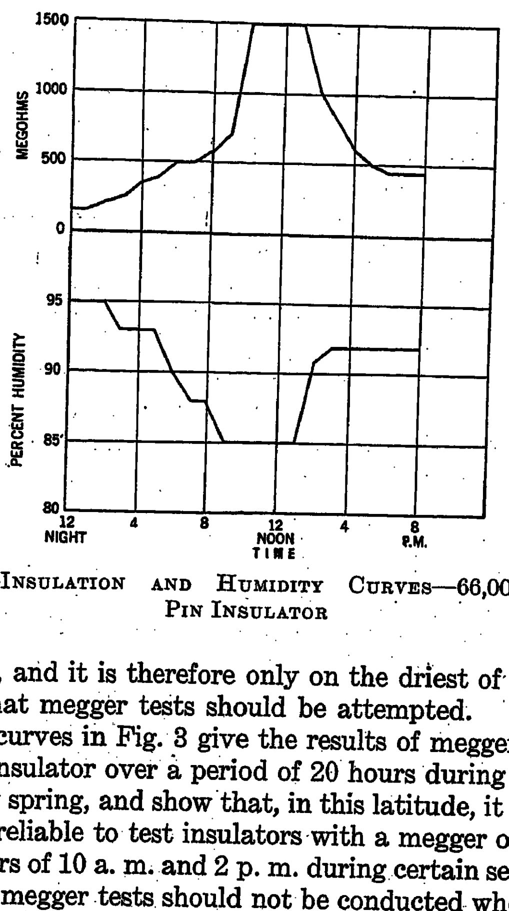

Fig. 3—Insulation and Humidity Curves—66,000-Volt Pin Insulator

megger, and it is therefore only on the driest of sunny days that megger tests should be attempted.

The curves in Fig. 3 give the results of megger tests on an insulator over a period of 20 hours during a day in early spring, and show that, in this latitude, it would not be reliable to test insulators with a megger outside the hours of 10 a. m. and 2 p. m. during certain seasons, or that megger tests should not be conducted when the percentage of humidity is much over 85.

It would seem therefore, that where, owing to porosity, the insulator may be a partial conductor, as for instance an old insulator which has been in service some years, and with no other means of test at hand, the megger may be used to advantage, but with recently made insulators, being tested for acceptance, the megger test could be dispensed with. Factory inspection has reached a stage in which faulty insulators, that could so easily be detected, would surely never leave the factory.

High-Tension Tests at Working Frequency

When no other means are available, this method—provided each shell is separately tested to flash-over—is useful.

This can be arranged where working pressure is available, and, provided each shell is tested separately at working pressure, the aggregate flash-over of the whole insulator may be assessed.

To subject an insulator to working pressure, applied from head to pin, as an acceptance test is misleading, and the results are of practically no value. It will find those which are defective in all shells—a state of affairs hardly to be expected with the present-day makes of insulators—but it will not betray any single shells that are faulty; and if there are any such, the seeds of trouble for the transmission line are sown.

A section of three miles of the Lake Coleridge transmission lines runs in duplicate alongside a steam railroad. After two years' service, 12 insulators were taken down at random for testing purposes. In every one of these 12 insulators the inner shell of the four was completely coated with a black deposit, and a test showed the shells so covered to be conductors, and hence it can be reasonably assumed that the factor of safety of all insulators near the railroad was reduced by 25 per cent, due to this deposit. With mechanical troubles developing on the top shell, due to cable loading, cable clamps, etc., the factor of safety is still further reduced, and if there happen to be one or two bad shells coupled with a mild surge due to switching or dropping of load, the insulator will break down so much earlier.

It is noteworthy that 47 or 19.8 per cent of the number (264) along the line of railroad have failed or had to be replaced during six years. A few of the breakages were mechanical but it is most probable some of the shells were "electrically down" before being put on the line.

On one occasion, about one-half mile from the railroad section, a single inner or fourth shell insulated the line for eight hours, the other three having punctured decisively.[1] This certainly could not have taken place on the railroad section, where each fourth shell was coated as described.

It therefore appears that it is absolutely essential that all shells must be tested individually.

Tests with High-Frequency Oscillator
(Prof. E. E. F. Creighton's Method)

Where this apparatus is available, it has been found to be more effective in detecting faulty insulators, provided they are dry and non-porous, but as stated previously, to test from head to pin, by running up to the full capacity of the oscillator set, is very misleading, although if two or more shells are "down" (which is hardly likely with the modern makes of insulators), then indications will be quite clear.

1. Birks & Ferguson, N. Z. *Journal of Science*, Vol. 3, No. 4, page 184.

If a 300,000-volt set is available, then head to pin tests could be resorted to in order to save time, but it would still be very necessary to note that each shell must definitely flashover.

With the present-day makes of insulators, where perfect vitrification is aimed at, the megger and low or working frequency tests could be safely discarded in favor of testing individual shells by high frequency, combined with a percentage subjected to the hydrostatic pressure tests for porosity, for it has been found that where other methods have proved doubtful and some even shown the insulator to be apparently sound, the high-frequency pressure has shown them to be "down" at a comparatively low voltage.

Some engineers are doubtful as to the advisability of subjecting insulators to "flashover" on high frequency before being put to service, fearing undue stress resulting in possible damage.

Local experience tends to show that insulators so tested are quite undamaged, for upwards of 1000 insulators have been so tested (*i. e.* each shell up to flash-over on high frequency for 15 seconds) and as previously stated, over 500 have been put on the lines referred to and, although nearly five years have elapsed since the first replacement was made and over 200 breakdowns have occurred, not one of those so tested has yet failed electrically. One had to be replaced owing to damage due to rifle fire, but although mechanically damaged it was electrically as good as the day it was placed in service.

The authors have a special insulator, which has been used for hundreds of demonstrations of Creighton's Super Spark Potential Test[2]; and a certain suspension insulator which supports the high-tension lead of the high-frequency oscillator, receives full punishment every time the set is used, yet both these insulators are apparently quite undamaged. Such authorities as Creighton,[3] "consider that such tests are quite mild, and correspond to a rare case of switching and further are nothing more than the insulator may get in operation in due time;" and Peaslee,[4] states, "accumulated evidence of a large number of tests, covering combined electrical and mechanical tests, fatigue tests, and high-frequency tests, indicates such stressing has no effect whatever upon the properties of the insulators."

Many suggest, for safety, taking each shell up to bare working pressure only, but the authors have found in seven instances at least a pin hole or other fracture at or about 1 in. from the edge of the shell which it did not betray itself at bare working pressure, but at approach of flashover, the arc concentrated at the point of fracture, and in less than one minute the shell cracked. These would have been passed on a bare working pressure test.

The authors are therefore of opinion that it is absolutely essential to see that each shell should withstand flashover pressure at high frequency for at least 15 seconds continuously.

Deterioration

On the Lake Coleridge transmission lines there are over 5000 insulators and over 800 or 16 per cent have had to be replaced in six years, either owing to failure in service, or to patrolmen's observations of mechanical defects, and our experience indicates that this is due mainly to initially porous insulators, coupled with mechanical weakness.

We have found from experiment and experience that porcelain can be made which is nonporous to the limit of the somewhat severe tests we have applied, and in that case, moisture will not get into it, whether the insulator be in service or otherwise.

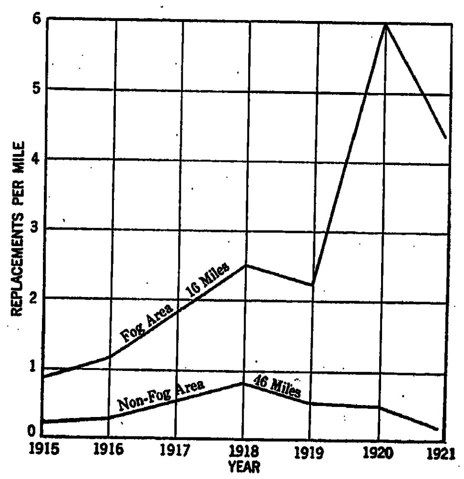

Fig. 4—Curves Showing Insulators Replaced on Transmission Lines

Curves are shown in Fig. 4 giving the numbers that have failed in a fog or mist area, and we consider that there is no doubt that the cause is due to porous insulators, absorbing moisture to such an extent as to render some shells practically conductors, when attacked by high-frequency surges or even at working pressure.

No doubt many other bad insulators are on the lines in other areas, where fog or mist is not prevalent, and in course of time these will be weeded out by breaking in service.

The diameter of the capillary tubes in even the most porous insulators we have tested is extremely small. In the first experiment we used fuchsin as the coloring agent, by which the penetration could be traced. Finding however, some difficulty in photographing the color, though it was strongly visible, we discarded it for the time being for red ink, or rather a solution of red ink powder in water. It was noticed, however, that it seemed extremely difficult to force the red ink into

the porcelain. A faint coloration was frequently noticed, but not such as might have been expected from the red ink. It seems likely that the size of the capillaries was less than 10^{-5} cm. in diameter. It must be remembered that both capillary "suction" and the tendency of moisture to condense in a capillary tube, increase as the diameter of the tube decreases. In the case of capillary "suction," the effect is inversely proportional to the diameter. In the case of condensation the ratio of the saturation vapor pressure on a plane surface and in a capillary tube is given by the expression

$$\log_{10} \frac{\omega}{\omega'} = \frac{5.6 \times 10^{-8}}{r}$$

where ω is the saturation vapor pressure for the plane surface and ω' that for the capillary.

Taking this latter effect, it is well-known that for capillary tubes, where the radius is 10^{-5} cm. the saturation and vapor pressure on a plane and in such a capillary are very approximately the same, whereas for tubes of 10^{-7} cm. radius 30 per cent humidity on a plane surafce would be enough to cause saturation of such a tube.

It will therefore be seen that for the capillary tubes in insulators as we find them, the air is always practically saturated, and if tubes exist whose size is greater than 10^{-8} (the ordinary molecular size) and less than 10^{-6}, there will be a very strong tendency for moisture to condense, and it is this tendency, both owing to capillary "suction" and to condensation, which we consider has been the cause of the deterioration that has been experienced.

It cannot be too strongly emphasized that a porous insulator is certain sooner or later to give trouble. The pores of such an insulator consist of extremely fine capillary tubes, and the whole tendency of moisture, is to condense in such tubes, which never, even on the warmest day, a corresponding tendency for the moisture to evaporate. Thus the moisture is always increasing in quantity within the body of the insulator until a time comes when the insulator is electrically so much weakened by the accumulated moisture, that it punctures and serious trouble results. The authors consider that no laboratory test for porosity, however severe, can be as drastic as prolonged exposure to the atmospheric conditions in all weathers. Any batch of insulators showing porosity should be rejected unhesitatingly, or trouble is certain in the long run.

The observations made in the fog area referred to are interesting. The area extends from Christchurch, westward for a distance of 16 miles, and is no doubt due to the prevalent easterly winds blowing in from the sea, carrying westward the smoke particles of Christchurch, and moisture laden air from the sea. It is on these smoke particles that the moisture condenses and forms the mist in the region referred to. Further out than 16 miles the effect is not so perceptible. See Fig. 4.

The two 66,000-volt transmission lines referred to were erected in 1914 and have been in continuous service since 1915, and Table I shows the number of pin insulators which have failed in the consecutive years of service.

This table is plotted in Fig. 4, and Fig. 5 shows the total replacements.

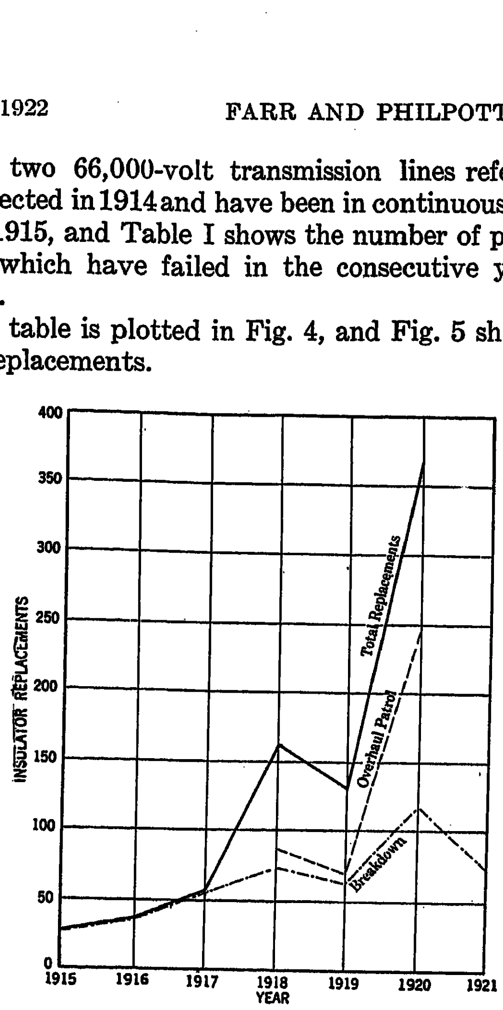

FIG. 5—CURVES SHOWING INSULATOR REPLACEMENTS

In addition to these, 72 suspension disks (12 strings of 6 each) used at anchor towers, were replaced as a result of the complete failing of two strings (12 disks).

Dealing first with the pin type, it will be seen for the year 1919-1920 that over 360 were replaced due to all causes and 100 of these were selected at random and tested on the high-frequency oscillator.

58 were found to be "down" on 2 or more shells.

42 were found damaged on top shell only. It will therefore be seen that not even one per cent was electrically whole.

36 of the suspension type were tested and 22 or 60 per cent were found to be "down" and a test under hydrostatic pressure showed the porcelain to be of a porous nature.

TESTS AND RESULTS—PIN-TYPE INSULATORS

The following is a summary of the average results of many tests on insulators by various makers.

Tables of Dry Flash-over Pressures in Kilovolts (high frequency) 4-Shell and 3-Shell Pin Typo

G.	65 "	55 "	..	

Maker A—66,000-Volt 4-Shell Pin Type. This insulator which had not been in service, was, after testing all right on each shell at both high and low frequency, subjected to hydrostatic pressure test of 246,000 lb-hr. with an average of 1440 lb. per sq. in.

After immersion, a repetition of the electrical tests showed the insulator to be as good electrically as it was before immersion, and when broken up, not the slightest sign of penetration could be seen.

Maker B—66,000-Volt 4-Shell Pin Type. This insulator had been in service since 1914, but had been removed 5 years later owing to having shown signs of puncture on one shell on overhaul.

Electrical test showed the shells to be in the following condition:

	Shell 1	Shell 2	Shell 3	Shell 4
Before Immersion.	O. K.	O. K.	Punctured	O. K.
After Immersion...	O. K.	Conducting	Punctured	O. K.

It will be noted that No. 2 shell failed under the hydrostatic pressure test, which consisted of 280,000 pound-hours.

After leaving the porosity vessel and undergoing the after-immersion electrical tests, the insulator was broken up and examined for penetration of the dye. Color was seen in the crown of the first shell, but the penetration was apparently insufficient to cause the shell to fail on the electrical test. The discoloration

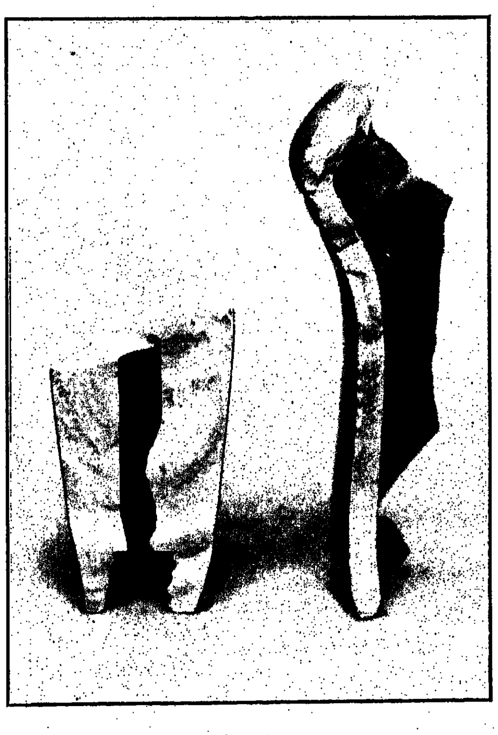

FIG. 6—SHOWING ON RIGHT PENETRATION IN SECOND SHELL, AND ON LEFT, GOOD PORCELAIN WHICH HAS BEEN SUBJECTED TO SAME TESTS

of the second shell was most marked. It would seem as if the dye had found its way into the shell through the glazing, and as seen above, the tests showed the shell to be practically a conductor after the porosity test.

In the third shell, the only sign of penetration was found just around the small hole in the shell where puncture had taken place prior to immersion and was evidently the cause of the puncture.

In the fourth shell, the porcelain was white and satisfactory throughout. It seems reasonable to assume this insulator was sound as far as the factory tests could reveal when first put on the line, but had gradually deteriorated, owing to the material being initially porous. Fig. 6 shows the penetration in a section of shell No. 2 mentioned above.

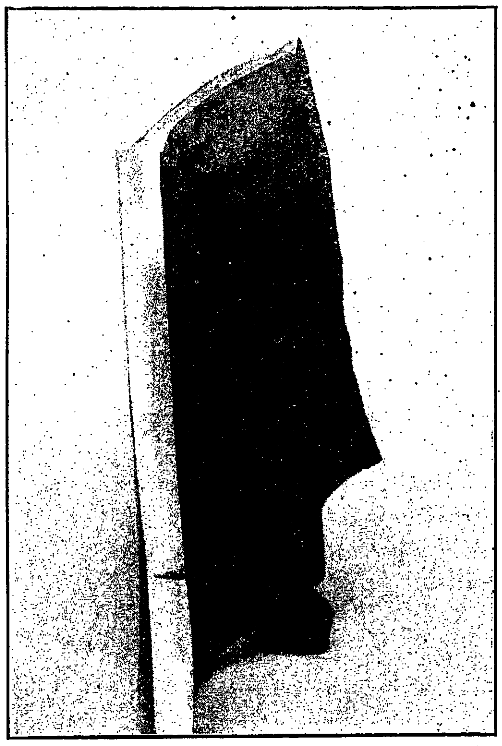

Fig. 7—Showing Piece Selected at Random from Whole Insulators

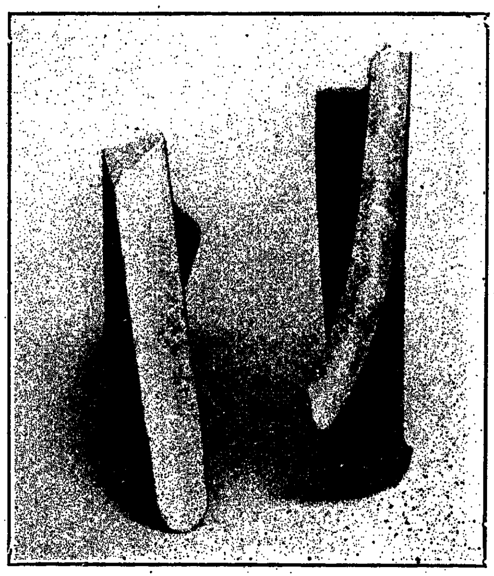

Fig. 7a

Another insulator of the same type, by the same maker, had been on the line a year longer than the previous one, and was removed owing to a mechanical fracture having been observed, probably due to rifle fire or other external cause. Pieces of this insulator were subjected to a hydrostatic pressure of 280,000 lb-hours, after which, when broken into very small pieces, not the slightest sign of penetration of the dye could be observed.

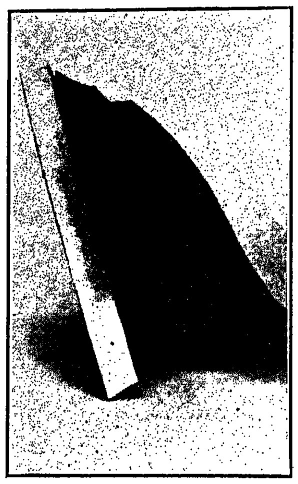

Fig. 8—Showing Piece of the Bad Shells

Fig. 8a—Showing Piece of the Top Shell

It is therefore reasonable to assume, that apart from the mechanical fracture, the insulator was electrically as good as when first put on the line and would have remained so indefinitely, had it not been replaced.

Another insulator of the same type and maker (B) was immersed in water at atmospheric pressure for four years.

The electrical tests made in 1917 before immersion,

wed the insulator to be good after flashover for one nute on each shell, at both high and low frequency.

After leaving the tub, in 1921, the insulator was ed and allowed to dry for one hour in the ordinary nosphere after which it was, where possible, taken to flashover on high frequency, with the following ults:

	Shell 2	Shell 3	Shell 4
Shell 1			
ctured under 50,000 volts.	O. K.	O. K.	O ·K.

t was then subjected to the hydrostatic pressure t of 290,000 lb-hours, after which it was again ted, with the same electrical results.

On being broken up, no sign of penetration was ible in Shell No. 1. This was probably due to the t that four years immersion had saturated the shell, l no more water (colored) could be forced in.

Another insulator, by the same maker (B) which had n in service over six years and which had failed in vice was subjected to hydrostatic pressure test of ,000 lb-hours and when broken up after leaving the rosity vessel the penetration was extremely marked oughout every part of the whole four shells, it was possible to find even a most minute part, where the e had not penetrated.

It seems only reasonable to assume, that this insula- let the line down; not due to surge or the like, but ply that it had become impregnated with moisture, ough being porous, and had therefore eventually ome practically a conductor for extra-high-tension ssure (Figs. 7 and 7A).

Still another 66,000-volt pin-type insulator by Maker which had been in service for six years, and failed m no apparent cause, was subjected to the hydro- tic pressure test of 280,000 lb-hours and when taken t of the porosity vessel and broken up, it was found t whereas two of the shells were the same as the last ntioned, *i. e.*, penetrated right through, the other shells were of quite good material.

There seems no doubt that this breakdown was used by the power arc tending to flash over the insu- or, that the two shells were practically conductors, d therefore ruptured by being in the direct path of e arc, thus causing the complete wreck of the other ells.

The individual testing of each shell as urged in this per, would have obviated this trouble. (Figs. 8 d 8A.)

Maker C—66,000-Volt 4-Shell Pin Type withstood electrical tests and showed no sign of penetration ter having been through the hydrostatic pressure st.

Maker E—66,000-Volt 4-Shell Pin Type. A firm ich specializes in the manufacture of E. H. T. insu- tors, sent a special sample insulator which was pected to withstand any electrical tests applied, ving withstood all the maker's tests.

Each shell was tested separately up to flashover on cycle pressure, which each shell withstood.

Each shell was then tested on the high-frequency oscillator, shells 1 and 2 withstood flashover satisfactorily, but No. 3 punctured decisively in the thickest part, under 40,000 volts.

The puncture path was quite perceptible when the shell was broken up, and had the appearance of a seam of flint, which apparently had not been "found" by the low frequency test.

If such results are obtained with a specially selected sample, what risk has an undertaking in accepting many thousands which have been passed by the maker, due to perhaps less than 10 per cent of their number having passed a mild low-frequency test?

In fairness to the maker, it should be mentioned that all his tests were made on 25-cycle pressure and the whole insulator, after being subjected to the hydrostatic pressure test, showed absolutely no signs of penetration.

Maker F. Another case of a world-known porcelain firm but not insulator makers, who desired to enter the electrical field, submitted a three-shell 66,000-volt pin type insulator for test. This insulator was guaranteed tested, by certified authorities, to 125,000 volts head to pin.

Each shell was taken up to flashover on 50-cycle pressure, which it withstood for two or three seconds, but on the high-frequency pressure, one shell only stood up to flashover, while the remaining two failed decisively under 30,000 and 40,000 respectively.

The insulator was then subjected to the hydrostatic pressure test. The number of pound-hours submersion was 300,000 and the insulator was tested after immersion and showed the first shell to be satisfactory in so far as flashover was concerned. The application of high pressure completely wrecked the other two shells, and when broken up, signs of penetration of the dye were quite obvious in all shells. It is reasonable to assume, that had the hydrostatic pressure been kept on for a longer period the dye would have been forced right through, sufficiently to form a path electrically through the first shell.

This again demonstrates the necessity for individual shell testing, because this insulator had been tested by authorities as good for 125,000 volts. This was true, because even after the insulator had been under the hydrostatic pressure test, it would withstand 120,000 volts from head to pin. But should such an insulator be put on a line? And yet how many, in such a condition are unwittingly put on a line?

Maker D. A particularly good insulator by this maker, although it has only three shells, has nearly as high flashover as some of the four-shell type.

It withstood all electrical tests satisfactorily and was then subjected to the hydrostatic pressure test, after which it also withstood the repetition electrical tests. It was further given Creighton's super-spark potential tests on each shell for five minutes, and withstood this test. On breaking up, not the slightest sign of penetration could be seen; and if the maker could only guarantee consistency, this insulator, by

virtue of its shape (Fig. 13) and quality of material, should make many friends, but as seen from the foregoing tests, purchasing engineers have reason to be suspicious, unless some guarantee is given that each and every shell of each insulator has been subjected to such tests as those described.

Tests and Results 66,000-Volt Suspension Insulators

66,000-Volt Suspension Type	
Maker	Flash-Over kv.
H.	110.
H.1	98.
B.1	88.
B.2	80.
A.3	80. Approx.

In addition to the several types of pin insulators tested, three makes and five samples of different shapes of suspension insulators were included in the investigations, and the results have been that three samples or 60 per cent failed to withstand the prescribed tests satisfactorily; the two that did withstand the tests coming from one Maker H who has undoubtedly specialized in this type and succeeded in attaining something unassailable in his product.

The flashover pressures are given below, and it will be noted that apparently makers have opposite aims; Maker H having, in his latest product, increased his leakage distance, while Maker B in his latest product, has decreased his leakage distances as shown:

Maker H.	received in	1917	has flashover of	98,000	volts
" H.	"	" 1921	" "	" 110,000	"
" B.1	"	" 1914	" "	" 88,000	"
" B.2	"	" 1921	" "	" 80,000	"

The product of Maker H has successfully withstood all tests, while that of Maker B has failed badly in both samples.

Maker A, who has a reputation for pin insulators, equal to the best known, had failed up to that time in his attempt to produce a suspension insulator. There is an inherent weakness in the design, in that the insulator punctures much below flashover pressure, also the porcelain was found to be unmistakably porous, illustrating the fact that even the best of porcelain makers are inconsistent in their products in the case of new types or shapes.

Maker B. (*1*). This supension insulator supplied in 1918 had been in service over six years, being one of a string of six which failed completely in service, from no apparent cause, just prior to the day load coming on. It was subjected to the hydrostatic pressure test, and on breaking up, after leaving the porosity vessel, it was found that the dye had penetrated to a considerable depth. (Figs. 9 and 9A.) From the above it can be reasonably assumed that the failure of this and the rest of the string of disks from which it came, was due to deterioration caused by the material being initially porous and moisture had gradually accumulated, until the material lost its insulating properties.

Maker B. (*2*). This was a new type supplied recently by the same maker who was seeking to redeem his reputation, which was seriously jeopardized, by results obtained from his earlier insulators. The sample withstood all electrical tests, both before and after having been subjected to the hydrostatic pressure test, and when broken up, no signs of penetration of the dye were observed, but a second sample, when tested dry, punctured decisively at 75,000 volts at 50 cycles.

The two pieces of the broken second sample were subjected to the hydrostatic pressure test, and on breaking up after leaving the porosity vessel, it was found that the dye had penetrated deeply at the weakest and most critical point of the insulator. This was

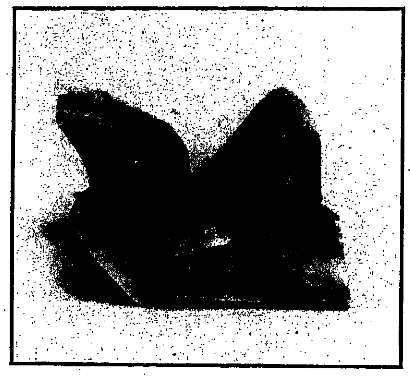

Fig. 9—Piece of Suspension Insulator Showing Marked Penetration. Maker B's Early Product

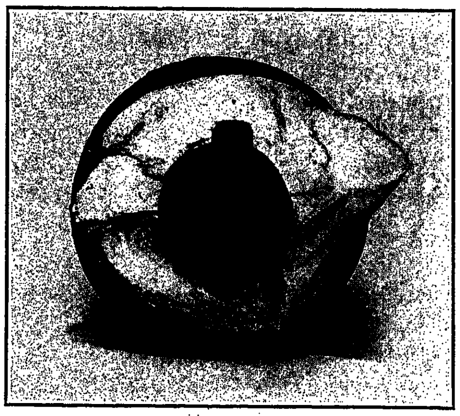

Fig. 9A

regrettable with such a recent production (1921), but certainly goes to confirm the author's contention regarding individual tests (Figs. 10 and 10A.)

Maker A. (*3*). *66,000-Volt Strain Insulator.* This insulator apparently has an inherent weakness in its design, inasmuch as several samples, punctured decisively under 60,000 volts (flashover should be about 80,000 volts).

One of the unbroken samples was subjected to the hydrostatic pressure test, and when broken up, after leaving the porosity vessel, it was found that the dye had penetrated throughout the whole thickness, in fact,

this was amongst the worst material handled in these investigations, although as before stated, this maker's material in the pin type productions, is unassailable and equal to the best handled by the authors.

Maker H. 66,000-Volt Suspension Insulator. This maker claims to have produced a porcelain that is unassailable in that it is perfectly vitrified and will

Fig. 10—Showing Maker B's Later Product in Suspension Type

Fig. 10a

withstand any electrical, mechanical or porosity tests. The insulator was subjected rigidly to the whole of the tests mentioned herein, and after the porosity tests, was further given Creighton's super-spark potential tests for five minutes. On breaking up, after having successfully stood all tests, not the slightest sign of penetration of the dye could be seen.

It is this type of insulator that is mentioned under Tests with High Frequency Oscillators, and goes to show that insulators can be made that will successfully withstand the tests shown, and there seems no reason why such insulators should not remain good in service for an indefinite period.

Maker E. Sample (3). 33,000-Volt Pin Type Insulator. This insulator successfully withstood all electrical tests both before and after having been subjected to the hydrostatic pressure tests, and when broken up, not the slightest sign of penetration of the dye could be seen; and the material was of a particularly good satin-like appearance.

Maker G. 33,000-Volt Pin Type Insulator. This also withstood all electrical tests, successfully, both before and after having been subjected to the hydrostatic pressure tests. When broken up, not the slightest sign of penetration could be seen, and this ranks as the finest sample of electrical porcelain seen by the authors.

11,000 Volt Pin Type Insulators

The testing of these insulators is regarded as particularly important, because they are within the range of local New Zealand manufacture, and the difficulty and cost of obtaining imported insulators during the war made it important that local insulators should be developed if possible. Investigations were made on those of two New Zealand makers (I and L) one Australian (K) and one American (E).

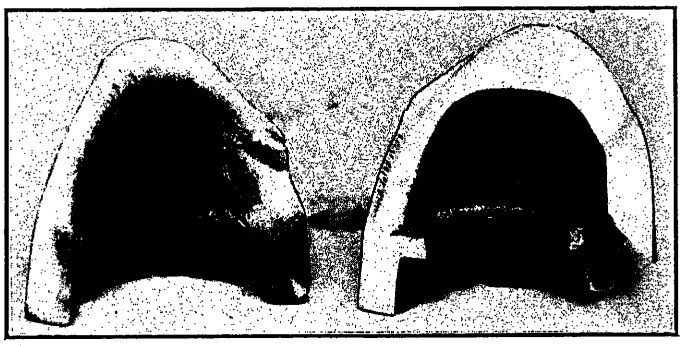

Fig. 11—Showing Local Products, on Left by Maker K (bad) and on right by Maker I (good)

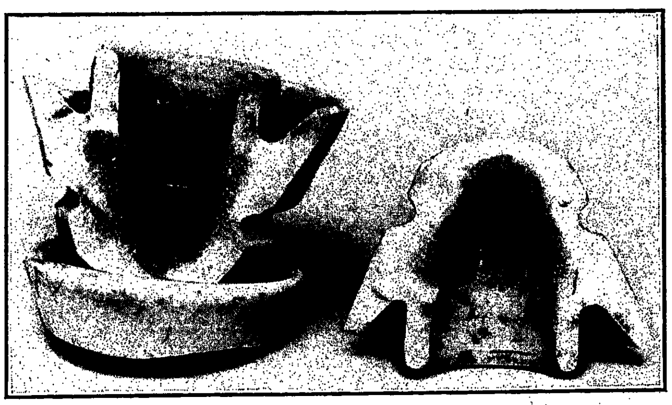

Fig. 11a—Local Product by Maker K. (Very Bad)

Maker E. Sample 4. This insulator punctured just below flashover during acceptance test, and was subjected to hydrostatic pressure test. Under this it showed distinct signs of penetration through the glaze, and particularly to a depth of about ¼ inch on each side of the puncture path, which was through the thickest part of the insulator, well down from the neck. Evi-

dently there was a porous seam existing where the insulator broke down. Three other samples failed in the same way out of thirty selected at random from a shipment of 30,000, indicating a very high proportion of defective porcelain.

Maker K. A special batch of insulators by this maker failed to withstand even working pressure, and a few were subjected to the hydrostatic pressure test.

FIG. 11B—LOCAL PRODUCT BUS-BAR PILLAR (VERY BAD)

FIG. 11C—LOCAL PRODUCT (VERY BAD)

Figs. 11, 11A, 11B and 11C show broken samples after leaving the porosity vessel. It will be seen that the dye had penetrated deeply through the entire body, hence their puncture at such a low pressure. Apparently in this case no effective factory test whatever could have been employed.

New Zealand Manufacturers. The insulator by Maker I withstood all electrical tests successfully, both before and after being subjected to hydrostatic pressure test, and when broken up showed no sign of penetration. Later insulators have given equally good results, and the quality of the porcelain has apparently improved, indicating that local manufacture of this type of insulator is quite successful.

Another maker "L", after several attempts produced a very good insulator for use on low-tension work up to 500-volts, but for high-tension work failed distinctly, all his porcelain being porous.

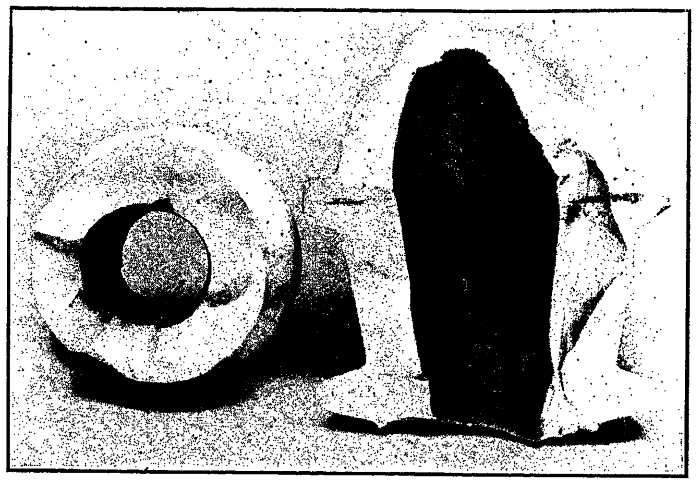

FIG. 12—MAKER M. SHOWING MARKED PENETRATION IN APPARENTLY A SEAM OF POROUS MATERIAL ON RIGHT AND A DEPTH OF ABOUT ¼ INCH FROM INSIDE EDGE ON LEFT

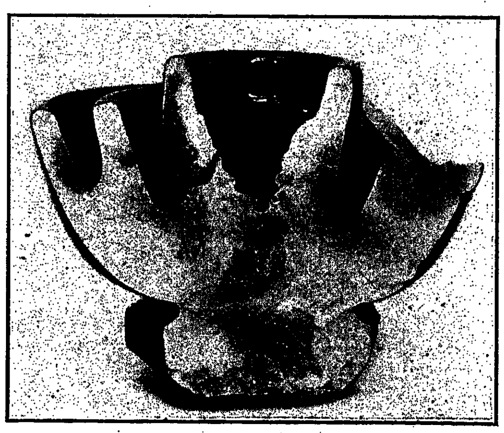

FIG. 12A—SHOWING SAMPLE OF HEAVILY GLAZED INSULATOR INTO WHICH THE DYE HAS BEEN FORCED THROUGHOUT THE ENTIRE MASS

Extra-High-Tension Bushing. A bushing for 66,000-volt circuits was supplied by Maker M—manufactured in England—who was seeking to enter the electrical field. It is assumed that the insulator was given some kind of test before being sent out such a distance, but on being tested electrically dry as received it punctured decisively in the thickest part, on approaching 40,000 volts. On being subjected to hydrostatic pressure test distinct signs of penetration were obvious, the dye being forced through the glazing to a depth of nearly

inch, and in the thickest part there was a distinct us band, which had been apparently moulded with insulator. Needless to say no further insulators purchased from a manufacturer allowing such to be exported. (Figs. 12 and 12A.)

ape of Insulators. The shape of high-tension pin lators has undergone a radical change since 1917, nly on the lines suggested by Gilchrist and Kline er (*Electric Journal*, Vol. 15, No. 11, page 445). original type adopted in the Lake Coleridge system, 13, manufactured by Maker B did not give good lts owing to the shells practically enveloping each r so that it was impossible for the weather or wind lean the inner shells, thus lowering the factor of ty of the insulator. In later designs the shells are e open so that not only is the weather able to dis- e such deposits, but the planes between the shells w more closely the equipotential surfaces, and the y of the insulator conforms to the lines of electro- ic field as suggested by Gilchrist and Kline Felter.

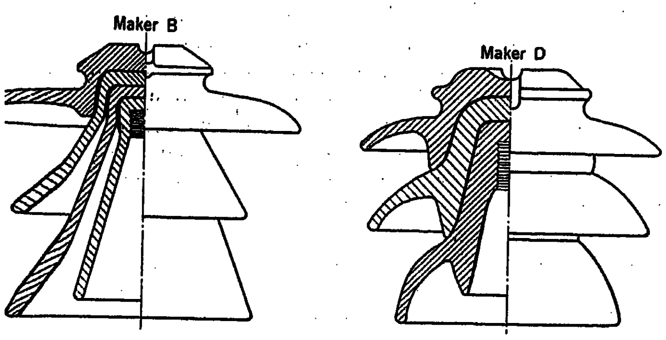

FIG. 13

improved shape, coupled with the real improve- t and greater consistency in quality of the porcelain effected a substantial improvement in the life of high tension insulators.

azing. Our experiments showed that glazing, even n over the entire shell of the insulator is no protection nst impregnation by moisture. In the early stages isulator manufacture apparently some importance attached to the insulating quality of the glaze, experience of puncture tests either in oil or in air to confirm this, in that when approximately the ture value is reached, there is a definite time lag re the glaze starts to crack or craze, but when it so, complete puncture quickly follows. Ap- ntly then, the glaze has some value as a dielectric, when once it breaks down it is no further protection, when crazed, it is of course easily penetrated by ture. Several of the figures herewith show pene- ion all along the glazed edges, indicating that the ture must have entered through the glazed surface. consider that our experiments demonstrate that ing is no protection against the penetration of ture, and that the insulator can be and should be e non-porous. Glaze should certainly not be put make good the defects of indifferent body material, it will not do so.

General. The great importance of the transmission line insulator in the early construction days of most undertakings is usually lost sight of owing to the numerous urgent requirements of the rest of the plant, and as a rule, testing of insulators is left until trouble arises from breakdown on the transmission line. Extraordinary care is usually taken in testing the generators, water wheels, and other details, but the insulators are left to work out their own salvation, relying in some cases, quite without justification, on the makers' guarantees. The usual method is to dump the crates of insulators in the yard or alongside the poles, and leave them there exposed to the weather until they are ready for erection. During this period any porous insulators will certainly become more or less penetrated with moisture, and unless the factory tests are very thorough, trouble will ensue sooner or later. The authors consider that their observations indicate that there is need for much more co-operation between the manufacturer and the operating engineer with the object of reducing the maintenance. It is now general practise on the part of manufacturers to reduce as far as possible the stresses due to expansion and contraction and temperature variations, and with this object various types of jointing material have been introduced between the shells, which are intended to take the stresses due to temperature changes, thus reducing the cracking of shells due to such stresses.

Annual Overhaul. Annual overhaul on the transmission line is also very essential for the detection of defects not perceptible from the ground. This work of course has to be done as expeditiously as possible and in the best weather.

SUMMARY

From the tests and investigations described herein the following conclusions may be drawn:

1. That insulators for extra-high-tension work, before they are put into service should be subjected individually in the case of suspension units and on each shell in the case of pin insulators, to flash-over pressure for a definite period at both high and low frequency, or at least at high frequency, either by the maker, or preferably by the purchaser after delivery, when the maker should be prepared to bear the cost of rejected ones.

2. That a percentage of each shipment of insulators should be subjected to a hydrostatic pressure test at least as severe as that described herein. One manufacturer describes his competitor's specification for porosity as "a joke," and proposes instead a porosity test of 4800 lb-hours; which appears to the authors to be equally a joke.

3. That insulators can be made and are being made that will not be overstressed by such tests, and which should remain good in service for an indefinite period.

4. That a proportion of insulators supplied hitherto have been porous, and should be replaced at once by insulators that have been thoroughly tested.

5. Extreme care should be exercised in the selection

of the type and shape of insulator, having regard to the form of electrostatic field and to the self-cleansing form of the insulator.

6. There is room for more co-operation between the maker and the user in the matter of handling and maintaining insulator service.

7. That in a country such as New Zealand where it is proposed to develop hydroelectric power to the utmost limit of its resources, a public testing laboratory should be established, where various undertakings could arrange for tests herein described, thus giving them a guarantee that the material received would be of the best quality, and eliminate the annoyance and mistrust engendered in the public mind by insulator breakdowns.

We desire to express our most cordial thanks to Mr. L. Birks the Chief Electrical Engineer for the Dominion, for the support and help he has given us in this work. Much of the information contained in the paper is Departmental, and for permission to publish this we are indebted to him.

Our thanks are also due to The New Zealand Institute which gave us the monetary grant which enabled the porosity tests described to be developed.

Discussion

W. A. Hillebrand: I will confine my discussion principally to the paper by Messrs. Farr and Philpott. The energy and care with which they prosecuted this research is highly commendable, and the results are extremely interesting. On the other hand it is characteristic of a great deal of such work that an attempt is made to draw general conclusions from incomplete data. For example, the insulators on which they made their tests were evidently of very poor material.

Another factor which they have overlooked, and which is very frequently overlooked in such a series of tests is the time-puncture characteristic of the material. That must be known fairly well before one can obtain definite results. Of any lot of insulators a small percentage will puncture at dry flashover voltage. This percentage depends upon the quality of the porcelain, and is proportional at least to the first power of the time the voltage is applied. This always enters as an unknown factor in any series of tests involving periodic applications of voltage.

The insulators reported upon are of designs now largely obsolete, which has a bearing on the question of time constants and the superior ability of an oscillator to puncture under test, which has been known for a number of years. A long, deep shell similar to the type used in the earlier pin-type insulators manufactured ten years ago, may have a 60-cycle flashover of 50,000 volts. Under an impact or oscillation that flashover will run up to seventy-five, eighty thousand—perhaps double. The design is such that when a steep wave front is impressed upon it the porcelain withstands a very much higher flashover than do designs that are such as are used today, with consequently greater liability to puncture.

One very interesting thing which they bring out is that whole insulators were used in their porosity test, and that they succeeded in a very large number of cases in driving the fuchsine right through the glaze. That is not altogether surprising in view of the fact that the glaze is continuous with the porcelain body and of composition similar to the binding material in the porcelain itself. Except for the fact that it is on the outside and more exposed to the heat of the kiln, it should have a density similar to that of the body of the porcelain.

One fault to be avoided in such work is to draw conclusions from old material and attempt to apply them to ware as it is manufactured today. As a result, the authors are apparently in a mood to impose a rigorous specification upon the manufacturer, a procedure which often has been disastrous in the past. That is, an insulator can be designed to meet almost any requirement desired, but there is a very great danger, and it has very often happened, that such insulators will be very short-lived. There are a number of disastrous examples on record.

With regard to the possible cause of failure of insulators due to lap checks, sand streaks and so forth. One very interesting example of that was brought to my attention last year by an engineer who had dissolved the caps of a large number of insulators in acid. He showed me one shell that was absolutely down by the megger, which probably had a sandstreak or a lint streak in the head. Over many square inches of area he had with true Oriental patience, searched until he located a spot perhaps one-sixteenth of an inch in diameter, or less, where alone the porcelain was porous and down.

H. V. Carpenter: I am convinced that the manufacturers are now giving us some porcelain which is different from that which we have had in the past, and a great deal of data which we have had presented to us in past papers refer to the older type. Now the manufacturers will probably tell us that the old troubles are all taken care of, but is it not likely that we are doing the thing which has been done so many times in other things, substituting something which is really a new product now in the better porcelain? It is better undoubtedly but perhaps it has some new peculiarities which we still have to learn; so I am very much interested in the suggestions made in regard to the tests for the mechanical difficulties which are likely to arise, and to determine whether the failures which are now coming may not be almost entirely mechanical.

H. H. Schoolfield: I recently had occasion to make a test on one of our 66,000-volt transmission lines with the Johnston buzz-stick method. The insulators on this line had not been tested by megger or any other method since they were installed in 1912. I made the test this last spring and found only about three per cent of the insulators showed bad by that method. I consider this a very good record for a line built with insulators purchased in 1912.

There is no question but that we are getting a better grade of insulators now than we did then, and I expected to find a great many more failures than I did. The line was somewhat under-insulated too, compared to the way we insulate lines nowadays. It is a 66 kv. line with three cap and pin type units in suspension and four at strain points. One thing I did find though, that bears out some of the discussion this morning—that the larger percentage of failures was at the point of support, at the pole or cross-arm end of the string.

I also took a good many of the insulators that showed failure under the buzz-stick method, and checked them up with the megger after they had been taken down, and I am satisfied in my own mind that the megger does not give an accurate test; does not show accurately the bad insulators in the line. Some of the insulators that would show bad with the buzz-stick might show a high rating under the megger, but put on an oscillator test they would fail. Give them a high-potential test they would fail, although the megger did not show them bad.

There are a great many factors entering into testing with the megger. Atmospheric conditions, have to be watched very carefully, so I am very much inclined to favor a method similar to the buzz-stick for picking out bad insulators. I think a good many insulators might show bad under a megger test that should not be removed. A few years ago we made a practise of taking out an insulator from a string that would megger anything below 4000 megohms; between 3000 and 4000 megohms. Under that practise I think we took out a great many insulators that should

not have been condemned. If we had left them in they would have stood up.

The line that I speak of, however, was in a very dry section of country, where we don't have very much rain. It wasn't in Portland, but was in the north central part of Oregon, around The Dalles. That may have had something to do with the low percentage of bad insulators we found.

R. J. C. Wood: Mr. Schoolfield's remarks have led me to think that it might be interesting to give a little outline of an instrument we have developed—under the direction of the engineers of the Southern California Company—to do the same work as the buzz-stick without some of the dangers that are inherent in its use. It seems to me that Mr. Schoolfield had his nerve with him when he used a buzz-stick on a line that had not been tested for so many years; with only three units on 66,000 volts. If he had happened to strike two bad units in the same string it would have resulted in an accident. In order to eliminate this danger, which is not so great on a 66 or 60,000-volt line where there are four units, but is very great on a 15,000-volt line where there are perhaps only two units, we made a little device, which is practically an electroscope. It is constructed of a piece of one-inch square bakelite tube with two vanes inside. Another electrode is wrapped around the central portion of that tube, the tube being a foot or so long, and some more square bakelite tube is slipped over the outside so that there is nothing hot exposed, the connection of the two vanes is brought out to one of the prongs on the end of the device and the outer piece of metal connected to the other prong, and the whole thing is mounted upon an insulating stick. Putting the prongs across an insulator if there is voltage across it the loops inside vibrate, and sighting through the end of the open one-inch square tube it is easily seen whether the vanes vibrate or not, and there is no danger incurred as there is no metallic circuit through the testing device.

H. L. Melvin: As far as the operating engineer is concerned, what they do want is a product which is uniformly good. Just what tests are necessary to weed out poor material we are not prepared to specify. Both design and tests are primarily manufacturing problems. The manufacturer must cooperate with the operating engineer to find out what the particular problems are. Operating companies are at fault in that until just recently, with the exception of a few of the larger companies, they have not kept records of failures or really studied the problem.

If we are now satisfied with the standard types of insulators it is the manufacturer's problem, to introduce as many logical improvements in the manufacturing and assembling of parts as they are able to devise to insure life to the insulator under operating, mechanical and electrical stresses. They must also devise tests which will insure the purchaser against the purchase of defective material.

However, I am convinced that further study of operating stresses both mechanical and electrical, must be made and tests devised to duplicate them. These tests may lead to a modification of the present general design as operating conditions become more severe.

Allen E. Ransom: During the war, I was Chief Electrical Officer, Major Commanding 137th Engineers at Base Section No. 1 St. Nazaire, and had occasion to use a good many insulators throughout that base. We were connected up with the French systems through the large Central Stations at St. Nazaire, Nantes, Angers, Saumur and other points. The Haviland works at Lyons were making insulators for the use of the American forces and put out a very fine grade of white porcelain insulator for 5000 and 20,000 volts. These with intermediate voltages were used on our temporary lines all through Base No. 1 and also at Brest and Bordeaux and the intermediate sections up towards the Front. We built something like 200 miles of primary and secondary lines and never had any insulator failures.

The machinery we had to use was mostly French which we obtained from the Westinghouse Works at Le Havre and the General Electric works at Lyons. We had no trouble with their motors and transformers at all. A great deal of the American machinery sent over was 2300 volts, 60 cycle. Standard French distribution primary voltage is 5000 volts, 3 phase, 50 cycle and 230 and 460 volts on secondary power circuits so American 60 cycle motors were all right.

The transmission lines throughout the Atlantic Coast section of France were almost all 20,000 volts and using power and light from steam turbine generating stations in the principal cities there being no hydroelectric stations in this district. Our experience with the French insulators was very satisfactory.

Conservation or Waste of Material in Educational Institutions

BY J. W. UPP
Member, A. I. E. E.
General Electric Company, Schenectady, N. Y.

THE successful operation of a republican form of government depends in large measure upon an educated people. It is obviously impossible to let the people rule unless their intellectual training has reached the point where they can distinguish between what is right and what is wrong. The better they are educated, the more likelihood there is that the governmental agencies will function in a proper manner.

These facts have been clearly recognized in this country ever since the present form of government was established with the result that our educational institutions have always received the active interest and support of an intelligent and generous people. We have pointed with pride to the country schools in which so many of our greatest men received their early educational training and have always given to such schools much of the credit for the successes achieved by those who attended them.

In other words, the American people have always believed so thoroughly in scholastic training that it was natural for them to exalt this work and to furnish funds for its continuance.

The same applies equally to the college and university. Early in our history we set up institutions of higher learning to supplement the work of the common or public schools and these institutions have constantly grown in number, size and importance to the present day.

The point we are trying to make is that no one without good reason would find fault with a system we all believed in. We do not believe, however, in all the details of its present day administration and accomplishments. We are forced to conclude that although our system of education has an uncounted number of highly commendable features, it has also some faults which should be corrected.

In discussing the work of the educational institution as regards the conservation or waste of material, we shall compare its activities and results to those of a modern manufacturing establishment. We shall do this because it is a convenient method to illustrate the points we have in mind.

Is it fair to draw comparison between a modern manufacturer and a modern educational institution? To the writer it seems quite in order to do so. Modern business is conducted on a very high ethical plane and directed by men of education and ability who must meet the keenest competition and have their accomplishments measured by actual values. The most efficient management is the one which obtains the largest amount of high grade finished product at moderate cost from a given amount of raw material. Surely there can be no objection to applying this standard to measure our educational institutions.

In a successful manufacturing establishment, close attention is always given to the material which will enter into the finished product, and the most careful specifications are drawn to insure the material purchased being of a grade suitable for the article which is to be produced. And these specifications are always supplemented by rigid inspection of the material when it is received. When the material has been accepted, it is the obligation of the management to use it to advantage and through efficient direction to obtain the maximum number of finished articles. It is also the duty of the management to use to advantage all by-products, and to salvage the material which has been damaged in handling or through careless workmanship, or which may have been spoiled by workmen who are not properly instructed or supervised.

Do our educational institutions accept the responsibilities for output that they should accept? Do they give the same attention to conservation of material that is a necessity in ordinary business undertakings? To the writer, it does not appear that they do and it is the purpose of this paper to draw attention to what appears as a profitable point for consideration.

Our educational institutions are furnished with the finest grade of material that the world produces. This material is selected under rigid specifications. It is not accepted until it is found of the grade that is considered suitable for the product that is desired. It comes to the educational institutions under the very best conditions with the certainty of every assistance that can possibly be given to maintain the standard. Every young man who enters an educational institution comes with the unqualified backing of family and friends and the kind of backing that should be of the greatest value. What is done with this material after it is received? It is beyond understanding that in the first period of the freshman year it is found that the material which has been selected under such carefully prepared specifications is defective to so large a degree. It is equally disturbing to find there is further rejection in the succeeding periods of freshman, sophomore, junior and even senior years. Is the fault with the material? If so, there are serious faults in the specifications. Is

Presented at the Pacific Coast Convention of the A. I. E. E., Vancouver, B. C., August 8-11, 1922.

the fault with the handling of the material? If so, the methods of handling are inefficient.

The writer in looking over the records of many of the highest grade educational institutions cannot find a single one which to a business man would be considered satisfactory. The results, if duplicated in a modern business, would be the cause for criticism and there would be certain failure.

Is the comparison unreasonable? Is it proper to ask that the college or university give a better accounting of the resources which are under its immediate direction?

Each year, we find very great attention being given to the size of the entering classes, also attention to the number of those who have received degrees and diplomas; but has there ever been a published statement at commencement as to the number who have failed to complete the work which they started four years earlier? How many of our instructors would be commended if they pointed to a class which had completed the course without a failure? How many of our professors would feel that they had properly conducted their work if they did pass every one in their classes? How many accept personal responsibility for the failure of any individual under their supervision who does not complete the prescribed work in a satisfactory manner?

The selection and training of the teacher is probably the most important phase of college administration. The teaching professions is justly recognized as of very great importance. It calls for leaders of the highest type. The mere ability to impart to the student the information contained in the text books is only one of the requirements. There must also be wise sympathetic and forceful leadership to direct the students' efforts or there will be much confusion, conflict and waste. On every staff and in every faculty there are many with all the fine characteristics that are required. Of these, we wish to voice our appreciation and to commend the success they have obtained in directing the students along paths which have been so productive. The teacher to be of maximum value must have a tremendously vital interest in his subject and in the great responsibility of his position. He should be of a type which appeals strongly to a vigorous, energetic young man, of a type which takes as much interest in student affairs as the student himself. How, otherwise, can he hold their interest and how, otherwise, can he make them believe that the things he teaches are worth while?

The teacher must be selected with great care and must then receive a sufficient salary to enable him to take his proper place in the community. He must be a successful man himself if he can ever be hoped to teach success to others. The difference between the successful and the unsuccessful teacher is certainly not determined entirely by the book knowledge each possesses. It depends largely on their comparative attributes for real leadership.

These leaders are necessary. How to obtain them, I leave for the college authorities to decide. That they do not exist in sufficient numbers at this time is evidenced by the results obtained.

One of the greatest wastes of human material in connection with our colleges results from the student following the wrong course. This is also one of the most difficult things to remedy.

The particular courses the students take depend to some extent upon the family's general desire to have them enter some certain profession. Very little detail or analytical study is given to the problem. The courses selected are usually determined by the relative popularity of some branch of engineering, law, medicine, etc., and have no relation whatever to the actual capabilities of the prospective students. The individual characteristics of the students, the type of training they have had in their homes, the ever changing needs of social, intellectual and industrial life, complicate the problem tremendously and make its attempted solution worthy of the deepest study.

The purpose of a college is to give an education to those who enter its doors but of what that education should properly consist is surrounded by much hesitancy and doubt.

The subjects for study and the arrangement of the courses have always received considerable attention but there is still much to be done along this line. When it is necessary to force the sudents into studying subjects which they cannot see will be of advantage to them in later life, it is obviously very difficult to hold their interest. On the other hand, the students will give all the necessary time and intensive study to those things that interest him deeply. To create that interest is one of the most important duties that is met successfully by the real teacher. When the students fail, the teacher must take most of the blame.

It cannot be said that the educational institutions have not had the backing of the people, and that it is, therefore, difficult to obtain sufficient funds to pay for a sufficient number of teachers to give the students individual attention.

If the financial support received has been insufficient to meet the requirements, it is because of a weak presentation of the case. The people of this country will not knowingly let their educational institutions suffer if the matter is put before them in the proper light.

A college or university should be run according to the best modern business principles. That is, the administrators should be able to show a satisfactory return on the investment. The stockholders of any business corporation would soon withdraw their support if it should appear that the management was inefficient

in carrying on its affairs; and the college or university will naturally receive the same treatment.

There is no doubt that even after the most careful selection, some of the material will be found defective, but can it not be used in some other manner? It will also be found that some of the material has been damaged in handling, but that too, can be usually repaired or used for some other equally valuable service. Some material too becomes defective because it has been handled by careless workmen or by workmen who have not been properly instructed and it is this material which it would appear should have the most attention.

That errors have been made in reference to this material which has been rejected as unsatisfactory, there can be no doubt. In the writer's experience, there have been many cases where not only has the damage been repaired, but later the material has been found of the most excellent grade, in some cases of such high grade that it required special attention in order that it might be most effectively used. It was rejected because its qualities were not understood, not because it was defective.

The modern manufacturer has a research department which devotes the entire time to finding ways of using to advantage materials which have heretofore been of little service, also to use materials where the results desired have not been obtained. Is there not a parallel work for educational institutions? Cannot a division of college work be made which would make it possible for a group of men connected with the faculty to study the causes of failure, to make the new applications, to revise the methods or change the work so that the ability of the individual could be properly developed and applied?

The writer has had an opportunity to observe young men and young women under various conditions,—those who have been marked as successful and those who have been marked as unsuccessful,—but in almost every case careful selection has given satisfactory results, and in practically every case it has been possible to encourage the individual to do what he set out to do and to accomplish the thing that was desired.

One of the most common causes of failure in the earlier years of educational work seems to be the improper direction of those who are immature. It would seem in order to apply more stringent regulations to those who are far from the years of discretion, and it certainly would be in order to do this if the results should prove that such regulations were warranted.

No doubt if the writer was actively engaged in directing the work of an educational institution, he would find the problems overwhelming. But as a business man, the solution of those problems would always be desired and sought for until the percentage of finished product was many degrees higher than it is in our educational institutions at this time. There is no desire to lower in any degree the very high standards which have been set. There is no desire to recommend that diplomas be given for work that has not been completed, but there is a firm belief that with different methods with more study given as to the causes of failure, it would be possible to effect a very considerable saving of material.

Is there a college or university today which is advertising the fact that anything short of 100 per cent output is viewed as a matter of concern, which has found the reasons for failure and is applying the remedies, which is holding itself up as a standard of excellence because its output is equal to its input?

We know of no such institution. We doubt if it exists. We doubt if it will ever exist, but we shall be satisfied that our colleges and universities are properly directed only when this condition is far more closely approximated than it is at the present time.

We wish to say again that there is not, nor can be, a more worthy purpose than the proper education of every young man and young woman, and everything should be done which can be of assistance in this direction.

Waste in every form should be eliminated.

Discussion

For discussion of this paper see note, page 639.

Training to Think Versus Gathering Information

BY TALIAFERRO MILTON
Fellow, A. I. E. E.
Electric Storage Battery Company, Chicago, Ill.

THE time allotted to me is not sufficient for me to go into details of how I have arrived at my conclusions, and I will, therefore, content myself with the expression of some of my opinions.

Many professional educators may not agree with me and I shall be very glad indeed to debate the subject with them in such detail as cannot be used in this short summary of my opinions.

I regret that I have not any very useful suggestions of a constructive nature to offer to educators in regard to what should be done to correct and improve the systems of education now in use in this country. If, however, these mere expressions of opinion will serve to stimulate the professional educators in discovering cures for the evils which are patent to many of us engaged in practical every-day work, then what I have to say will be worth something.

I do not claim any originality in these opinions; in fact they have been formed not only through my own personal observations, but through many discussions with other work-a-day men with whom I have come in contact. I left the educational field because I did not think I was suited to it, and all I can do is to point out to professional educators evils for which they may, through their study and experience, find a cure.

The crime of most of the colleges today is that they do not teach their students to think. They spend too much time in cramming facts into the student's heads when, in my opinion, the short four years available to the average student for college life is all too little time for teaching the student to think. After all, it really doesn't matter very much whether a young man in the early 20's leaving college, knows a great deal of a concrete nature, provided he has learned to think.

It is of course, necessary that certain fundamental principles be taught; moreover, they should be drilled into the heads of the students, but beyond that, the work to be performed by a student should always be laid out with the one idea in mind of increasing the student's capacity and ability to think. Why should time be wasted in college, in shop work? What does it matter whether or not a young fellow, graduating from college, can file a flat surface or do a good blacksmithing job, or a hundred other odd mechanical jobs, unless the doing of such jobs is entirely incidental to the training of his thinking apparatus? Suppose he *is* a fair mechanic when he leaves college—he will find in the shops mechanics who have never even been through high school who are ten times as good as he is at a hundred different jobs. These mechanics who have had little schooling have learned every step in their trade in an empirical fashion and I have known some of them who were crammed full of a thousand and one facts some of which were not true. Not long ago I was talking to an older man about a certain young fellow, and I remarked that this young man seemed to have had a lot of knowledge. The older man answered, "Yes, he knows a lot, but unfortunately most of it isn't true."

Several of the cleverest engineers with whom I am acquainted spent most of their time in college on one piece of research work and when they started their careers as engineers, they were very *very* "green" from the shop-man's and practical engineer's viewpoint. They had practically no acquaintance with the thousand and one details of shop equipment, central station equipment, etc. However, the particular piece of research which each had done had involved a great deal of study and thought and in completing this research they had learned to think. Before making the research, they had, in each case, been thoroughly drilled in the fundamental underlying principles of mathematics and physics which were the tools they used in thinking out the problem in hand. The fact remains that (without going into further detail of how I have arrived at these conclusions) these men today *are* great constructive engineers. I know other men who have never had any college education who are also great engineers and I find that they are great thinkers.

I go so far as to believe that if a man is born a great thinker it matters not whether he has any college education. Some extreme examples are John Marshall, the great Chief Justice, and Abraham Lincoln, the great "Emancipator" and President. These men, to be sure, were not engineers, but I think none of us doubt that had they turned their hand to engineering instead of law and politics they would have been just as successful in the engineering field as they were in their chosen professions. Those of you who have read biographies of these men, especially the recent "Life of John Marshall" by Senator Beveridge, cannot help but be impressed with the fact that even though these men obtained very little standard education in the common schools and colleges they did get in their particular scheme of study and work a tremendous training in how to think.

Right here I want to say that I believe there should be no fundamental difference between the general methods of engineering education and education for any other profession. All education for the young man during his school and college courses should be with the one idea in mind—to increase his capacity for thinking straight, thinking clearly and thinking ener-

Presented at the Pacific Coast Convention of the A. I. E. E., Vancouver, B. C., August 8-11, 1922.

getically through each problem to a conclusion. Once he has acquired such a habit, each problem will be conquered as it arises regardless of how much concrete knowledge on the subject one has to start with. This reminds me of a definition of an engineer which was given to me some time ago by an engineer who is a member of this Institute. He said, "An engineer is one who learns how to do something before the people find out that he doesn't know how." It is obvious that he couldn't function in this manner unless he were trained in the fundamental principles and knew how to think.

No one could claim that an exact knowledge of a great many facts is in itself detrimental. My whole contention is that the time is so short in the grammar school, high school and college that the teaching of empirical knowledge should not crowd out the training in the thinking processes and it has been my direct observation that that is exactly what has happened to a large percentage of college graduates. Their minds have been crammed full of facts and they are unable to think clearly. A man taught a lot of facts can only copy work previously done. He will never build anything new, unless along with these facts he has learned how to think. He cannot produce synthetic results because he cannot think things out to a conclusion. He has become mentally lazy because others have done his thinking for him and have supplied him with the finished result in the form of a fact.

A student, even if he starts with an inclination to think will soon abandon effort in that direction if he is drilled by his professors to accept their teachings as immutable laws. The student should be trained at all times to keep his mind open. He should never be allowed to accept any working hypothesis as an indisputable law. The best picture I know of the danger of teaching students that the working hypotheses which we now accept as laws are indisputable and immutable is contained in the French astronomer Flamarion's little story, at the end of his chapter on the LaPlace Nebula Hypothesis. Those of you who are not familiar with this story will, I am sure, get something out of it and I recommend that you look it up.

The overemphasis which, in my opinion, is being given to the laboratory method seems to have extended backward into the high school and grammar school. I say extended backward because I believe that the prodigious use of the laboratory method now in vogue in the grammar and high schools is because of the entrance requirements of the colleges. I have a fine opportunity just now of observing the methods in the grammar school because I have two children in one of the finest public grammar schools in America. It certainly seems to me that the laboratory method is being overworked.

While I believe that a large part of the trouble with most of our college graduates today is due to the waste of time in teaching them facts, I would like to point out what, in my opinion are other indirect causes of the student's lack of thinking capacity. One of the main troubles with modern colleges, especially the large ones is the lack of democratic spirit. Above all things we should make the college really democratic and drill into the student's heads that all they obtain at college is a training in the groundwork and the fundamental principles and the process of real thinking so that when they leave college they are ready to *start* life's work. The college student, who starts life's work with an idea that because he has been to a certain college he is better than other men has a serious handicap and he loses several years in getting a fresh start.

Some years ago I sent my business card into the office of a young engineer who had quite an important position with a large concern in the northwest. He came out into the reception room and his greeting was, "Are you a salesman or an engineer? I do not care to talk to a salesman; I want to talk to one of your company's engineers." I asked him, "Are you an engineer?" and drawing himself up stiffly, he said, "I am a graduate of —" (naming one of our largest and best known engineering colleges). I had difficulty in restraining the explosion which began to accumulate in my insides. I got to be quite friendly with this fellow but I learned in a short time that he was not an engineer at least not one in accordance with the definition I have given above. It so happens that the college he was graduated from has turned out a great many thinkers, but I have often wondered whether they learned to think at college or whether they were just born that way, or whether some good old-fashioned teacher in the grammar or high school started them off right so that even the college couldn't ruin them. *Lack of the democratic spirit is not conducive to clear thinking.*

A college should teach modesty. Most modest men are thinkers. Perhaps that's the reason they are modest and perhaps I am mixing up the cause and effect.

I have in mind several of the smaller colleges in this country who are turning out men, the great majority of whom seem to be able to think; and in looking around for a cause of this I have noticed that the men at these colleges work. The athletic and social side is not over exaggerated as it is in some of the larger and wealthier colleges. If the athletic and social functions are made of too much importance, a man hasn't time to think. When he isn't attending a football game or a dance, he is trying to cram up sufficient "*facts*" to pass his examination.

Everything that is said above could apply as well to any other form of education as it could to engineering education and I believe that other branches of education are just as derelict in these respects as is the modern form of engineering education.

Some of the college courses for engineers are, however, even worse than the college courses for other professions in that they slur over the teaching of English, literature, philosophy and history. I know some pretty good, practical engineers who are college graduates and who

get pretty good results, but who are almost illiterate. I do not believe that many of us agree with one of our most prominent automobile manufacturers that such education is useless. Certainly those of you who agree with me that the main principle of education should be enhancing a man's thinking capacity cannot admit that a broad education is not necessary in an engineering course. What can stimulate the thinking powers more than a good general knowledge of literature, philosophy and history?

Summing up, it is my firm opinion that in the United States today we are overdoing empirical, shop and laboratory practise in our educational institutions all the way from the beginnings of the kindergarten through the university. I believe that by overdoing these methods we are cramming the student's minds instead of enlarging them.

Teach the student to think and give him just such facts as are necessary to make him think.

Engineering Graduates in Business

BY L. A. FERGUSON
Fellow, A. I. E. E.
Vice-president, Commonwealth Edison Company, Chicago, Ill.

IN a business in which engineering talent is required to produce its output or operate its plants, the engineering graduate is looked to as the supply of timber from which to build up the personnel of the technical and supervisory forces. Without a capable personnel no organization can be effective, and without knowledge such as the engineer is trained to use in an accurate way, no such business can make headway against its competitors.

The engineering graduate has been trained in the fundamentals of pure science and mathematics, and has been given an acquaintance with applied sciences which, if he has been conscientious, has provided for him the foundation of his future work. He is started in his first position as a draughtsman, inspector, laboratory assistant, tester, or in some similar line of work where he will be able to render service of some value while he is learning enough about the business to fit him for a position of responsibility. In some cases he may be shifted from one minor job to another several times before he is definitely placed. In other cases he may voluntarily shift from one business to another in the hope of finding something which looks more promising. In this process he discovers work for which he has an aptitude and in most cases the work is of a specialized nature in which he makes use of but a small part of the knowledge gained in school. The result is that those whose natural talents qualify them to excel at highly technical kinds of work are chosen promptly for such work, giving the impression that the highly technical man is the one most sought after and desired.

A considerable part of the men who entered with a given class and whose talents run rather to construction and installation work, or to sales engineering, have either fallen by the wayside under the discouragement of the tests encountered, or, if graduated, have drifted away after a time into some other line of activity where their talents are better appreciated. Men of the latter class may be and often are those having business ability, and after the first few years they are likely to be found in positions of greater responsibility than those whose ability as students was much more marked. Every class of any large engineering school which has been out of school for five to ten years affords examples of this.

There are, of course, the exceptional men who were good students and had also the talents for the larger positions in life, and these exceptions but prove the rule.

Thus in the past decade there has been a distinct tendency to develop a large body of engineering technicians who are highly skilled in the treatment of special problems and who have as a result contributed in a large way to the sum of human knowledge. But too many of these men have become so highly specialized that they have lost the breadth of view which is essential to a proper sense of perspective and are, therefore, incapable of seeing the broader problems of industry or of suggesting solutions for them.

Now, how is a recital of conditions affecting graduates of engineering schools in past years related to the education and training of the coming generation? The answer is that history will repeat itself unless changes are made in the general scheme of education in the future.

The training of the student has been conducted thus far from the point of view of giving him a general fund of technical knowledge. This is perhaps only the natural result of an atmosphere where scholarship is made the chief criterion of excellence, and other lines of ability are largely subordinated to it.

The training of the students of the future should make provision for the type of men who though they may not shine in technical work will nevertheless take places of importance in the industrial world where leadership, salesmanship, and executive ability are in great demand.

It is true that men of this type will usually make a place for themselves in the world whether they enter engineering schools or not, but the engineering world

Presented at the Pacific Coast Convention of the A. I. E. E., Vancouver, B. C., August 8-11, 1922.

is losing many men under present conditions whom it will very much need in the coming years.

The engineering courses as at present constructed appear to be unattractive to this type of men and we find many of the sons of graduates of the last generation substituting courses in general science for engineering courses in order to get more of the general culture of a college training, and to come more into touch with the the non-technical life of the school.

Just how the details of engineering courses should be modified to make them more attractive to this class of students I do not presume to say, but it would seem that the elective courses could have a broader scope and the required work could be made less exacting than has been the custom in most schools.

The situation may be likened in many respects to the conduct of a saw mill enterprise, conducted by a lumber company which is cutting its own timber. The business is covering the rough pine lumber market for general construction purposes and its mill and other facilities have been planned for this business exclusively. It turns out heavy timber for railroad and mill construction and smaller shapes for building purposes and general uses. Its supply of timber is chiefly pine, but there are occasionally "stands" of certain kinds of hardwood which yield logs of higher value than the general run of pine, and though a few of these come through with the rest, the majority are left standing. The mill is not equipped to handle these few properly for the hardwood market, so they go into the output and are sold with the pine. The consumer finding these occasional pieces of hardwood is not able to take advantage of their increased value and they are hidden in a structure where their worth is not likely to be recognized by the owner. Occasionally it is true such a piece comes to the attention of a foreman by chance, and after proper seasoning and finishing operations is given a place befitting its value. After a time, the mill owners realize they are losing a valuable part of their output, and provide for proper finishing of their hardwood as it passes through. It is thereafter turned out in such shape that it can be seasoned and finished for the more important uses to which it is adapted. This makes it possible for the lumber company to take the hardwood with the pine, thus clearing up the entire stand of available timber as it goes.

The available timber entering the universities and engineering schools has many things in common with the stand of timber described in the foregoing illustration.

If technical experts are to be the chief output of the schools the timber which doesn't make good ones will be and is being eliminated as it goes through. And if perchance a few exceptional men get through who are capable of being more than technicians, they are as likely as not to become buried in the technical work so deeply that the fact that they are capable of greater responsibilities is not discovered until a long time after it should have been known.

The establishment of a course designed for treating the hardwood, that is, the men who do not aim to take positions where the work is highly technical, will perhaps not result in any output of men of any higher average ability than are graduated from other courses, but it should serve to increase the available supply of timber for general uses, for which there is now a firm demand with a diminishing supply.

Discussion

Exciter Instability

BY R. E. DOHERTY
Associate, A. I. E. E.
Engineer, General Electric Co., Schenectady, N. Y.

PART I—DISCUSSION OF THE PROBLEM

A. Introductory

Instability of an exciter has come to have a number of meanings: (1) large change in voltage for a small change in load; (2) creeping of voltage, up or down, without apparent cause; (3) temporary removal, partial or total, or even reversal of the excitation accompanying sudden short circuit of the alternator; (4) slow oscillation, or possibly reversal, of excitation following a sudden readjustment of either the shunt field or alternator field rheostat;[1] (5) "grabbing" the load, etc. when in parallel with other exciters. The last mentioned trouble, which is experienced largely, although not altogether, on compound-wound machines does not occur if respect is given to well-known characteristics of direct-current machines as discussed in any text book on the subject. Therefore this paper deals only with the first four phenomena mentioned above.

Experience. All these phenomena have occurred in actual practise. While they have been relatively rare and not confined to exciters of any particular manufacture, there have been enough cases where the consequences have been serious, such as the shut-down of large generating units, to warrant investigation into the causes and character of the phenomena.

Experience has shown that these phenomena occur when the exciter is operating at low magnetic densities; that is, below or near the bend in the saturation curve as at e or below, in Fig. 1.

Historical. In 1920 a number of Institute papers[2] were read on exciters and excitation systems. These papers were largely statements of experience and of opinions as to the factors which should predominate in the selection of an excitation system. One of them[3] however, dealt fully with certain phases of exciter design, particularly with reference to successful operation with automatic voltage regulators. In the same year a paper by Kelen[4] discussed the reversal and loss of residual magnetism of exciters, giving equations which showed voltage reversal, under a certain assumed current transient. However, it appears that there has not been a comprehensive mathematical study of the particular system of circuits involved in this problem to determine the behavior of the exciter under conditions which may arise in practise.

Scope. The present investigation comprises (a) a mathematical study of circuits involved, as shown in Fig. 2, assuming the exciter is operating within the range of the straight portion of the saturation curve; and (b) an experimental confirmation of the calculated results. From these two viewpoints it is possible to draw definite conclusions as to the influence upon stability, of the different design features of the exciter and alternator and of the circuits involved.

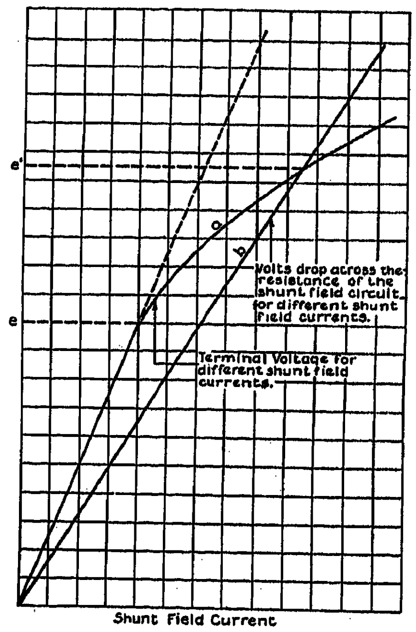

Fig. 1

B. Form of Equation

The most interesting and fundamental result of the investigation is the fact that the differential equation relating the alternator field current with time, is identical in form with the classic differential equation of the electric circuit involving resistance, inductance and capacity. Thus in the present case the equation relating the alternator field current with time is,

$$\frac{d^2 i_2}{d t^2} + \alpha \frac{d i_2}{d t} + \beta i_2 = A \text{ (amperes/sec.}^2\text{)} \quad (7)$$

Presented at the Pacific Coast Convention of the A. I. E. E., Vancouver, B. C., August 8-11, 1922.

2. These are given in the accompanying bibliography.

3. "Application of D-C. Generators to Exciter Service," by C. A. Boddie and F. L. Moon, from A. I. E. E. Journal, Vol. 39, 1920, pp. 1595-1616.

4. Elektrotechnik und Maschinenbau, May 16, 1920, V. 38, pp. 225-226.

where

i_2 = alternator field current

t = time

α and β = constants depending upon circuit constants as defined by equations (8) and (9)

A = constant depending upon the *sustained* value of exciter voltage as defined by equation (10).

The classic equation of the electric circuit involving resistance, inductance and capacity is

$$\frac{d^2 i}{d t^2} + \alpha_c \frac{d i}{d t} + \beta_c = A_c \quad \text{(amperes/sec.}^2\text{)}$$

where i = current in the circuit

t = time

α_c = constant $= r/L$

β_c = constant $= \dfrac{1}{LC}$

A_c = constant $= E/L$

r, L and C = circuit constants

E = constant rate at which the impressed voltage increases.[5]

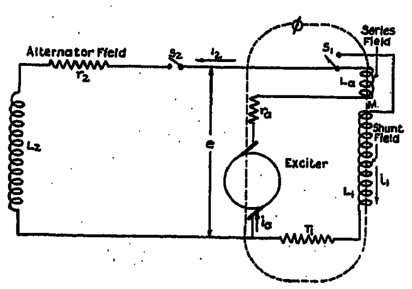

Fig. 2

Since the equations in the two cases are identical, there must, of course, be found in the solution of the former the same oscillations and transients as are given in the well known solution of the latter. That is, the present case falls in the category of transients designated by Steinmetz as "double energy" transients.[6] In other words, if on the one hand an exciter is closed upon an alternator field circuit, and on the other hand, a voltage which increases in direct proportion to time is suddenly impressed upon a circuit containing resistance, inductance and capacity, then one may expect the current as related to time to be of precisely the same form in either case. Depending upon the relation of circuit constants the current may gradually build up to a final value, or may finally reach this value after a number of progressively smaller oscillations.

Transients of the same character will also occur if a sudden readjustment of circuit constants is made, which is equivalent to suddenly impressing a different voltage. Thus Fig. 6 shows a transient oscillation following the application of the exciter voltage to an alternator field circuit; Fig. 14, the oscillation following a sudden readjustment (increase in resistance) of shunt field rheostat; Fig. 16, the gradual (logarithmic) decrease of current to a final value following a similar sudden increase in shunt field rheostat, but with different circuit constants; Fig. 9, the surge and decay of current following a sudden short circuit of the alternator, which, as explained in Part II, is equivalent to a sudden change in circuit constants.

It will be observed that while these transients are of the same form as those of the electric circuit containing resistance, inductance and capacity, they are of much longer duration and lower frequency.

C. Conditions for Instability

Conditions of instabilty are; low magnetic densities,[7] in combination with one or more of the following:

(a) low residual voltage.

(b) relatively large voltage drop in the armature, due either to large demagnetizing component of armature reaction or to large ohmic resistance in the armature circuit between the points where the shunt field terminals are connected.

(c) relatively large inductance in the load circuit, such as always exists in the alternator field.

(d) alternator transient of greater duration than exciter transient.

(e) excessive series field strength.

Discussion of Conditions. Consider the conditions of low magnetic densities. It is well known that a saturated exciter is usually stable since it requires a relatively large change in ampere turns to produce a given change in the magnetic flux. The degree of stability is roughly gauged by the magnitude of the angle θ, Fig. 3. The operating point p on the saturation curve is determined by the condition that the $r\,i$ drop of the shunt field circuit shall equal the terminal voltage of the exciter. Above that point, the terminal voltage is less than that required to sustain the shunt field current; below, it is more than required. That is, the greater the angle θ the more stable the exciter. It is thus obvious from Fig. 3 that on the straight portion of the saturation curve, the stability

5. That is, $e = E\,t$. This merely determines the final value of current, and has nothing to do with the character of the transient, since the transient is determined by making $A_c = 0$. It was so chosen in this illustration to make the two cases exactly parallel, including both the transient and the final value.

6. In the circuit containing r, L and C, the "double energy" refers to the two forms of energy storage $1/2\,L\,I^2$ and $1/2\,C\,E^2$.

In the present case, while there is no condenser capacity involved, and therefore no electrostatic energy, there are nevertheless two different magnetic circuits—alternator and exciter fields—in which energy can be stored. Obviously, in an oscillation all of the relatively large energy in the alternator field cannot be transferred to the small exciter field. Most of it is dissipated as $i^2\,r$. Only a small percentage is transferred to the exciter, but it is sufficient to start the exciter to build up again, the energy supplying the subsequent oscillations thus coming from the mechanical drive of the exciter.

7. That is, operation on straight portion of the saturation curve.

is low; and if it were not for the residual voltage e_0, θ would be zero and the exciter would be inoperative; that is, a single value of shunt field resistance would correspond to *all* voltages on the straight portion of the curve.

Thus it follows that residual voltage is essential to stability in operation on the straight portion of the curve. However, operation beyond the bend, that is involving a significant degree of saturation, would be stable with zero residual voltage.

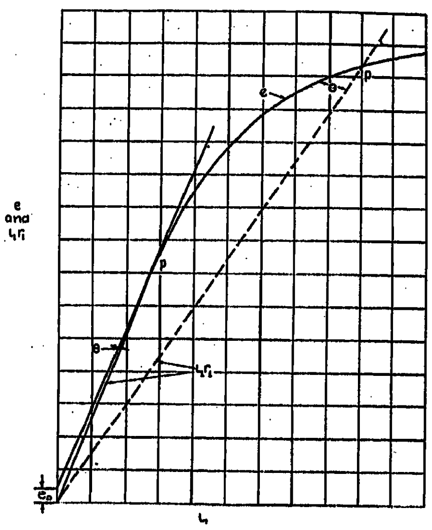

Fig. 3

The condition of large voltage drop in the armature means a large droop in the volt-ampere characteristic of the exciter, Fig. 4. Curves a and b are volt-ampere characteristics of the particular exciter used in this investigation; a being for normal brush position, b for a forward shift of 2.7 mechanical degrees. Curve c is the volt-ampere characteristic of the receiving circuit, that is, it gives the voltage required to maintain the current i_2 in the resistance r_2 of the receiving circuit, which in the present problem is the alternator field circuit. The exciter must obviously operate at the intersection of the volt-ampere characteristics of the exciter and receiving circuit. The unstable condition of relatively large voltage drop in the armature is thus illustrated in Fig. 4 by the intersection of b and c, that is the point n. Stability could evidently be obtained by increasing r_2, which would increase the slope of c, moving n upward to a less steep portion of curve b; or, with the same r_2, a change in the exciter characteristic to correspond to a, thus giving the stable intersection m.[8]

The existence of a large inductance in the load circuit, which means relatively large magnetic energy storage is the fundamental condition for the occurrence of "double energy" transients as distinguished from slow "creeping" of voltage. This energy storage makes possible a "pump back" of power into the exciter under certain conditions. For instance, any sudden condition which tends to lower the exciter voltage—such as the large load current thrown on the exciter when the alternator is short-circuited, or a sudden increase in the shunt field rheostat, or a decrease in the alternator field rheostat—such conditions cause the load current of the exciter to decrease. But the large inductance in the alternator field will not permit the current to decrease as rapidly as it would if its decrease were determined by the exciter alone. Thus under certain conditions the alternator field tends to hold the decreasing load on the exciter always at a higher value than the decreasing voltage of the exciter could alone maintain, and when zero magnetic flux in the exciter is reached, the current is maintained through the armature by the external voltage generated by the alternator field. This means that the voltage across the armature and therefore across the shunt field is reversed, and thus the voltage builds up reversed. While it is reversed, and before the decreasing current reaches zero, the alternator field is obviously supplying power to the exciter. After reversal the alternator field inductance holds the current always at a *lower* value than would exist by the exciter voltage alone. Therefore such a condition makes it impossible, theoretically, for the exciter to ever reach equilibrium. Actually, of course, it is reached after a few oscillations, as shown in Fig. 7.

The condition under which this reversal may occur is that the duration of the alternator transient is greater than that of the exciter. It is thus a race between these two transients. Obviously if the alternator tends to reach equilibrium before the exciter, its influence in holding up the load on the exciter will have disappeared before the exciter voltage reaches zero, and the exciter, once more on its own resources, if only for a moment, will again build up. Thus the inductance of the alternator field makes possible oscillations and voltage reversals; and the condition under which this is possible is that the duration of the alternator transient is greater than that of the exciter.

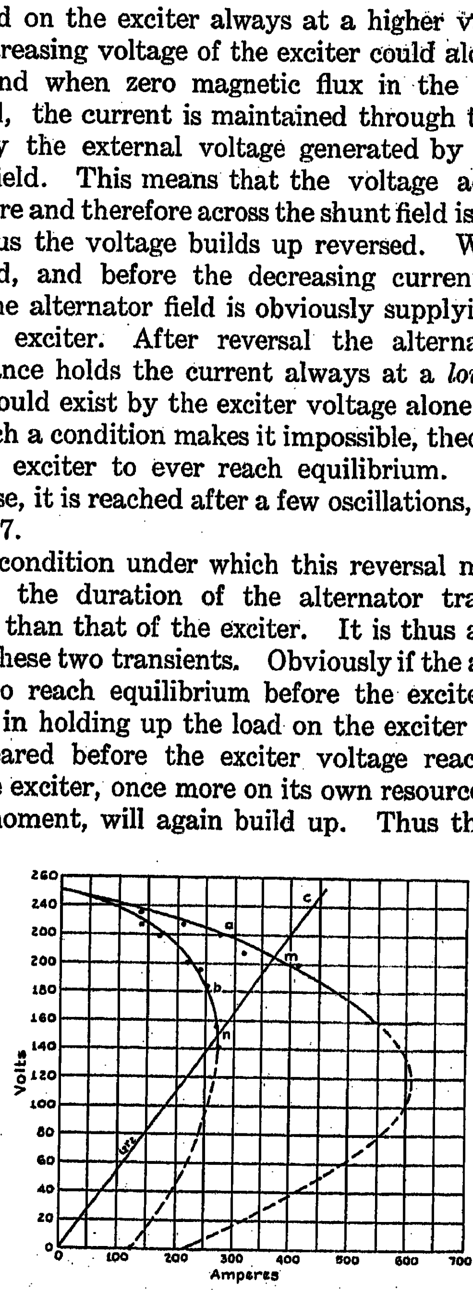

Fig. 4

Excessive series field strength obviously gives to the exciter characteristics approaching those of the series generator. Such characteristics may be obtained as

8. This, of course, is merely reciting, in the interest of completeness, a fact already given in text books.

well by connecting a normally designed exciter on a receiving circuit of too low resistance, as by designing for too great series field strength. For instance, a 125-volt exciter connected to an alternator field requiring only 60 volts for normal exciting current, (rated current on exciter) means practically doubling the relative strength of the series field; and quadrupling the strength, assuming the same kilowatts excitation.

D. Causes of Instability

The principal causes are:

(a) speed transients

(b) temperature transients

(c) slight undulations in exciter voltage, which may modify the local effect of hysteresis and thus cause a gradual shift in the saturation curve and a corresponding change in voltage.

(d) sudden, relatively large change in rheostat setting.

(e) short circuit of the alternator.

Discussion of Causes. The first three causes may produce voltage "creeping," the last two "double energy" transients. The effect of speed transients, which is to shift the operating point p Fig. 3 on the saturation curve, is discussed in the paper by Boddie and Moon, loc. cit.

Temperature transients produce slow voltage changes in a similar manner. Rising temperature, and therefore increasing resistance, in the shunt field circuit slowly increases the slope of the $i_1 r_1$ line Fig. 3, but does not change the saturation curve. It thus shifts the point p downward.

Slight undulations in the exciter voltage[9] mean repeated traversal of the local hysteresis loop, which, by this process, moves the center of the loop gradually toward the *average* saturation curve, thus in effect eliminating or seriously reducing the residual magnetism. The result is a large downward shift in the operating point p.

A sudden change in rheostat setting of either the shunt or alternator field circuit, is equivalent to suddenly impressing a different voltage, and therefore under conditions discussed in the foregoing, may cause oscillation and reversal of the excitation. This may easily occur on hand controlled exciters if the resistance steps in the shunt field rheostat are too large, or if the operator suddenly makes too large an adjustment.

Short circuit, or a sudden large increase in inductive load on the alternator, induces an increase in the direct current[10] through the exciter armature—that is, an increase in load, the greater the current increase in the alternator armature. This initiates the "double energy" transients already discussed.

9. This might be caused by speed variations as on direct-connected or belted exciters driven by reciprocating machines such as steam or gas engines, or compressors.

10. There is also an alternating component, but its frequency is too high to significantly affect the exciter flux.

E. Stabilizers

Voltage "creeping" can be minimized by special design to increase the angle θ Fig. 3 at low voltages. The same result can be obtained by a few cells of a storage battery in series with the shunt field, thus giving the effect of greater residual voltage, e_0, Fig. 3. Separate excitation of the shunt field by storage battery gives practically perfect stability, but of course involves obvious disadvantages.

The most effective stabilizer against shocks due to alternator short circuits, or sudden change in circuit constants, is the series field. By minimizing the voltage drop of the exciter, that is the drop in voltage impressed across the shunt field terminals, and therefore also minimizing the tendency toward a further reduction of exciter magnetic flux, the foremost factor in causing removal or reversal of excitation is practically eliminated. The influence of the series field in these cases is illustrated by Figs. 9 and 10, showing respectively the excitation following a sudden short circuit of the alternator, first without series field, then with series field. Figs. 14 and 16 show the excitation following a change in the setting of the shunt field rheostat, first without series field, then with. That is, a properly designed series field appears to be the greatest protection against instability following shocks, particularly against a serious decrease of excitation, and therefore of synchronizing power of large generating units under short-circuit conditions.

The next is the automatic voltage regulator. Its effect is to instantly decrease the shunt field resistance, that is, to greatly decrease the slope of $i_1 r_1$ Fig. 3, thus adjusting the exciter instantly for a greater load. In other words, when an exciter transient starts, the regulator instantly introduces a rapid transient in the opposite direction, and therefore stabilizes the exciter under most conditions arising in practise. Its influence on the exciter following a short circuit of the alternator is shown in Fig. 13. The combination, therefore, of a properly designed compound wound exciter controlled by an automatic voltage regulator, gives excellent stability.

Resistance in the alternator field circuit increases stability by shortening the alternator transient and lengthening the exciter transient[11], thus doubly increasing the ratio of the durations of these transients. If sufficient resistance is put in the alternator field circuit, the exciter voltage may reach values above the bend of the saturation curve, and so further increase the stability by saturation. Figs. 9 and 11 show respectively the transient following a short circuit on the alternator, first without and then with a rheostat in the alternator field circuit.

F. Summary

1. The form of equation for exciter voltage and current is the same as the well known equation for the

11. By causing the exciter to operate at a higher voltage, thus requiring lower resistance in the shunt field circuit.

electric circuit containing resistance, inductance and capacity. Hence the same form of oscillations and transients are involved, the only difference being that in the present case the duration of the transients is much longer.

2. Instability may occur when the exciter is operating on the straight part of the saturation curve, if in addition some combination of the following conditions exists:

(a) very low residual voltage—say 1 per cent or so.

(b) a relatively large voltage drop in the armature.

(c) large inductance in the load circuit, as always exists in the alternator field.

(d) alternator transient of greater duration than the exciter transient.

(e) excessive series field strength.

3. Instability may be classed, for convenience, under two headings: (a) voltage "creeping," and (b) "double energy" transients. The former may be caused by slight speed transients of the exciter; or by temperature transients causing corresponding resistance transients in the shunt field circuit; or by hysteresis effects which may be caused by small undulations in the exciter voltage. The "double energy" transients, such as oscillations and reversal of excitation, may be initiated by a shock, such as a short circuit on the alternator, or sudden, relatively large change circuit in constants, for instance a large change in resistance in the shunt field circuit.

4. The exciter can be stabilized against voltage "creeping," (a) by special design to increase the angle θ Fig. 3 at low voltage; (b) by a few battery cells connected in series with the shunt field, thus giving the effect of greater residual voltage e_0 Fig. 3; (c) by separately exciting the shunt field; (d) by automatic voltage regulator; or (e) by rheostat in the alternator field, requiring the exciter to operate at voltages involving saturation. It can be stabilized against "double energy" transients (a) by a properly designed series field; (b) automatic voltage regulator, or both (a) and (b); (c) alternator field rheostat.

The author wishes to acknowledge the valuable assistance of Mr. R. F. Franklin in the preparation of this paper.

PART II—EQUATIONS AND TESTS

A. Mathematical Analysis

Equation for Alternator Field Current. The following assumptions are made:

Constant speed of exciter

Operation below bend of saturation curve

Residual voltage, constant

Resistance of armature circuit, constant.

Fig. 2 shows the arrangement of circuits and defines the different currents, voltages and circuit constants.[12] The differential equations for the voltage in the different circuits are as follows:

Alternator field circuit,

$$e = i_2 r_2 + L_2 \frac{d\, i_2}{d\, t} \qquad \text{(volts)} \qquad (1)$$

Exciter shunt field circuit,

$$e = i_1 r_1 + L_1 \frac{d\, i_1}{d\, t} + M \frac{d\, i_a}{d\, t} \qquad \text{(volts)} \qquad (2)$$

Exciter armature circuit,

$$e = e_a - i_a r_a - M \frac{d\, i_1}{d\, t} - L_a \frac{d\, i_a}{d\, t} \qquad \text{(volts)} \qquad (3)$$

Also,

$$i_a = i_1 + i_2 \qquad \text{(amperes)} \qquad (4)$$

where,

e_a = generated voltage of exciter

r_a = ohmic resistance of exciter armature circuit[13] including series and interpole fields, if any.

Assuming that the exciter is working at low magnetic densities, *i. e.*, on the straight part of the saturation curve, the equation for the generated voltage is,

$$e_a = e_0 + K\,\phi \qquad \text{(volts)} \qquad (5)$$

where,

ϕ = flux per pole in magalines

K = total generated armature volts per megaline of flux per pole.

e_0 = residual voltage.

The flux ϕ is a function of both the shunt field current and the armature current. Thus,

$$\phi = k_1 i_1 + k_a i_a \qquad \text{(megalines)} \qquad (6)$$

where,

k_1 = megalines per pole per shunt field ampere

k_a = megalines per pole per ampere in the armature circuit. It is thus the net result of the armature, interpole and series field magnetomotive forces, and may therefore be either positive or negative. It is positive if magnetizing, *i. e.*, if it adds to the shunt field flux; and negative if demagnetizing.

Solving the above simultaneous equations for the relation between i_2 and t, the following well known differential equation is obtained:

$$\frac{d^2 i_2}{d\, t^2} + \alpha \frac{d\, i_2}{d\, t} + \beta\, i_2 = A \qquad \text{(amperes/sec.}^2\text{)} \qquad (7)$$

where,

$$\alpha = \frac{r_2 (L_a + M) + r_1 (L_a + L_2) + [r_a - K (k_1 + k_a)] (L_2 - M) - [K k_a - (r_a + r_2)] (L_1 + M)}{(L_2 - M)(L_a + M) + (L_1 + M)(L_a + L_2)} \qquad \text{(1/sec.}^2\text{)} \qquad (8)$$

$$\beta = \frac{- K (k_1 r_2 + k_a r_2 + k_a r_1) + r_a r_2 + r_1 r_a + r_1 r_2}{(L_2 - M)(L_a + M) + (L_1 + M)(L_a + L_2)} \qquad \text{(1/sec.}^2\text{)} \qquad (9)$$

12. For detailed definition see "notation."

13. Armature circuit up to the points where the shunt field terminals are connected.

$$A = \frac{e_0 r_1}{(L_2 - M)(L_a + M) + (L_1 + M)(L_a + L_2)} \quad \text{(amperes/sec.}^2\text{)} \quad (10)$$

Equation (7) is a second order, linear differential equation whose solution, as given in all texts on differential equations, is,

$$i_2 = C_1 \epsilon^{m_1 t} + C_2 \epsilon^{m_2 t} + A/\beta \quad \text{(amperes)} \quad (11)$$

where, C_1 and C_2 are integration constants, and

$$m_1 = -\alpha/2 + \sqrt{\alpha^2/4 - \beta} \quad \text{(1/sec.)} \quad (12)$$

$$m_2 = -\alpha/2 - \sqrt{\alpha^2/4 - \beta} \quad \text{(1/sec.)} \quad (13)$$

Let,

$$\gamma = \sqrt{\alpha^2/4 - \beta} \quad \text{(1/sec.)} \quad (14)$$

and,

$$i_0 = A/\beta = \frac{e_0}{(r_2 + r_a) + r_2/r_1\,[r_a - K(k_1 + k_a)] - K k_a} \quad \text{(amperes)} \quad (15)$$

Substituting these relations in (11) the final equation for the alternator field current becomes,

$$i_2 = \epsilon^{-\frac{\alpha}{2}t} (C_1 \epsilon^{\gamma t} + C_2 \epsilon^{-\gamma t}) + i_0 \quad \text{(amperes)} \quad (16)$$

Integration Constants

The integration constants C_1 and C_2 will be determined for four different boundary conditions.

Case I. Switches S_1 and S_2, Fig. 2, are closed at the same instant.

Thus at $t = 0$, $i_1 = 0$, $i_2 = 0$, $e = e_0$.

Hence from (16)

$$C_1 + C_2 + i_0 = 0. \quad \text{(amperes)} \quad (17)$$

Another relation between C_1 and C_2 is necessary. This is given by equation (1). Since at $t = 0$, $i_2 = 0$.

$$\frac{d\,i_2}{d\,t} = e_0/L_2 \quad \text{(amperes/sec.)} \quad (18)$$

Differentiating (16) and substituting $t = 0$,

$$\frac{d\,i_2}{d\,t} = m_1 C_1 + m_2 C_2 \quad \text{(amperes/sec.)} \quad (19)$$

Equating (18) and (19)

$$m_1 C_1 + m_2 C_2 = \frac{e_0}{L_2} \quad \text{(amperes/sec).} \quad (20)$$

Solving (17) and (20) for C_1 and C_2, and substituting (12), (13) and (14)

$$\left.\begin{aligned} C_1 &= \frac{e_0/L_2 - i_0(\gamma + \alpha/2)}{2\gamma} \\ C_2 &= -\frac{e_0/L_2 + i_0(\gamma - \alpha/2)}{2\gamma} \end{aligned}\right\} \quad \text{(amperes)} \quad (21)$$

Case II. After switch S_1 has been closed and the exciter voltage has built up to its permanent value, close S_2, Fig. 2.

Thus at $t = 0$, $i_2 = 0$, $e = e'$ where e' is the exciter terminal voltage previous to closing S_2. Hence from (16)

$$C_1 + C_2 + i_0 = 0 \quad \text{(amperes)} \quad (22)$$

and from (1)

$$\frac{d\,i_2}{d\,t} = e'/L_2 \quad \text{(amperes/sec.)} \quad (23)$$

Since (22) and (23) are identical in form with (17) and (18), the integration constants for Case II are, by analogy with (21),

$$\left.\begin{aligned} C_1 &= \frac{e'/L_2 - i_0(\gamma + \alpha/2)}{2\gamma} \\ C_2 &= -\frac{e'/L_2 + i_0(\gamma - \alpha/2)}{2\gamma} \end{aligned}\right\} \quad \text{(amperes)} \quad (24)$$

Case III. Switches S_1 and S_2 have been closed and the currents i_1 and i_2 have reached the permanent values i_{11} and i_0 respectively. Short circuit occurs on alternator.

In this case the boundary values are taken as those existing the instant after the alternator short circuit and are determined by the condition that neither the magnetic interlinkages with the alternator field winding nor that with the shunt field circuit can change, in the first instant, from the values existing before the short circuit occurred. That is, the alternator field flux which, before short circuit traversed the low-reluctance path through the armature iron, inductance L_2, must now pass through the higher reluctance of the leakage paths, inductance L_2', between field and armature windings. But since the magnetic interlinkages of this circuit[14] has not changed.

$$L_2 i_0 = L_2' i_2'$$

where

$$i_2' = L_2/L_2'\, i_0 \quad \text{(amperes)} \quad (25)$$

There is also, of course, a large alternating component of current through the exciter armature, but its effect on the exciter is practically negligible, since the frequency is so high. Likewise, since the flux ϕ[15] linked with the shunt field circuit has not changed, it is by (4), (6) and (25)

$$\Phi = \overbrace{k_1 i_{11} + k_a(i_{11} + i_0)}^{\text{before}} = \overbrace{k_1 i_{11}' + k_a(i_{11}' + i_2')}^{\text{after}} \quad \text{(magalines)} \quad (26)$$

From (25) and (26)

$$i_{11}' = i_{11} + i_0(1 - L_2/L_2')\,\frac{k_a}{k_1 + k_a} \quad \text{(amperes)} \quad (27)$$

Thus at $t = 0$, $i_2 = i_2'$, $i_1 = i_{11}'$

From (16)

$$C_1 + C_2 + i_0 = i_2' \quad \text{(amperes)} \quad (28)$$

Another relation is necessary. This is given as before, by

$$\frac{d\,i_2}{d\,t}$$

at $t = 0$. Substituting in (2) and (1) respectively equation (4) and the values of i_1 and i_2 at $t = 0$, as determined by (25) and (27), and equating, a relation

14. Equation (25) neglects the relatively small inductance L_a of the exciter armature circuit.

15. Strictly this should be magnetic interlinkages instead of *flux*, since the flux may increase due to partial interlinkages in the leakage paths. However, the approximation is justified in the present case, since the change in flux is relatively very small.

is obtained between $\frac{d\,i_1}{d\,t}$ and $\frac{d\,i_2}{d\,t}$. It is,

$$\frac{d\,i_1}{d\,t} = \frac{i_2\,r_2 - i_{11}'\,r_1}{L_1 + M} + \frac{L_2' - M}{L_1 + M}\,\frac{d\,i_2}{d\,t} \qquad \text{(amperes/sec.)} \quad (29)$$

Equating (1) and (3) and substituting (4), (5), (26) and (29),

$$\frac{d\,i_2}{d\,t} = G = \frac{e_0 + i_{11}'\,[K\,(k_1 + k_a) - r_a] + i_2'\,(K\,k_a - r_a - r_2) - \frac{L_a + M}{L_1 + M}\,(i_2'\,r_2 - i_{11}'\,r_1)}{(L_a + L_2') + \frac{L_a + M}{L_1 + M}\,(L_2' - M)} \qquad \text{(amperes/sec.)} \quad (30)$$

Thus from (11) and (30)

$$\frac{d\,i_2}{d\,t} = G = m_1\,C_1 + m_2\,C_2 \quad \text{(amperes/sec.)} \quad (31)$$

Solving (28) and (31) for C_1 and C_2, and substituting (12) and (13)

$$\left.\begin{aligned} C_1 &= \frac{G + (i_2' - i_0)\,(\gamma + \alpha/2)}{2\,\gamma} \\ C_2 &= -\,\frac{G - (i_2' - i_0)\,(\gamma - \alpha/2)}{2\,\gamma} \end{aligned}\right\} \quad \text{(amperes)} \quad (32)$$

In calculating α and β from (8) and (9), the value of leakage inductance L_2' should, of course, be used instead of the total inductance L_2.

Case IV. Switches s_1 and s_2 have been closed and i_1 and i_2 have reached the permanent values i_{11} and i_2'' respectively. The shunt field resistance r_1 is suddenly changed from $r_1{}^0$ to r_1'.

As in Case III, boundary values are taken as those existing the instant after r_1 is changed, and are determined by the condition that the magnetic interlinkages of shunt field and alternator field circuits must, for the moment, each remain the same. It is necessary to know i_2 and $\frac{d\,i_2}{d\,t}$ at $t = 0$.

$$i_2 = i_0 \quad \text{and} \quad \frac{d\,i_2}{d\,t} = 0.$$

The latter may not be obvious. In the first instant, that is at $t = 0$, the exciter flux ϕ has not changed. $\frac{d\,\phi}{d\,t}$ is not zero, but at $t = 0$ no appreciable change has occurred. Hence e has not changed, neglecting the insignificant voltage $M\,\frac{d\,i_1}{d\,t}$, and therefore i_2 has not changed.

From (1), $\frac{d\,i_2}{d\,t} = 0$. Therefore from (11) and (16) at $t = 0$,

$$C_1 + C_2 + i_0 = i_2'' \qquad \text{(amperes)} \quad (33)$$

$$\frac{d\,i_2}{dt} = m_1\,C_1 + m_2\,C_2 = 0 \quad \text{(amperes/sec.)} \quad (34)$$

Solving (33) and (34) for C_1 and C_2, and substituting (12), (13) and (14),

$$\left.\begin{aligned} C_1 &= \frac{(i_2'' - i_0)\,(\gamma + \alpha/2)}{2\,\gamma} \\ C_2 &= \frac{(i_2'' - i_0)\,(\gamma - \alpha/2)}{2\,\gamma} \end{aligned}\right\} \quad \text{(amperes)} \quad (35)$$

That is, the same as for Case III when $G = 0$. In calculating i_0 from equation (15), substitute r_1' for r_1; in calculating i_2'' from (15), substitute $r_1{}^0$ for r_1; and in calculating α and β from (8) and (9) respectively, the total inductance L_2 should be used, as in Cases I and II.

Consider the character of C_1, C_2, m_1 and m_2. These may be either real or imaginary since each contains γ, which may be either real or imaginary depending upon whether $\alpha^2/4$ is greater or less than β. As discussed in texts on differential equations, if the exponent γ is real the solution involves only logarithmic functions, if imaginary it involves a combination of logarithmic and trigonometric functions, *i. e.*, a decaying oscillation.

If γ is real, the form of (16) is satisfactory for numerical calculation. However, if it is imaginary it becomes necessary to rewrite (16) in a different form for calculation.

For the latter case, that is when

$$\alpha^2/4 < \beta$$

let $\gamma' = \sqrt{\beta - \alpha^2/4}$ (1/sec.) (36)

Then $\gamma = j\,\gamma'$ (1/sec.) (37)

The constants of integration in all four cases are of the form

$$\left.\begin{aligned} C_1 &= \frac{a - j\,b}{j\,c} \\ C_2 &= -\,\frac{a + j\,b}{j\,c} \end{aligned}\right\} \quad \text{(amperes)} \quad (38)$$

where in

Case I

$$\left.\begin{aligned} a &= e_0/L_2 - \alpha/2\,i_0 && \text{(amperes/sec.)} \\ b &= i_0\,\gamma' && \text{(amperes/sec.)} \\ c &= 2\,\gamma' && \text{(1/sec.)} \end{aligned}\right\} \quad (39)$$

Case II

$$\left.\begin{aligned} a &= e'/L_2 - \alpha/2\,i_0 && \text{(amperes/sec.)} \\ b &= i_0\,\gamma' && \text{(amperes/sec.)} \\ c &= 2\,\gamma' && \text{(1/sec.)} \end{aligned}\right\} \quad (40)$$

Case III

$$\left.\begin{aligned} a &= G + \alpha/2\,(i_2' - i_0) && \text{(amperes/sec.)} \\ b &= -\,\gamma'\,(i_2' - i_0) && \text{(amperes/sec.)} \\ c &= 2\,\gamma' && \text{(1/sec.)} \end{aligned}\right\} \quad (41)$$

Case IV

$$\left.\begin{aligned} a &= \alpha/2\,(i_2'' - i_0) && \text{(amperes/sec.)} \\ b &= -\gamma'\,(i_2'' - i_0) && \text{(amperes/sec.)} \\ c &= 2\,\gamma' && \text{(1/sec.)} \end{aligned}\right\} \qquad (42)$$

Thus in all four cases the equation for i_2 is by (16)

$$i_2 = \epsilon^{-\frac{\alpha}{2}t}\left[\frac{a - j\,b}{j\,c}\,\epsilon^{j\gamma' t} - \frac{a + j\,b}{j\,c}\,\epsilon^{-j\gamma' t}\right] + i_0 \qquad \text{(amperes)} \qquad (43)$$

But, by Euler's relation,

$$\left.\begin{aligned} \epsilon^{j\gamma' t} &= \cos\gamma' t + j\sin\gamma' t \\ \epsilon^{-j\gamma' t} &= \cos\gamma' t - j\sin\gamma' t \end{aligned}\right\} \qquad \text{(numerical)} \qquad (44)$$

Substituting (44) in (43),

$$i_2 = 2/c\;\epsilon^{-\frac{\alpha}{2}t}\,(a\sin\gamma' t - b\cos\gamma' t) + i_0 \qquad \text{(amperes)} \qquad (45)$$

or, simplifying,[16]

$$i_2 = \frac{2\sqrt{a^2 + b^2}}{c}\,\epsilon^{-\frac{\alpha}{2}t}\sin(\gamma' t + \theta) + i_0 \qquad \text{(amperes)} \qquad (46)$$

where $\theta = \arctan(-b/a)$ (radians)

Exciter Voltage

From equation (1)

$$e = i_2\,r_2 + L_2\,\frac{d\,i_2}{d\,t} \qquad \text{(volts)} \qquad (1)$$

As discussed in the foregoing, there are two cases to consider: (1) when γ is real, and (2) when γ is imaginary.

(1) when γ is real. Use equation (16).

Thus

$$i_2 = \epsilon^{-\frac{\alpha}{2}t}\,[C_1\,\epsilon^{\gamma t} + C_2\,\epsilon^{-\gamma t}] + i_0 \qquad \text{(amperes)} \qquad (16)$$

Differentiating (16),

$$\frac{d\,i_2}{d\,t} = \epsilon^{-\frac{\alpha}{2}t}\,[\,(\gamma - \alpha/2)\,C_1\,\epsilon^{\gamma t} - (\gamma + \alpha/2)\,C_2\,\epsilon^{-\gamma t}] \qquad \text{(amperes/sec.)}$$

Hence from (1)

$$e = \epsilon^{-\frac{\alpha}{2}t}\,[\,\{r_2 + L_2\,(\gamma - \alpha/2)\}\,C_1\,\epsilon^{\gamma t} + \{r_2 - L_2\,(\gamma + \alpha/2)\}\,C_2\,\epsilon^{-\gamma t}] + i_0\,r_2 \qquad \text{(volts)} \qquad (47)$$

C_1 and C_2 being determined by—

(21) for Case I.
(24) for Case II.
(32) for Case III.
(35) for Case IV.

(2) when γ is imaginary. Use equation (45).

Thus,

$$i_2 = 2/c\;\epsilon^{-\frac{\alpha}{2}t}\,(a\sin\gamma' t - b\cos\gamma' t) + i_0 \qquad \text{(amperes)} \qquad (45)$$

Differentiating (45),

$$\frac{d\,i_2}{dt} = \frac{\epsilon^{-\frac{\alpha}{2}t}}{c}\,[\,(2\,\gamma'\,b - \alpha\,a)\sin\gamma' t + (2\,\gamma'\,a + \alpha\,b)\cos\gamma' t] \qquad \text{(amperes/sec.)}$$

Hence, from (1)

$$e = \frac{\epsilon^{-\frac{\alpha}{2}t}}{c}\,[\,\{2\,r_2\,a + L_2\,(2\,\gamma'\,b - \alpha\,a)\}\sin\gamma' t - \{2\,r_2\,b - L_2\,(2\,\gamma'\,a + \alpha\,b)\}\cos\gamma' t] + i_0\,r_2 \qquad \text{(volts)} \qquad (48)$$

where a, b and c are determined by—

(39) for Case I.
(40) for Case II.
(41) for Case III.
(42) for Case IV.

B. Discussion of Assumptions

Fig. 2 shows the circuits considered. The equations therefore apply strictly to an individual exciter connected to an alternator field, and not to a number of exciters in parallel. However, if the exciters in parallel have the same characteristics, and operate at constant speed, as assumed, then the group can be considered as a single unit with constants as resultant of those of the several exciters; and the alternator field connected to the bus can be considered as a single circuit with resultant constants. Then the equations will apply.

However, the object of the equations is much less to calculate the behavior of exciters in service than to investigate and determine, once for all, the factors which cause unstable exciters and the factors which make them stable. Because, if an exciter is stable when operating as an individual unit under the shocks of alternator short-circuit and other conditions, here considered, it may be safely assumed that it will also be stable when in parallel with others.

Do not misunderstand. Load "grabbing," etc., due to lack of respect for fundamental characteristics of d-c. machines when making connections or adjustments of such machines in parallel, is not considered. It is not fair to blame the exciter for "grabbing" the load or reversing if thrown on the bus at too low or too high voltage, or if it is not properly "equalized." No one would blame an engine for running away if its governor were out of adjustment. This sort of "instability" is not considered, and in the other respects which are considered, an exciter which is stable as an individual unit can be regarded as stable also when in parallel.

The fact that the alternators operate in multiple does not significantly affect the behavior of the exciters under the conditions considered.

Constant speed is assumed. A change in speed will produce a transient in the voltage designated in Part I as "creeping." This transient may be determined from the equation by using the value of e_0 and k_1 corresponding to the new speed, and substituting the existing currents, etc., before the change as boundary conditions to determine integration constants. In this type of transient the voltage differences which

16. For plotting results (45) is perhaps the better form, because although it requires two curves to be plotted, there is no difficulty in keeping signs straight, as there may be if (46) is used.

sustain the transients are very small. In the other type *i. e.*, "double energy" transients, due to shock, such as alternator short circuit, the voltage differences involved in the transients are very large. Therefore in the latter case, any small variations in voltage due to slight speed change, being a small percentage of the large voltage difference involved, do not materially affect the results as calculated on the assumption of constant speed.

Operation on the "straight" part of the saturation curve, and a constant residual voltage are assumed. That is, the saturation curve is expressed by the linear equation (5). Actually, the curve, especially on small exciters, is neither absolutely straight at the lower densities nor does it have a constant intersection e_0 as residual voltage. Hysteresis determines both. However, the curve is *approximately* straight, and the residual *approximately* constant, sufficiently so to warrant the assumption—particularly, since the purpose is not to calculate magnitudes with great accuracy, but only to investigate the character of phenomena and the factors upon which they depend. Thus it will be observed that the tests in this respect compare well with the calculated results. If an oscillation is predicted, it occurs. Its frequency may be different, but it is an oscillation. Just so for logarithmic transients. But in the main, even magnitudes are close.

C. Calculations and Tests

Calculations and tests were made on a 25,000 kv-a. 25-cycle 300-rev. per min. alternator excited by a six-pole compound-wound, interpole, 150-kw., 1200-rev. per min., 250-volt, induction-motor-driven exciter.

Tests were made as far as possible under conditions of the four different "Cases"[17] for which integration constants were determined. Change of constants in each different Case[18] was also made with corresponding calculations and tests.

The data substituted in the equations for results to compare with tests, are calculated[19] from designs of the exciter and alternator.

Tests

Case I. Switches S_1 and S_2 closed at the same instant. See Fig. 2.

(a) Shunt exciter[20] with interpoles; brushes two bars (3.5 mechanical degrees) forward[21] *from the neutral position.*

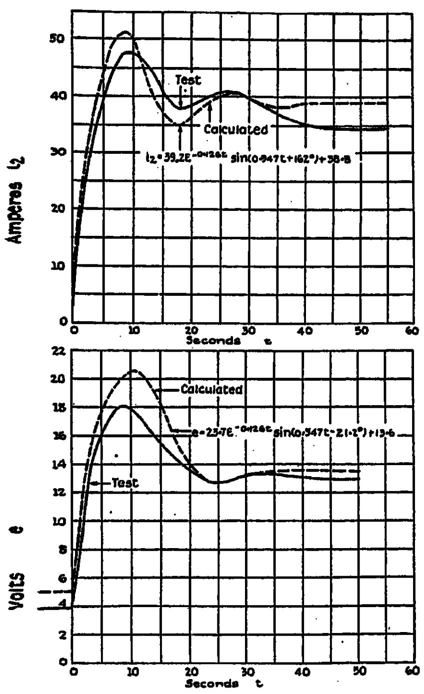

Fig. 5

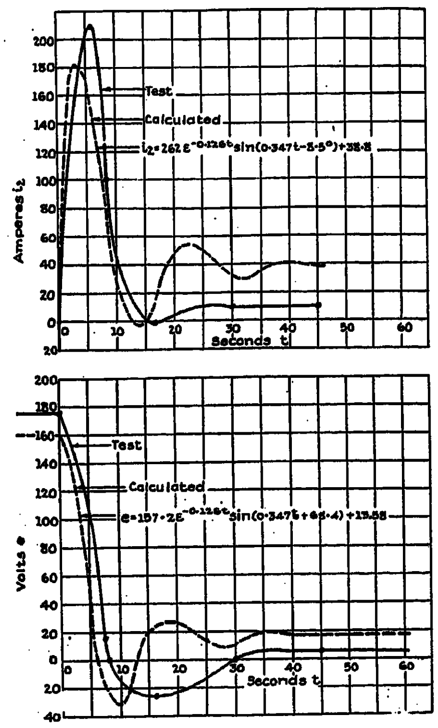

Fig. 6

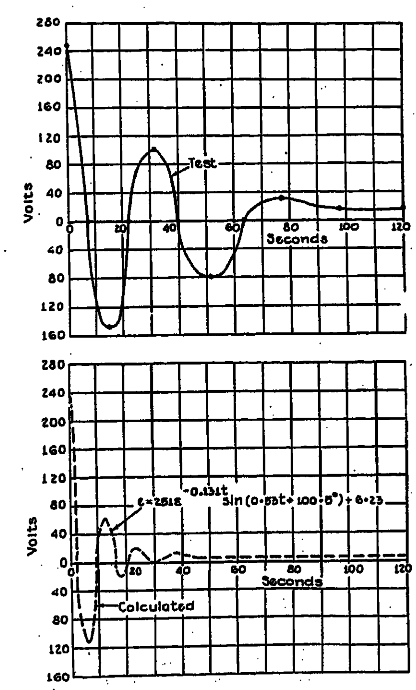

Fig. 7

Data:[22]

L_1 = 37.6
L_2 = 1.69
L_a = 0.000075
M = − 0.055
k_1 = 0.805
e_0 = 5
r_2 = 0.35
r_1 = 68.2
r_a = 0.015
K = 82.0
k_a = 0.00125

Fig. 5 shows the calculated and test results. With the above constants, γ is imaginary. Hence the cal-

17. Thus Case I, Case II, etc.
18. Case Ia, Case IIa, etc.
19. Except k_a, which was measured.
20. Series field omitted.
21. In direction of rotation.
22. For definition of symbols see "D. NOTATION."

culated curve for current was obtained from equations (39) and (46); voltage, from (39) and (48). The test curves are taken from oscillograph records.

Case II. After switch S_1 has been closed and the exciter has built up to permanent condition, S_2 is closed.

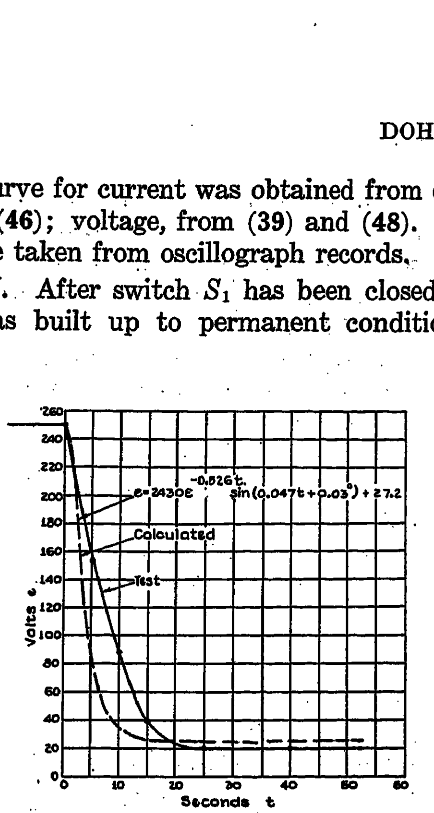

Fig. 8

(a) Shunt exciter with interpoles; brushes two bars forward from neutral.

Data: same as in Case I a.

Fig. 6 shows the results. The calculated curve for current was obtained from equations (40) and (46); for voltage, from (40) and (48). The tests curves were taken by stop watch and meter readings.

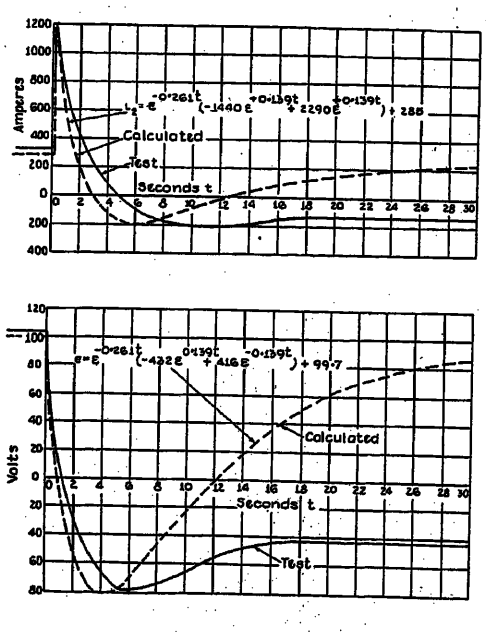

Fig. 9

It will be observed that the current and voltage actually pass through negative values before finally settling at positive values.

(b) Shunt exciter without interpoles; brushes 1/2 bar forward.

Data: Same as in Case Ia, except:

$$k_a = -\ 0.00317$$
$$r_1 = \ 67.3$$
$$M = -\ 0.142$$
$$r_a = \ 0.013$$

Fig. 7 shows voltage transient. The calculated curve was obtained from equations (40) and (48). The test curve was taken by stop watch and meter readings.

It will be observed, as in Case IIa, the voltage passes through negative values before finally settling at positive values. The lower frequency of the test curve as compared to the calculated curve is probably due to slowing up of the transient by hysteresis as explained under "B. Discussion of Assumptions."

(c) Shunt exciter without interpoles; brushes 1/2 bar forward: 1.35 ohms external resistance in the alternator field circuit.

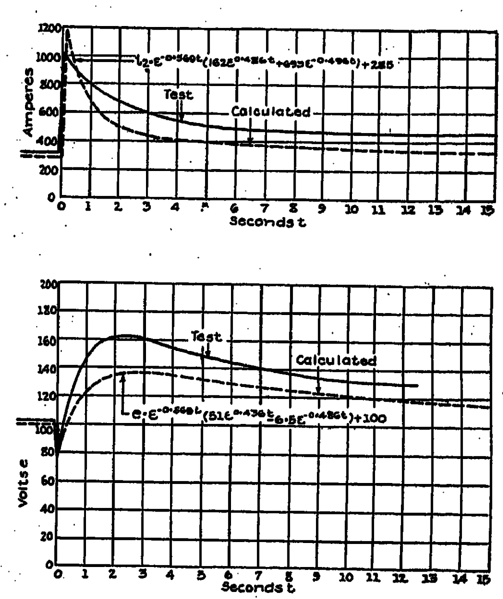

Fig. 10

Data: Same as Case IIb, except, $r_2 = 1.70$.

The voltage transient is given in Fig. 8. The calculated curve was obtained from equations (40) and (48). The test curve was taken by stop watch and meter readings.

In contrast with Case IIb, it will be observed that the voltage does not oscillate and pass through negative values in going from the one condition to the other. The large increase in alternator field resistance r_2 sufficiently increases the relative magnitude of α with respect to β (see equations (8) and (9)) to make

$$\gamma = \sqrt{\alpha^1/4 - \beta} \text{ real.}$$

Case III. Switches S_1 and S_2 have been closed and currents i_1 and i_2 have reached their permanent values. Alternator suddenly short-circuited.

(a) Shunt exciter with interpoles: brushes two bars forward.

Data: Same as Case Ia except:

$$r_1 = 51.2$$
$$L_2 = L_2' = 0.42$$

Fig. 9 shows the calculated and test results. With the above constants γ is real. Hence the calculated curve for current was obtained from equations (**32**)

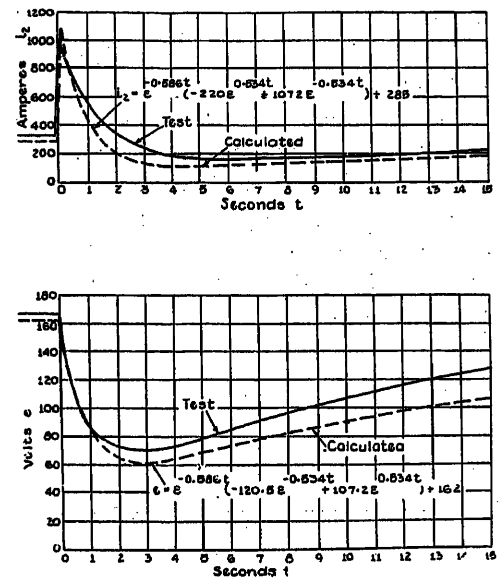

Fig. 11

and (**16**); voltage, from (**32**) and (**47**). The test curves are taken from oscillograph records.

The calculated curves both pass from positive to negative values and return again to positive, whereas the test curves, although following the calculated

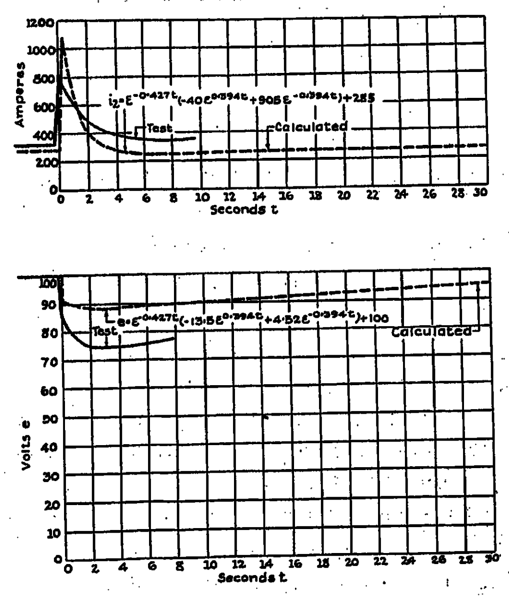

Fig. 12

reasonably close to the maximum negative value, nevertheless do not return to positive values but remain negative. This is explained by the fact that the equation assumes the residual voltage e_0 to be constant and thus always positive. Hence the current and voltage must, by the equation always return to positive values Actually, however, the residual reverses when the voltage and current reverse and hence in this case the test curves remain negative.

If it appeared worth the trouble, the equation could be made to apply by step calculations. That is, a second set of boundary conditions could be taken as those existing at maximum negative *e*, *i. e.*, at $t = 4$ seconds, Fig. 9, and reversing the sign of e_0.

(b) Compound wound exciter with interpoles; brushes two bars forward.

Data: Same as in Case IIIa except:

$$k_a = +\ 0.00055$$
$$r_1 = 76.2$$
$$r_a = 0.016$$
$$M = +\ 0.0247$$

Calculated and test performance of the exciter is shown in Fig. 10. Thus comparing this with Fig. 9, the addition of the series field prevented decrease of

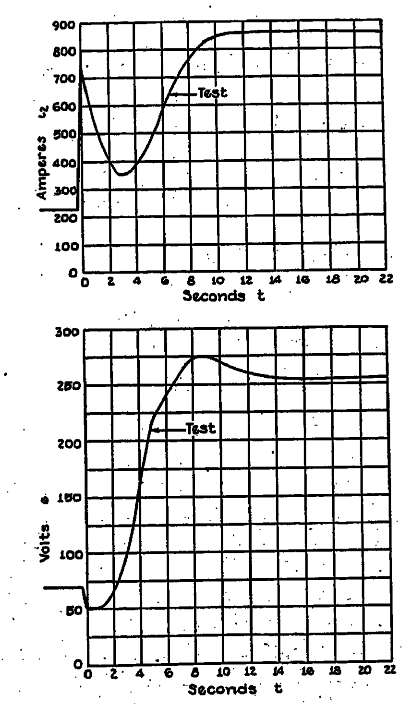

Fig. 13

excitation under the condition of sudden short-circuit of the alternator.

The calculations were made by the same equations as in Case IIIa, and the test curves were taken from oscillograph records.

(c) Shunt exciter with interpoles; brushes two bars forward; 0.22 ohms external resistance in alternator field circuit.

Data: Same as in Case Ia except:

$$r_2 = 0.57$$
$$L_2' = 0.42$$
$$r_1 = 56.0$$

Performance curves in Fig. 11. Calculations from same equations as in IIIa; test curves from oscillograph records.

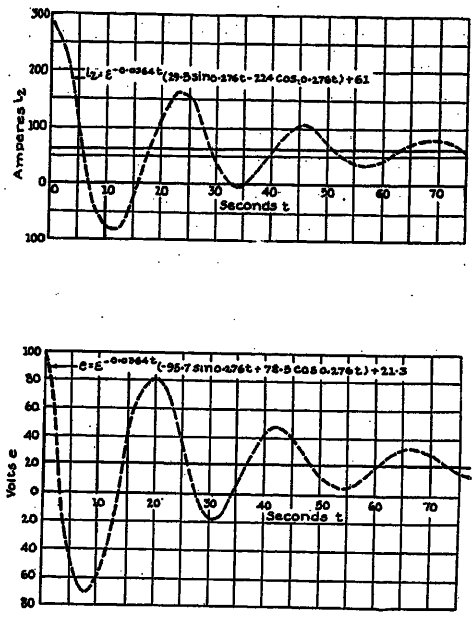

FIG. 14

The alternator field resistance prevented reversal, but permitted the exciting current to decrease to about half the value existing before short circuit.

(d) Shunt exciter with interpoles; brushes one-half bar forward; no external resistance in alternator field circuit.

Data: Same as in IIIa except:

$$L_2' = 0.42$$
$$k_a = 0.00012$$
$$M = -0.0055$$
$$e' = 100$$
$$r_1 = 64.5$$

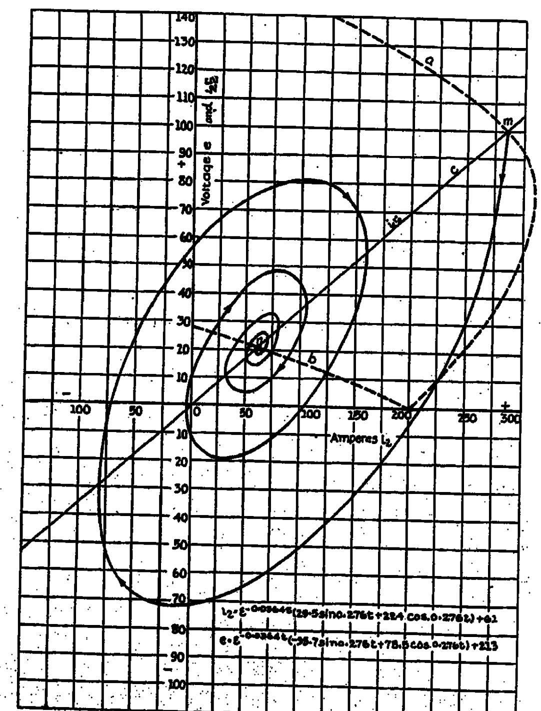

FIG. 15

Fig. 12 shows the exciter to be stable under this condition. That is, with only one-half bar forward shift of brushes from neutral, the droop in the volt-ampere characteristic, as shown in Fig. 4, is not sufficient to cause instability under the conditions of this test.

(e) Shunt exciter with interpoles; brushes two bars forward; automatic voltage regulator; low exciter voltage, to give the least favorable condition for the regulator operation.

No calculations made. Fig. 13 shows the exciter performance under test. The regulator thus prevented decrease in excitation following alternator short-circuit.

Case IV. Switches S_1 and S_2 have been closed and i_1 and i_2 have reached the permanent values i_{11} and i_2'' respectively. The shunt field resistance r_1 is suddenly changed from r_1^0 to r_1'.

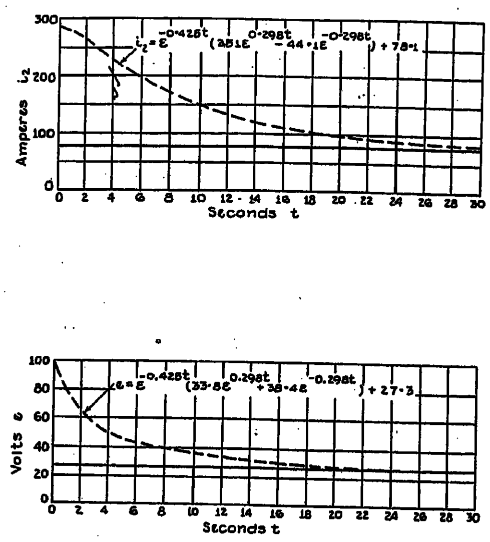

FIG. 16

(a) Shunt exciter with interpoles; brushes two bars forward.

Data: Same as in Case Ia except:

$$r_1 = r_1^0 = 51.2 \text{ before}$$
$$r_1 = r_1' = 60.0 \text{ after.}$$

Calculated curves are shown in Fig. 14. From the above data γ is imaginary. Hence equations (42) and (46) were applied for current; (42) and (48) for voltage. This condition gives very long, low-frequency oscillations, similar to Case Ia. Tests were made, and such oscillations were observed, but were not recorded.

These same calculations are plotted in different form in Fig. 15. Here, the exciter voltage is plotted against the current i_2, both being sine functions of time. This makes it possible to show the transient current and voltage in relation to the volt-ampere characteristics a and b of the exciter, and c of the receiving circuit, *i. e.*, alternator field. The volt-ampere characteristic a corresponds to

$$r_1 = r_1^0 = 51.2$$

and b, to

$$r_1 = r_1' = 60.0$$

The curve c corresponds to

$$r_2 = 0.35$$

Before the change the point of operation must be on a and c, thus at m; after, it must ultimately be on b and c, thus at n. The transition is shown by the spiral curve.

(b) compound wound exciter with interpoles; brushes two bars forward.

Data: Same as in Case Ia except:

$$M = + \quad 0.0247$$
$$r_1 = r_1^0 = 76.2 \text{ before}$$
$$r_1 = r_1' = 90.0 \text{ after}$$
$$r_a = \quad 0.016$$
$$k_a = + \quad 0.00055$$

Starting at the same values of exciter voltage and current as in IVa, but now with series field, of course requires higher voltage of r_1.

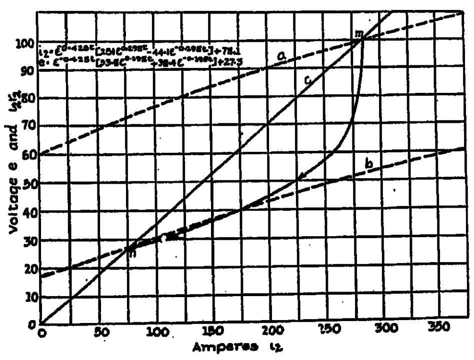

FIG. 17

From this data, γ is real. Hence apply equations (35) and (**16**) for current; (**35**) and (**47**) for voltage.

The result is shown in Fig. 16. Thus the series field eliminated the oscillation, giving a gradual decrease of excitation to the new permanent value. As in Case IVa, these data are also plotted in Fig. 17, showing the transient in relation to the volt-ampere characteristics. The curve shows a gradual decrease from the point m on a, to n on b, a and b being the volt-ampere characteristics of the exciter with the series field.

D. NOTATION

Discussion

W. A. Hillebrand: A rather startling instance of an oscillation such as Mr. Doherty has just described, came within my observation some three years ago. There was a two-pull electro magnet for a Paulson high-frequency arc converter, the magnet weighing approximately 30 tons, and they had only 5-kilowatts of arc converters at the station. Now the magnet itself was perhaps the most powerful that was ever delivered, and it was excited by a 250-kw., 500-volt d-c. generator, direct connected to a 2400-volt induction motor. Now what happened was that the power went off. The energy stored in the magnetic field was sufficient to stop the motor-generator set, reversing it. This reversal of rotation of the motor generator demagnetized the magnet, magnetizing it in the opposite direction, and again brought the set to rest. That is, there was a highly damped oscillation of very low frequency lasting for a cycle and a half. We ran saturation curves under various conditions, and finally after the last run the current was cut off, and I think some three or four minutes after the machine was completely disconnected, while we were stripping it, we still got an arc, showing the current was still flowing. That is, it took several minutes, due to the very slow decay before the current came to zero.

R. J. C. Wood: This question of exciter instability and the results shown in the paper seem to make a pretty good argument for the individual exciter direct connected on the generator shaft. That is a type of construction to which we are going with our latest large units. When the construction is in that form the exciter can be properly designed to meet the conditions of the generator, and so on, so it will not be working on the low portion of the saturation curve.

While it is not an illustration exactly of exciter instability, yet this calls to my mind the conditions that exist when there is a long transmission line connected to a generator and the generator becomes self-exciting due to the charge on the line. You then get an instability not because the exciter is unstable, but because the whole excitation of the machine is unstable. A certain definite voltage on the transmission line causes a charging current of a certain definite magnitude to flow, and that current leading the voltage excites the armature and the field exactly in an opposite direction to the ordinary demagnetizing effect of a lagging load, consequently if the voltage produced by this exciting current is greater than that necessary to produce the current which caused the excitation, the machine will build up until saturation of the iron causes a balance.

G. F. Brown: Mr. Wood raised the question of the saturation curve. Where a voltage regulator is used, and machines are operated as they are on these large transmission systems, they require a broad range of regulation. A considerable margin in voltage over your operating point of exciter voltage is required, which in general means that you must operate all these machines lower on the saturation curve.

There are some points in this paper on the question of application that bring out the point that more attention should be paid to the application of exciters. For instance, in large steam turbine stations in the east, where there are no extensive lines attached, the results indicate that we should use compound-wound machines. Perhaps I had better carry that a little further. On a system such as you are operating in the West, on long lines, a compound wound exciter has some disadvantages. For instance, the point Mr. Wood spoke of, under conditions of self-excitation it is difficult to carry the regulation of voltage down as low as you would like. In conditions of run-away, it is impossible with the series field on the exciter unless you have a lot of applications in the way of voltage relays and devices for switching resistance into the circuit. It would seem that the simplest application i. e. broad range regulators, shunt-wound exciters, would be preferable for such cases.

R. E. Doherty: I agree with Mr. Wood that for large, important generating units the individual exciter is preferable. There are, of course, the well known points of controversy as to whether a direct-connected exciter is preferable to one driven by other means; not with respect to stability of operation, but to freedom from shut-downs. But, whether direct connected or separately driven, the individual exciter is, in my opinion, preferable.

I agree also with Mr. Brown that there are instances, such as he mentions, where shunt-wound exciters may be preferable to compound-wound. It simply means that in such cases, other considerations, deemed more important, make it necessary to sacrifice the inherently stable feature possessed by the compound exciter.

Electrical Characteristics of Transmission Systems

BY HERBERT BRISTOL DWIGHT
Member, A. I. E. E.
Canadian Westinghouse Company, Ltd.

In making the electrical calculations for a long transmission line, it is desirable to include the effect of the step-up and step-down transformers and to make a direct calculation for the complete system, without any trial and error procedure. A method for doing this is described for constant-voltage lines, since long, high-power lines, especially those of 220,000 volts, usually require to be operated at constant voltage by means of synchronous condensers. The necessity of using the hyperbolic theory in calculating such lines is pointed out.

THE electrical characteristics of a simple transmission line of uniform design throughout are usually calculated from the resistance, reactance and capacitance of the line. However, the characteristics of the line alone are often not so useful to know as the characteristics of the complete system, including transformers and synchronous condensers, and sometimes with different types of conductors used on different parts of the line. Where synchronous condensers are used, it is usual to assume that they hold the voltage constant at certain points.

In this article is shown a method of calculating the characteristics of a constant-voltage transmission system, including the effect of the transformers, the distributed capacitance of the line, and changes in size and grouping of conductors.

It may be stated as a well-established fact that any transmission line long enough, and with a power load large enough to justify the adoption of 220,000 volts, will require to be operated as a constant-voltage transmission line, using synchronous condensers.

The adoption of 220,000 volts means increased cost of transformers, circuit breakers, line insulators, and towers which must be large enough to provide wide spacing between conductors. It will therefore, be economical to use such a high voltage only for a large block of power transmitted a long distance, and this is found to require a low resistance conductor of large size, approximating one inch in diameter. This large size of conductor is required also in order to avoid trouble from corona, though a large diameter for this purpose may be secured by the expedient of using a large steel core. Now, overhead conductors of very large size have several times as much reactance as resistance, so that the maximum load which may be carried by the line is determined by voltage variation and not by line loss. It is in such cases that synchronous condensers for holding the line voltage constant have been found to be most profitable.

It may also be stated that for any 220,000-volt transmission system, and, indeed, for much less important systems, it is necessary to take accurate account of the distributed capacitance according to the hyperbolic theory, in order to avoid serious errors in the calculated results.

This is very well shown by the transmission line problem given in Fig. 5 of F. G. Baum's paper on "Voltage Regulation and Insulation," JOURNAL of the A. I. E. E., August, 1921, page 648. Mr. Baum used an approximate method of calculation which was not based on the hyperbolic theory. As a result, he obtained a value of 124,000 kv-a. of synchronous condensers for a load of 104,000 kw. As a matter of fact, 82,000 kv-a. of synchronous condensers are required for the line in question at full load, which is the only condition considered in Mr. Baum's paper. Considering both no-load and full-load conditions, the required capacity to maintain constant voltage is 244,000 kv-a., or 235 per cent of the value of the load in kilowatts. There is also a considerable discrepancy in the calculated efficiency due to using the approximate method of calculation. The approximate method gives 71 per cent efficiency, but this should be 77 per cent, according to the data given.

It is doubtless true that synchronous condensers would be required at intervals in order to transmit power 800 miles at 220,000 volts, though possibly not at such close intervals as 150 miles. However, it is necessary to use the hyperbolic theory if even a rough estimate is to be made of the operation of the system or the amount of synchronous condensers required.

A very useful method of determining the size of conductor and the features of loading and controlling a constant-voltage transmission line, is to draw a circle diagram for the line in question. This shows the operation of the synchronous condensers under all conditions of load and it gives the maximum load which can be carried by the line at the voltages considered. The efficiency of transmission and power factor at the generators for various loads may also be conveniently plotted above the diagram. (See Fig. 2.)

The circle diagram is advantageous, first, because it gives results for all loads and not for one or two particular loads only. Second, because it is not a trial and error method but it gives results at once for the definite supply and receiver voltages chosen. In the third place, concentric circles may be drawn with practically no extra calculation whatever, to show the results for different values of the supply voltage E_s. (See Fig. 2.) In the fourth place, it is possible with very little extra work to obtain precise calculated results by means of the calculated data used in making the diagram.

The method of drawing a circle diagram of a constant-voltage transmission line, not including the step-up and step-down transformers, but taking account of the

Presented at the Pacific Coast Convention of the A. I. E. E., Vancouver, B. C., August 8-11, 1922.

distributed capacity according to the hyperbolic theory, has been published by the author in "Constant-Voltage Transmission," pages 78 and 99. The present article gives formulas for drawing the diagram or calculating the results when the transformer resistances and reactances are included in the circuit, the notation used being similar to that in the book referred to. Average values have been taken for the transformer core loss and magnetizing current, and for the condenser loss, and these have been included in the calculation.

A similar method for including the transformer characteristics in the transmission circuit calculation has been worked up by Messrs. R. D. Evans and H. K. Sels and published by them in the *Electric Journal.* A useful reference in connection with this kind of calculation is "The Calculation of Transmission Line Networks" by Prof. T. R. Rosebrugh, Bulletin No. 1. 1919, of the School of Engineering Research, University of Toronto, which gives the general circuit constants for several lines in parallel, in series-parallel, and with intermediate loads, etc. Such general constants are often applicable in the following circle diagram calculation.

By making allowance for the transformer characteristics, the preliminary calculation is made somewhat longer than for the line alone, but the construction of the diagram itself is not made any more complicated in any way.

Let the constant voltage at the low-tension side of the receiving transformers be E volts to neutral, (equivalent high-tension voltage). See Fig. 1. Let the load current combined with the reactive current from the synchronous condensers be $P + j\,Q$ amperes per conductor, (equivalent high-tension current). Q is a positive quantity when leading and negative when lagging. Let the average loss in the synchronous condensers be represented by the current P_c, in phase with E. Let the core loss and magnetizing current of the receiving transformers be represented by the admittance $G_{tr} + j\,B_{tr}$ at the average operating high-tension voltage. Let the corresponding quantity for the supply transformers be $G_{ts} + j\,B_{ts}$. The core loss current and the magnetizing current of a given transformer are assumed to flow in the primary winding of that transformer and not in the secondary winding. The impedance of the receiving transformers is $R_{tr} + j\,X_{tr}$, and that of the supply transformers is $R_{ts} + j\,X_{ts}$.

The process of calculating the data for the circle diagram consists in starting at the load end, where the voltage E and all other conditions are known except the current $P + j\,Q$. The voltage and current at each part of the system are then calculated, using numerical values of all quantities except that the letters $P + j\,Q$ will always appear. Thus finally the value of E_s will be obtained in terms of P and Q and numerical quantities, See Equation **(16)** and example I.

In Fig. 1 is indicated a typical constant-voltage transmission line. If the size of conductor, or the spacing, changes at a certain point on the line, the voltage E_{b1} at that point should be marked on the diagram and calculated in the usual way. Voltages in the calculation are considered measured to neutral, and currents are in amperes per conductor. The system is considered to be three-phase.

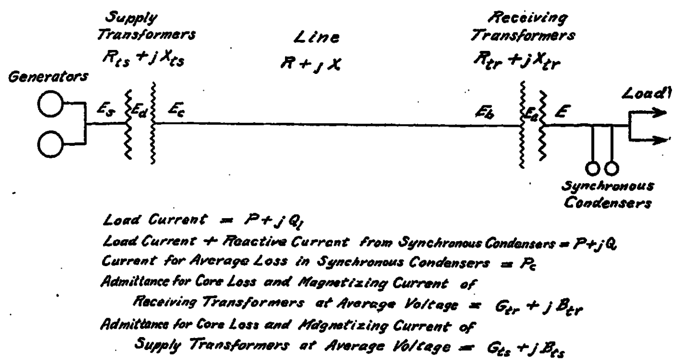

FIG. 1—SCHEME OF CONNECTIONS OF CONSTANT-VOLTAGE TRANSMISSION LINE

Numerical values, except for P and Q, are to be inserted in the following equations;

Current in secondary of receiving transformers

$$I_a = P + j\,Q + P_c \quad \text{amperes per conductor} \qquad (1)$$

Voltage induced in receiving transformers

$$E_a = E + 1/2\, I_a\,(R_{tr} + j\,X_{tr}) \quad \text{volts to neutral} \qquad (2)$$

Current in primary of receiving transformers

$$I_b = I_a + E_a\,(G_{tr} + j\,B_{tr}) \quad \text{amperes per conductor} \qquad (3)$$

Voltage at receiving end of transmission line

$$E_b = E_a + 1/2\, I_b\,(R_{tr} + j\,X_{tr}) \quad \text{volts to neutral} \qquad (4)$$

Voltage at supply end of transmission line

$$E_c = E_b\left(1 + \frac{Y Z}{2} + \frac{Y^2 Z^2}{2 \times 3 \times 4} + \ldots\right) + I_b\,Z\left(1 + \frac{Y Z}{2 \times 3} + \frac{Y^2 Z^2}{2 \times 3 \times 4 \times 5} + \ldots\right) \quad \text{volts to neutral} \qquad (5)$$

Current at supply end of transmission line

$$I_c = I_b\left(1 + \frac{Y Z}{2} + \frac{Y^2 Z^2}{2 \times 3 \times 4} + \ldots\right) + E_b\,Y\left(1 + \frac{Y Z}{2 \times 3} + \frac{Y^2 Z^2}{2 \times 3 \times 4 \times 5} + \ldots\right) \quad \text{amperes per conductor} \qquad (6)$$

The equations for the voltage E_{b1}, and current I_{b1}, etc., at an intermediate point or points where the line characteristics change, are of the same form as (5) and (6).

Note that $Y = G + j\,B$, the admittance of the line, (7)
and $Z = R + j\,X$, the impedance of the line, (8)

The series in $Y Z$ are very convergent at commerical

frequencies and can be quickly evaluated. It may be noted that

$$1 + \frac{YZ}{2} + \frac{Y^2 Z^2}{2 \times 3 \times 4} + \ldots = \cosh \sqrt{YZ} \qquad (9)$$

and

$$1 + \frac{YZ}{2 \times 3} + \frac{Y^2 Z^2}{2 \times 3 \times 4 \times 5} + \ldots = \frac{\sinh \sqrt{YZ}}{\sqrt{YZ}} \qquad (10)$$

Current in secondary of supply transformers $= I_c$ (11)

Voltage induced in supply transformers

$$E_d = E_c + 1/2\, I_c\, (R_{ts} + j\, X_{ts}) \quad \text{volts to neutral} \qquad (12)$$

Current in primary of supply transformers

$$I_d = I_c + E_d\, (G_{ts} + j\, B_{ts}) \quad \text{amperes per conductor} \qquad (13)$$

Voltage at generator terminals

$$E_s = E_d + 1/2\, I_d\, (R_{ts} + j\, X_{ts}) \quad \text{volts to neutral} \qquad (14)$$

Current at generator terminals

$C + j\, D = I_d$ amperes per conductor (15)

The voltage and current at the generator terminals may thus be found in terms of P, Q and numerical quantities. It is noteworthy that no trigonometrical calculations are required, but only the multiplying of complex quantitites, for which a slide rule is sufficient. The voltage E remains the reference vector throughout the entire calculation.

Let $E_s = E' + j\, E'' + (P + j\, Q)\, (R' + j\, X')$ volts to neutral (16)

where numerical values have been found for the letters with dashes, from (14).

Equation (16) is of exactly the same form as the equation for a transmission line alone, not including transformers. A circle diagram may therefore be drawn for the complete transmission system indicated in Fig. 1, in which E_s and E are voltages kept constant by means of synchronous condensers. Such a diagram will indicate the kv-a. required from the condensers for any given load.

If, as is sometimes done, the voltage at the supply end is kept constant on the high tension side of the step-up transformers, E_c, the constant supply voltage, would be in the place occupied by E_c, Fig. 1.

From equation (16) the absolute value of the supply voltage E_s may be obtained. Thus,

$$E_s^2 = (E' + P\, R' - Q\, X')^2 + (E'' + P\, X' + Q\, R')^2 \qquad (17)$$

In the case of a constant-voltage line, P and Q are the only variables.

Equation (17) is the equation of a circle. It reduces to

$$\left(P + \frac{E'\, R' + E''\, X'}{R'^2 + X'^2}\right)^2 + \left(Q - \frac{E'\, X' - E''\, R'}{R'^2 + X'^2}\right)^2 - \frac{E_s^2}{R'^2 + X'^2} = 0 \qquad (18)$$

Since P and Q represent currents, equation (18) should be multiplied throughout by

$$\frac{3\, E}{1000} \qquad (19)$$

to give a circle showing the relation between kw. and reactive kv-a. at the receiver end of the constant-voltage line.

The center of the circle is the point (a', b') where

$$a' = -\frac{3\, E}{1000}\; \frac{E'\, R' + E''\, X'}{R'^2 + X'^2} \text{ kw.} \qquad (20)$$

$$b' = +\frac{3\, E}{1000}\; \frac{E'\, X' - E''\, R'}{R'^2 + X'^2} \text{ kv-a.} \qquad (21)$$

The radius is

$$c' = +\frac{3\, E}{1000}\; \frac{E_s}{\sqrt{R'^2 + X'^2}} \text{ kv-a.} \qquad (22)$$

In order to plot the reactive kv-a. required from the synchronous condensers, first draw a straight line at

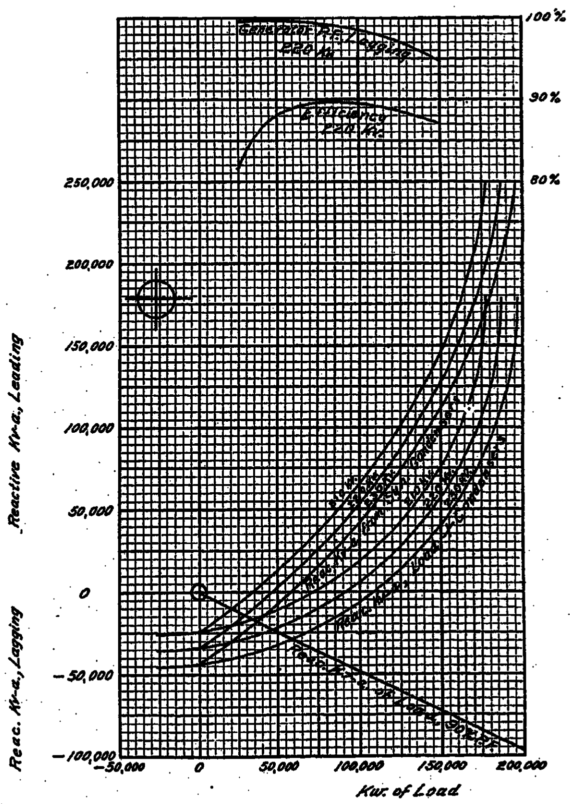

FIG. 2—CIRCLE DIAGRAM FOR 220,000-VOLT, CONSTANT-VOLTAGE TRANSMISSION LINE
(See example 1)

an angle θ below the base line, where $\cos \theta$ is the power factor lagging, of the load. If the power factor is not the same at all loads, the line will not be straight, but will be a curve showing the reactive kv-a. of the load from no load to full load. By means of a pair of dividers, add the reactive kv-a. of the load to the corresponding ordinate of the circle, thus plotting the curve of kv-a. required from the synchronous condensers. See Fig. 2.

Theoretical Limit of Load, in Kilowatts

Maximum Load $= c' + a'$ kw. (23)

This is numerically less than c' since a' is a negative quantity. It may read from the circle diagram as it is the farthest distance to the right reached by the circle.

Calculated Value of Reactive Kv-a. The method described in this article is not necessarily a graphical method. It is possible to calculate the reactive kv-a. directly, which is sometimes desirable in order to obtain a more precise result than that obtained graphically from the diagram. A direct calculation made in this way is less work than a "trial and error" method, which would generally involve calculating the problem more than once.

The value of the reactive kv-a., $\frac{3\,E\,Q}{1000}$, for a given power load $\frac{3E\,P}{1000}$, may be found from the following equation:

$$\left(b' - \frac{3\,E\,Q}{1000}\right)^2 = c' - \left(\frac{3\,E\,P}{1000} - a'\right)^2 \qquad (24)$$

The reactive kv-a. required from the synchronous condensers are equal to

$$\frac{3\,E\,Q}{1000} + \frac{3\,E\,P}{1000}\,\frac{\sin\theta}{\cos\theta} \quad \text{kv-a.} \qquad (25)$$

where the power load is $\frac{3\,E\,P}{1000}$ kw. at a lagging power factor $\cos\theta$. It should be remembered that b' is a positive quantity and a' is a negative quantity. It is worth while checking the results of equations (24) and (25) by drawing the circle diagram and obtaining the same results graphically.

Concentric Circles. Since a' and b' which give the center, are independent of the constant supply voltage E_s, and since the radius c' is directly proportional to E_s, it is evident that a number of circles corresponding to different values of E_s may be drawn about the same center. See Fig. 2.

Total Losses.

Let $A = E' + P\,R' - Q\,X'$ volts to neutral (26)

and $B = E'' + P\,X' + Q\,R'$ volts to neutral (27)

The losses in the transmission system equal

$$\frac{3}{1000}\,(A\,C + B\,D - E\,P) \quad \text{kw.} \qquad (28)$$

This does not include the generator losses. When the constant voltage E_s is on the high tension side of the step-up transformers the losses in the step-up transformers are not included in expression (28). As mentioned before, an average value was assumed for the transformer core loss and the condenser loss. The quantities C and D are found from equation (15).

Efficiency of the Transmission System.

$$\text{Efficiency} = \frac{100\,E\,P}{A\,C + B\,D} \quad \text{per cent} \qquad (29)$$

Kw. at supply end

$$\frac{3}{1000}\,(A\,C + B\,D) \quad \text{kw.} \qquad (30)$$

Kv-a. at supply end

$$\frac{3\,E_s\sqrt{C^2 + D^2}}{1000} \quad \text{kv-a.} \qquad (31)$$

Power factor at supply end

$$\frac{100\,(A\,C + B\,D)}{E_s\sqrt{C^2 + D^2}} \quad \text{per cent} \qquad (32)$$

The "supply end" is the point where the voltage E_s is kept constant. If this at the generator terminals, as indicated in Fig. 1, expression (32) gives the power factor of the generator load. Whether this is leading or lagging must be determined from the following expression:

Reactive kv-a. at supply end

$$\frac{3}{1000}\,(A\,D - B\,C) \quad \text{kv-a.} \qquad (33)$$

When this quantity is positive the reactive kv-a. and the power factor are leading, and when it is negative, they are lagging.

Example I

Length of line $= 200$ miles

Frequency $= 60$ cycles

$R + j\,X = 23.2 + j\,160$ ohms

$Y = +j\,0.00106$ mho

$1 + \frac{Y\,Z}{2} + \ldots = 0.91637 + j\,0.01195$

$1 + \frac{Y\,Z}{2.3} + \ldots = 0.97197 + j\,0.00403$

$P_c = 8.66$ amperes

$R_{tr} + j\,X_{tr} = 1.33 + j\,24.0$ ohms

$G_{tr} + jB_{tr} = 0.000,022,5 - j\,0.000,187,5$ mho

$R_{tt} + j\,X_{tt} = 1.61 + j\,29.0$ ohms

$G_{tt} + j\,B_{tt} = 0.000,018,6 - j\,0.000,155,0$ mho

$E = 115{,}470$ volts to neutral (line voltage 200,000)

$I_a = P + j\,Q + 8.7$

$E_a = 115{,}480 + j\,100 + (P + j\,Q)\,(0.7 + j\,12.0)$

$I_b = (P + j\,Q)\,(1.002 + j\,0.0002) + 11.3 - j\,21.6$

$E_b = 115{,}740 + j\,220 + (P + j\,Q)\,(1.3 + j\,24.0)$

$E_c = 109{,}680 + j\,2870 + (P + j\,Q)\,(22.9 + j\,178.0)$

$I_c = (P + j\,Q)\,(0.894 + j\,0.013) + 9.9 + j\,99.5$

$E_d = 108{,}240 + j\,3090 + (P + j\,Q)\,(23.4 + j\,191.0)$

$I_d = (P + j\,Q)\,(0.924 + j\,0.013) + 12.4 + j\,82.8$

$E_s = 107{,}050 + j\,3340 + (P + j\,Q)\,(23.9 + j\,204.4)$

$ = E' + j\,E'' + (P + j\,Q)\,(R' + j\,X')$

$a' = -26{,}600$ kw.

$b' = 178{,}300$ kv-a.

$c' = 213{,}800$ kv-a.

when $E_s = 127{,}020$ volts to neutral (line voltage $= 220{,}000$). See Fig. 2, which shows the desired characteristics of the system.

Discussion

For discussion of this paper see page 789.

A Graphic Method for the Exact Solution of Transmission Lines

BY COLLIS H. HOLLADAY
Associate, A. I. E. E.
Southern California Edison Company

Review of the Subject.—*There seems to be a popular superstition among engineers that the voltage and current relations at different points in a transmission line are peculiar and are not governed by Ohms law. This idea is not true. A transmission line is governed by Ohms law just as is any other alternating-current circuit containing resistance inductance and capacity. The only difference from an ordinary circuit is that in a transmission line we must make a correction for the effect of distributed constants.*

If we change the current flowing through a line by an amount I, there will be a voltage change equal to I Z between the two ends of the line. The Z in this case, however, is corrected for the distributed constants of the line. The hyperbolic formula which are so widely coming into use, since Doctor Kennelly has given us tables of complex hyperbolic functions, are merely short methods of determining this Z as well as certain other constants which we must use.

If we start with a certain voltage Eg at the generator; on open circuit, we will have a slightly higher voltage at the receiver, due to the line capacity drawing a leading current through the inductance. As we load the line with a lagging current this voltage rise is counteracted by the impedance drop.

In a similar manner the generator current is equal to the vector sum of the charging current, and the load current which has been multiplied by a constant.

It is possible to express these relations by a vector diagram. Drawing a voltage and current diagram on the same sheet and to suitable scales offers a very convenient method of calculation. From such a diagram it is possible to read directly power and power factor as well as condenser kv-a. necessary for voltage regulation.

CONTENTS

THE purpose of this paper is to describe a quick method of constructing the vector diagram of a power line, from which it will be possible to read directly the voltage, current, power and power factor at either end of the line.

THEORY

The solutions of the equations of voltage and current along a transmission line appear in several forms, of which probably the most useful in power line calculations are the well-known hyberbolic ones

$$E_g = E_r \cosh (n\,\theta) + I_r Z_o \sinh (n\,\theta) \qquad (1)$$

$$I_g = I_r \cosh (n\,\theta) + \frac{E_r \sinh (n\,\theta)}{Z_o} \qquad (2)$$

where

E_g = generator voltage E_r = receiver voltage
I_g = generator current I_r = receiver current
$n\,\theta$ is the hyperbolic angle of the line, depending on the length n, the size and configuration of the conductors, and the frequency.
Z_o is the surge impedance of the line, depending on the size and configuration of the conductors and the frequency.

The use of these equations and the technique of hyperbolic functions have been discussed by a number of authors to which a few references are given in the bibliography, so I will not burden this paper with a further discussion. The usual method of solving these equations is an analytical one. This works well enough when the power factor of the load is known, but when condensers are used for voltage regulation, the solution is very complicated. A graphical solution, however, offers several advantages which cannot be overlooked.

CONSTRUCTION OF VECTOR DIAGRAM

The voltage equation. Fig. 1, shows the voltage diagram. In both the voltage and current diagrams E_r will be used as the reference vector from which all angles will be measured. From O draw E_r the reference vector. $E_r \cosh (n\,\theta)$ will be shorter and lead E_r by a small angle. $E_r \cosh (n\,\theta)$ is the generator voltage when the line is on open circuit. The difference between it and E_r is the voltage rise or Ferranti effect in the line.

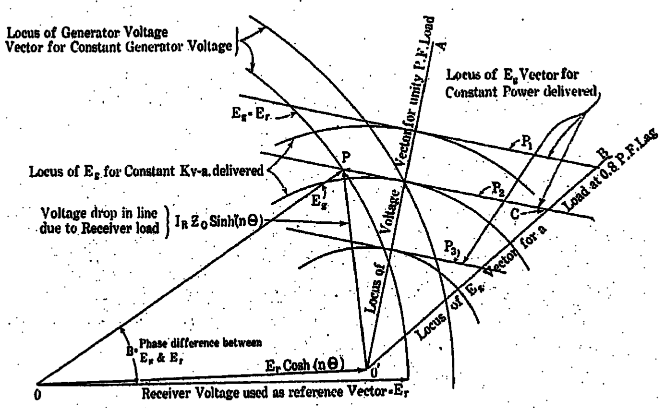

FIG. 1—VECTOR DIAGRAM OF HYPERBOLIC EQUATION $E_r \cosh (n\theta) + I_r Z_o \sinh (n\theta)$.

Now as we put a load on the end of the line, there will be an impedance drop or rise in the voltage between the receiver and generator ends, depending upon the power

Presented at the Pacific Coast Convention of the A. I. E. E., Vancouver, B. C., August 8-11, 1922.

factor of the load. This is no different from the usual impedance drop in a circuit and is proportional to the current delivered at the receiving end. It is described by the term $I_r Z_o \sinh (n\,\theta)$ and is represented by the vector $\overline{O' P}$.

The position of the vector $\overline{O' P}$ depends on the character of the load. With a unity power factor load at the receiving end the point P will move along $O' A$. If the amount of power delivered is kept constant while the power factor is varied, P will move along a line perpendicular to $O' A$. With a constant kv-a. load, P will move along the arc of a circle drawn from O' as a center. In order to keep the generator voltage constant as the load on the line is varied, the point P must follow the arc of a circle drawn from O as a center and having a radius equal to E_g.

Current Equation. This current equation:

$$I_g = I_r \cosh (n\,\theta) + \frac{E_r \sinh (n\,\theta)}{Z_o}$$

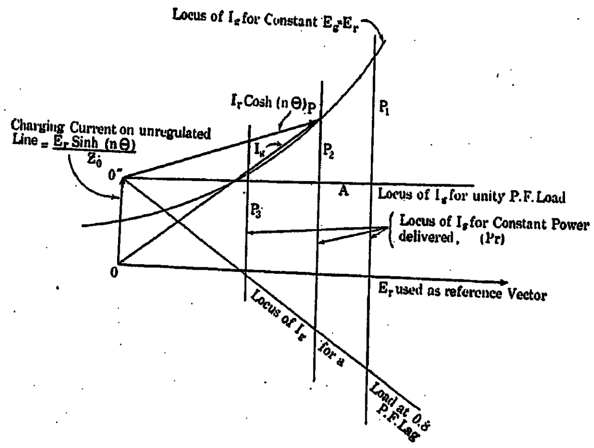

FIG 2—VECTOR DIAGRAM OF HYPERBOLIC EQUATION

$$I_g = I_r \cosh (n\theta) + \frac{E_r \sinh (n\theta)}{Z_o}$$

is similar to the voltage equation. It consists of one term which is proportional to the receiver voltage and one which is proportional to the receiver current.

As in the voltage diagram E_r will be used as the reference vector. From O in Fig. 2, draw $\overline{O\,O''}$ equal to

$$\frac{E_r \sinh (n\,\theta)}{Z_o}.$$

This is the charging current taken from the generator when the voltage at the receiving end of the line is E_r. It is necessary to state it in terms of the receiver voltage since all calculations are performed on the assumption of a predetermined receiver voltage. As we load the line at the receiver end by taking a current $I\,r$, a current $I\,r \cosh (n\,\theta)$ will be added to the charging current. This component is almost in phase with the receiver current and a little smaller in magnitude. It is represented by the vector $\overline{O'' P}$.

With a unity power factor load, P will be on the line $O'' A$. With constant power and varying power factor, P will travel along a line perpendicular to $O'' A$. Similarly the locus of P for constant kv-a. load will be a circle drawn from O'' as a center.

Let us examine the voltage and current diagrams together. Any point P on either diagram represents a certain amount of power at a certain power factor which is taken from the line at the receiving end. The vector $\overline{O\,P}$ on the voltage diagram is equal to the generator voltage necessary to maintain a receiver voltage E_r while P is being delivered. The vector $\overline{O\,P}$ on the current diagram represents the generator current while P is being delivered. For every point on the voltage diagram, there is a corresponding point on the current diagram.

Let us assume the system to which the line is connected takes a load from the line at 0.80 power factor. Then the locus of point P of the voltage vector E_g will be the line $O' B$ where $A\,O' B$ is the angle whose cosine equals 0.80; and there will be considerable voltage drop between the generator and receiver for a large amount of power transmitted.

In order to avoid raising the generator voltage to maintain constant receiver voltage, synchronous condensers are used. Their purpose is to draw sufficient reactive current through the line to change the power factor from that of the system load to that necessary for the point P to fall on the constant generator voltage curve. In Fig. 1, the drop caused by this current is the vector $\overline{C\,P}$. Changing the condenser excitation causes E_g to move along the constant power line P_2.

CALCULATIONS FOR A THREE-PHASE LINE.

The following calculation for a three-phase line is given to illustrate the technique and procedure.

Conductor	Aluminum Steel		
	605,000 cir. mil aluminum. 78,500 steel		
	Diameter = 0.953 inch		
Spacing	Horizontal three conductors		
	204 inches between conductors.		
Line Constants	n = length of line	=	241 miles
	f = frequency	=	50 cycles
	$w = 2\,\pi\,f$	=	3.14159 radians per sec.
	r = resistance	=	0.1511 ohm per mile
	L = inductance	=	0.0021015 henry per mile
	c = capacity	=	0.01425×10^{-6} farad per mile
	g = leakance, so small we will neglect it.		

From these constants we will determine the hyperbolic angle θ and the surge impedance Z_o. The mathematics of hyperbolic functions in line calculations has been treated so often before that I will do no more than give the formula. Reference to the theory is given in the bibliography.

$$\theta = \sqrt{(r + j\,L\,w) \times (g + j\,c\,w)} \text{ hyperbolic radians per mile}$$

$$Z_o = \sqrt{\frac{r + j\,L\,w}{g + j\,c\,w}} \text{ ohms surge impedance}$$

$$L\,\omega = 0.0021015 \times 50 \times 2\,\pi$$
$$= 0.660205 \text{ ohm per mile}$$

$$(r + j\,L\,w) = (0.1511 + j\,0.660205)$$
$$= 0.6773\ \underline{/77.^\circ 09} \text{ ohms per mile}$$

$$c\,w = 0.01425 \times 10^{-6} \times 50 \times 2\,\pi$$
$$= 4.4767 \times 10^{-6} \text{ mho per mile}$$

$$(g + j\,c\,w) = (O + j\,4.4767 \times 10^{-6})$$
$$= 4.4767 \times 10^{-6}\ \underline{/90.^\circ} \text{ mho per mile}$$

available, the complex functions can be easily calculated from tables of real circular and hyperbolic functions which are found in every handbook.

$$\text{Cosh } (n\,\theta) = 0.915\ \underline{/1.^\circ 20}$$
$$\text{sinh } (n\,\theta) = 0.410\ \underline{/83.^\circ 9}$$

$$Z_o \text{ sinh } (n\,\theta) = 389.0\ \overline{/6.^\circ 45} \times 0.410\ \underline{/83.^\circ 9}$$
$$= 159.5\ \underline{/77.45} \text{ ohms.}$$

It is decided to maintain a voltage between wires of 220,000 volts at the receiving end. This gives the voltage to neutral $E_r = 127{,}200\ \underline{/0^\circ}$ volts

$$E_r \cosh\,(n\,\theta) = 116{,}400\ \underline{/1.^\circ 20} \text{ volts}$$

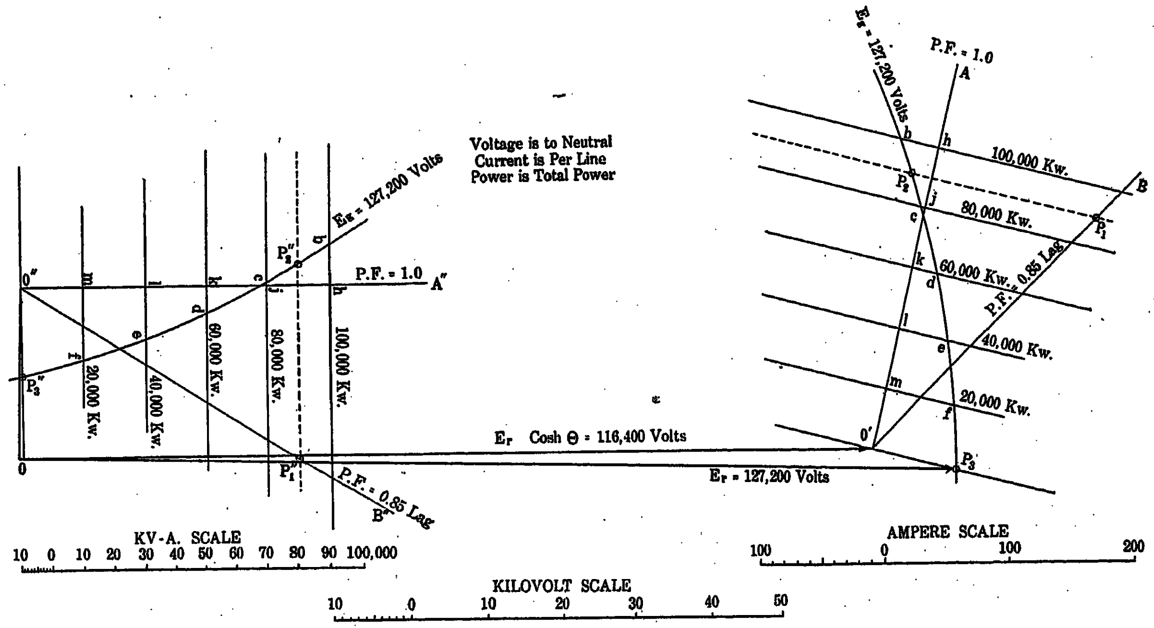

FIG. 3

$$\theta = \sqrt{0.6773\ \underline{/77.^\circ 09} \times 4.4767 \times 10^{-6}\ \underline{/90.^\circ}}$$
$$= \sqrt{3.0321 \times 10^{-6}\ \underline{/167.^\circ 09}}$$
$$= 1.7412 \times 10^{-3}\ \underline{/83.^\circ 54} \text{ hyperbolic radians per mile}$$

$$Z_o = \sqrt{\frac{0.6773\ \underline{/77.^\circ 09}}{4.4767 \times 10^{-6}\ \underline{/90^\circ}}}$$
$$= \sqrt{0.15125 \times 10^{6}\ \overline{\backslash 12.^\circ 91}}$$
$$= 389.0\ \overline{\backslash 6.^\circ 45} \text{ ohms surge impedance.}$$

$$n\,\theta = 241 \times 1.7412 \times 10^{-3}\ \underline{/83.^\circ 54} \text{ hyperbolic radians}$$
$$= 0.420\ \underline{/83.^\circ 54} \text{ hyperbolic radians.}$$

Since $(n\,\theta)$ is a complex hyperbolic angle, tables or charts of complex hyperbolic functions are of great advantage in determining sinh $(n\,\theta)$ and cosh $(n\,\theta.)$ Such charts and tables have been calculated and published by Doctor Kennelly.[1] If no such tables are

1. A. E. Kennelly, Tables of Complex hyperbolic and circular functions, Harvard University Press.
A. E. Kennelly, Chart Atlas of complex hyperbolic and circular functions, Harvard University Press.

$$\frac{E_r \text{ sinh } (n\,\theta)}{Z_o} = \frac{127{,}200\ \underline{/0^\circ} \times 0.410\ \underline{/83.^\circ 9}}{389.0\ \overline{\backslash 6.^\circ 45}}$$
$$= 134.1\ \underline{/90.^\circ 35} \text{ amperes}$$

Choose a suitable voltage scale, say 10,000 volts to the inch, and from O (Fig. 3) lay off E_r, the reference vector. Draw $\overline{O\,O'}$ equal to E_r cosh $(n\,\theta)$ leading E_r by an angle of 1.20 degrees. For 100,000 kw. delivered at the receiving end at unity power factor, I_r will equal 263. $\underline{/0^\circ}$ amperes per phase.

$$I_r\,Z_o \text{ sinh } (n\,\theta) = 263\ \underline{/0^\circ} \times 159.5\ \underline{/77.^\circ 45}$$
$$= 41{,}900\ \underline{/77.^\circ 45} \text{ volts}$$
$$= 4.19\ \underline{/77.45} \text{ inches}$$

From O' draw $O'\,A$ making an angle of 77.45 deg. with E_r. This is the unity power factor line. Measure up 4.19 inches from O' and through the point draw a line perpendicular to $O'\,A$. This is the 100,000-kw. line. Distances along $O'\,A$ are proportional to the power delivered at the receiver at unity power factor. We can therefore get a power calibration.

4.19 inches = 100,000 kv-a.
or 23,820 kv-a. = 1 inch

From O draw an arc the radius of which is equal to the generator voltage it is decided to maintain by means of condensers. This arc will intersect the constant power lines at b, c, d, e, f.

Current Diagram. For convenience in reading, we will construct the current diagram on the same sheet and to the same scale as the voltage diagram. Since $I_r Z_o \sinh(n\,\theta)$ and $I_r \cosh(n\,\theta)$ are both proportional to I_r, if we use the proper scales we can transfer power points from one diagram to the other with a pair of dividers. Such a current scale is one which will make $I_r Z_o \sinh(n\,\theta) = I_r \cosh(n\,\theta.)$

For 100,000 kw. at unity power factor

$$I_r \cosh(n\,\theta) = 263\ \underline{/0°} \times 0.915\ \underline{/1.°20}$$
$$= 241.8\ \underline{/1.°20} \text{ amperes}$$

$I_r Z_o \sinh(n\,\theta)$ = 4.19 inches
241.8 amperes = 4.19 inches
1 ampere = 0.01741 inch
1 inch = 57.7 amperes

From O draw $\overline{O\,O''}$ making an angle of 90.35 degrees with $E\,r$ and equal to

$$\frac{E_r \sinh(n\,\theta)}{Z_o} = 134.1 \text{ amperes} = 2.322 \text{ inches.}$$

Draw $O''\,A''$ making an angle of 1.20 degrees with E_r. With a pair of dividers, transfer the power points h, j, k, l, m, from $O'\,A$ to $O''\,A''$. In a similar way, the intersections of the power lines with the voltage curve (points b, c, d, e, f,) may be transferred to the current diagram. Draw a circle through these points. The diagram is now complete.

Use of the Diagram

It is desired to know the terminal conditions when 90,000 kw. is being delivered at the receiving end at 0.85 power factor. Draw $O'\,B$ the 0.85 power factor line. This is drawn at such an angle that $A\,O'\,B = \cos^{-1} 0.85$. Measure up 90,000 kw. along $O'\,A$ and draw the constant power line through the point. The intersection of the constant power line and the constant power factor line determines the power point P_1. The generator voltage required to deliver this power is the vector $\overline{O\,P_1}$ and is equal to 150,600 volts and leads E_r by 13.5 degrees. To bring the generator voltage down to 127,200 volts will require an amount of condenser capacity equal to $P_1 . P_2$ or 62,800 kv-a. The generator voltage vector will be $O\,P_2$ and will lead E_r by 18.6 degrees.

Locate P_1'' and P_2'' on the current diagram to correspond to P_1 and P_2 on the voltage diagram. Then $O\,P_1''$ is the generator current when no condensers are used, and is equal to 220.0 amperes. The generator power factor is the cosine of the angle $P_1\,O\,P_1''$. $P_1\,O\,P_1'' = 12.°3 \cos 12.°3 = 0.977$.

The total three-phase power delivered by the generator is $3 \times 150{,}600 \times 220.0 \times 0.977 = 97{,}100$ kw. The line loss is equal to $97{,}100 - 90{,}000 = 7100$ kw.

The vector $\overline{O\,P_2''}$ is the current when the generator voltage is regulated to 127,200 volts. It is equal to 275 amperes. The power factor is the cosine of the angle $P_2''\,O\,P_2$. Power factor = 0.945.

$P_g = 3 \times 127{,}200 \times 275 \times 0.945 = 99{,}000$ kw.
Line loss = $99{,}000 - 90{,}000 = 9000$ kw.

To keep the generator voltage constant at no load will require a lagging condenser capacity equal to $O'\,P_3$ or 28,900 kv-a. This is very small when compared with the full load condenser capacity. It would, therefore, be more economical from the point of view of buying condensers to choose a voltage which would require the same condenser capacity at full load as at no-load.

Appendix

Method of calculating complex hyperbolic functions.

To find sinh and cosh of $0.420\ \underline{/83.°54}$

$0.420\ \underline{/83.°54} = 0.04755 + j\,0.4170$

$\sinh(u \pm j\,v) = \sinh u \cos v \pm j \cosh u \sin v$

$\cosh(u \pm j\,v) = \cosh u \cos v \pm j \sinh u \sin v$

$u = 0.04755$ $v = 0.4170$

$\sinh u = 0.047567$ $\sin v = 0.4049$

$\cosh u = 1.001132$ $\cos v = 0.9143$

$\sinh u \cos v = 0.0435$

$\cosh u \sin v = 0.0450$

$\sinh 0.420\ \underline{/83.54} = 0.0435 + j\,0.4050$
$= 0.409\ \underline{/83.°9}$

$\cosh u \cos v = 0.915$

$\sinh u \sin v = 0.01923$

$\cosh 0.420\ \underline{/83.54} = 0.915 + j\,0.01923$
$= 0.915\ /\ 1.°2$

This method of calculation gives a little more accurate result than it is possible to get with the charts or tables.

If, instead of using the hyperbolic functions, it is found more convenient to use the Steinmetz equations:

$$E_g = E_r\,(a_1 - j\,a_2) + I_r\,(b_1 - j\,b_2)$$
$$I_g = E_r\,(d_1 - j\,d_2) + I_r\,(a_1 - j\,a_2)$$

the procedure will be just the same, except that in these equations the phase rotations are reversed.

Discussion

DISCUSSION ON "A GRAPHIC METHOD FOR THE EXACT SOLUTION OF TRANSMISSION LINES" (Holladay) AND "THE ELECTRICAL CHARACTERISTICS OF TRANSMISSION SYSTEMS" (Dwight)

Vancouver, B. C., August 10, 1922

R. J. C. Wood: Again we have an illustration of how, in different parts of the world, and at the same time, the same ideas arise simultaneously. The curves shown in this paper (Dwight) are—I think if you turn the diagram right over, or the wrong way up, according to who is talking about it, that it will be found to be very similar, if not identical with the curves to be shown in the paper by Mr. Holladay. That paper shows a diagram which represents the exact hyperbolic equations.

When it comes to the purity of the English language, doesn't equation simply mean that two things are equal, and if we have an approximate equation, why shouldn't we be satisfied to let it go at that, and not call it a formula. We have equations, I believe, which are expressed in the form of—well, suppose A equals B, plus or minus something, which represents the errors of observation of something else, I think that is still an equation, without calling it a formula. The dictionary states that a formula is a rule or principle expressed in mathematical language. An equation denotes the equality of two mathematical expressions.

J. R. Dunbar: The diagram in Fig. 2 of Mr. Dwight's paper shows reactive kv-a. in a circuit where the current leads the voltage, plotted upward, that is, kv-a. is plotted counter-clockwise with respect to kilowatts. The A. I. E. E. Standards, Section 3230, recommend that, in any vector diagram, the leading vector be drawn counter-clockwise with respect to the lagging vector.

The above rule is universally followed for vector diagrams involving volts and amperes. Although the apparent power is not strictly an alternating quantity admitting of vector representation, it is convenient to consider it a vector.

It is the usual custom when referring to kv-a. in a circuit to talk about "leading" kv-a. when the current is leading the

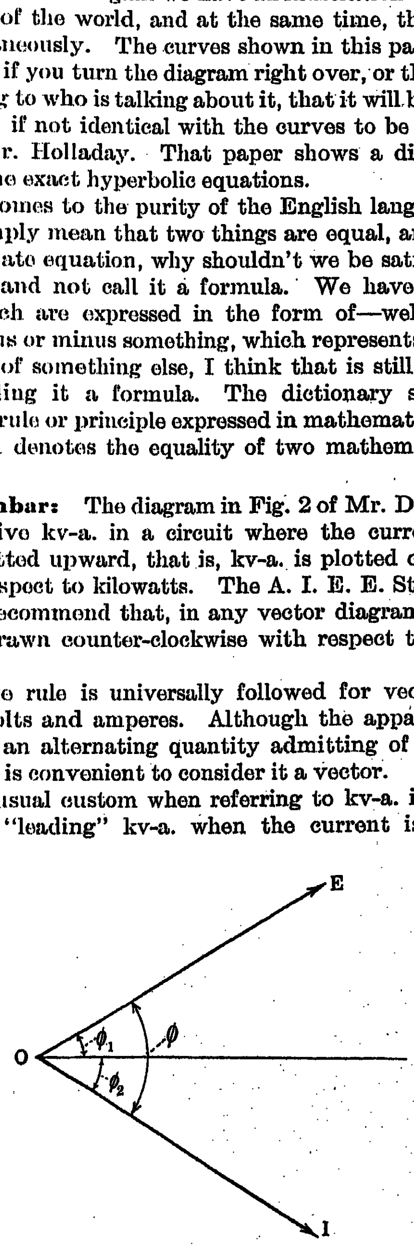

Fig. 1

voltage. If, then, kv-a. is considered as a vector, leading kv-a. must be plotted counter-clockwise from kw. in order to be consistent with Rule 3230. If apparent power is not considered as a vector, there is no justification for drawing any vector diagram of apparent power.

Section 3238 of the Standards defines volt-amperes as the product of the r. m. s. value of the voltage by the r. m. s. value of the current. If volt-amperes be considered as a vector, it is convenient to have a method of computing the vector value. The expression which at once suggests itself is $\underset{\cdot}{E}\,\underset{\cdot}{I}$, when $\underset{\cdot}{E}$ and $\underset{\cdot}{I}$ are the vector values expressed as complex numbers.

In a case such as is shown in Fig. 1 where $\underset{\cdot}{E} = E\,(\cos\phi_1 + j\sin\phi_1)$ and $\underset{\cdot}{I} = I\,(\cos\phi_2 - j\sin\phi_2)$ the expression $\underset{\cdot}{E}\,\underset{\cdot}{I}$ is very cumbersome and difficult of interpretation, because the real part is not equal to the watts. The use of the numbers conjugate to $\underset{\cdot}{E}$ and $\underset{\cdot}{I}$ simplifies this computation considerably.

Two complex numbers are conjugate to each other, as defined in elementary works on algebra, when they differ in the sign of the imaginary part only.

If the current is multiplied by the conjugate of the voltage, the expression $E\,I\,(\cos\phi_1 - j\sin\phi_1)\;(\cos\phi_2 - j\sin\phi_2)$ is obtained. This reduces to $E\,I\,(\cos(\phi_1 + \phi_2) - j\sin(\phi_1 + \phi_2)$ or $E\,I\,(\cos\phi - j\sin\phi)$.

This is an expression for volt-amperes, for its effective value is

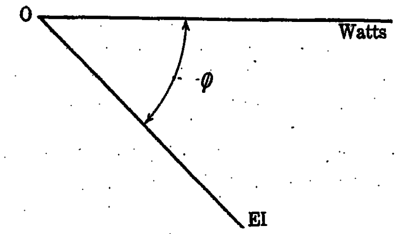

Fig. 2

equal to the volt-amperes of the circuit as defined by Rule 3238. It is in a much more useful form than if the conjugate had not been used, for the real part is equal to the watts, and the imaginary part is equal to the reactive volt-amperes, as shown in the foot notes to rules 3242 and 3246. Also the vector volt-amperes, in a circuit wherein the current lags the voltage, is plotted clockwise from watts, as shown in Fig. 2 which corresponds to the assumption made above.

If instead of the above procedure, the voltage were multiplied by the number conjugate to the current, as is sometimes done, the resultant expression reduces to $E\,I\,(\cos\phi + j\sin\phi)$. This is also an expression for volt-amperes, but it requires that the kv-a. in a circuit wherein the current lags behind the voltage be considered as leading kv-a. in order to be consistent with Rule 3230, which is not in accordance with the usual custom.

When the current and voltage are in phase, if either be multiplied by the number conjugate to the other, it is readily seen that the resultant expression is a real quantity; that is, watts.

It is to be hoped, therefore, that Standardization rules will be added defining volt-amperes as a quantity capable of vector representation for use in transmission line diagrams, etc. and giving rules as to the proper method of plotting volt-amperes.

H. B. Dwight: Mr. Dunbar's demonstration that a transmission line circle diagram should follow Standardization Rule 3230 for vector diagrams, is interesting and convincing. A diagram showing kw. and leading and lagging reactive kv-a. is to all intents and purposes a vector diagram, and Rule 3230 explicitly applies to *any* vector diagram. It would be inconsistent to draw a diagram of a certain shape to express a set of relations between currents in a transmission system, and then draw a diagram of a different shape to express the same set of relations between kv-a. which represent exactly the same currents.

The use of conjugate numbers, which are very advantageous in many calculations, does not require that the above conclusion be changed, but merely that the conjugate of the proper numbers be taken. Where the conjugate of an impedance is required, no difficulty is encountered.

The use of conjugates is both easy and natural. It will be remembered that a complex fraction is multiplied above and below by the conjugate of the denominator, in order to rationalize the denominator. In a somewhat similar way, when multiplying a complex voltage by a complex current, if the conjugate of the voltage is used, the resulting expression can be used to represent the volt-amperes, with the additional advantage that the real part is equal to the watts. It is necessary to use the conju-

gate of the voltage in order not to conflict with Standardization Rule 3230, but this can easily be done.

While the most usual and general problem is the multiplication of a voltage by a current, the matter is very clearly set forth by an example of a complex value of current $I(\cos\theta + j\sin\theta) = Ie^{j\theta}$ and an impedence $R + jX$. The voltage across the impedance is $Ie^{j\theta}(R + jX)$, and the conjugate of the voltage is $Ie^{-j\theta}(R - jX)$. If now, in accordance with the previous paragraph, the conjugate of the voltage be multiplied by the current, the resulting expression for v - a. is $Ie^{j\theta} Ie^{j\theta}(R - jX) = I^2R - jI^2X$. It is seen that the real part is equal to the watts and the unreal part is equal to the reactive volt-amperes, which are negative when lagging, thus agreeing with Standardization Rule 3230.

If, on the other hand, the conjugate of the current be multiplied by the voltage, as is sometimes done, the resulting expression for v-a is $Ie^{-j\theta} Ie^{j\theta}(R + jX) = I^2R + jI^2X$. In this, the lagging quantity is positive, and would be plotted in a counterclockwise direction with respect to the in-phase quantity. This is in disagreement with Standardization Rule 3230, and so the procedure of using the conjugate of the current should not be followed.

Since both methods described have been used in publications, it is desirable that a decision be made. A phrase could be inserted in Rule 3230 of the Standardization Rules of the A. I. E. E. stating that it applies also to the diagrams involving volt-amperes.

S. Barfoed: Referring to Mr. Dwight's paper and statement regarding transmission line problem, given in Fig. 5 of F. G. Baum's paper on "Voltage Regulation and Insulation" JOURNAL of the A. I. E. E. August 1921, page 648, it should be understood that all diagrams and computations were made as simple as possible for the sake of explaining the general nature and solution of the long distance high-voltage transmission problem by means of synchronous condensers at the receiving end as well as at intermediate points at nearly uniform intervals along the line. Studies which we have been making seem to indicate that condenser stations should be placed at intervals of about 100 to 150 miles, provided that the voltage is not less than 220,000 volts and that economical powers are transmitted of the order of magnitude of 150,000 to 175,000 kw. per 3-phase circuit. Kelvin's law must here not be forgotten.

If power is transmitted a distance of 300 miles I would by all means advocate any solution which is accurate, but not more so than the nature of the problem demands. A diagram which has been in use in our office for years for solving transmission line problems for lines from 100 to 200 miles in length, is shown in Fig. 1. It is no different from that given by Mr. Holladay and more easily understood by most engineers. The accuracy is all that may be desired for lines of that length.

The basis for the construction of the diagram was given by Mr. Baum 22 years ago (see A. I. E. E. TRANSACTIONS, pp.412-422, May 1900). I am glad to see that both Mr. Dwight and Mr. Holladay have adopted this same circle diagram, although they arrive at its construction by the use of the functions of the hyperbolic angle. Mr. Holladay's diagram is exactly of the same form as one of several gotten out by me and published in the *Pacific Service Magazine* several years ago. In these diagrams the constants of step-up and step-down transformers were taken account of, as well as the influence of the charging current.

The diagram may be constructed quickly and accurately as follows:—

Direction $O\,a$ is vector of reference. Distance $O\,a$ = 100 per cent = constant and equal generator and receiver voltage for all loads. Swing arc $a\,f$ which is then the locus of end of generator voltage vector for all loads.

At no load the Ferranti effect is represented by the triangle $a\,b\,c$, in which $a\,b$ is the resistance pressure and $b\,c$ the reactance pressure caused by the charging current flowing over ½ of line resistance and ½ of line reactance, including transformer, etc. Now load the line with a load of unity power factor, $c\,d$ is then the resistance pressure caused by the power current flowing over all resistance in series and $d\,c$ the reactance pressure caused by the power current flowing over all reactance in series. $e\,c$ is the resultant and is the impedance line for full load with unity power factor of load. The triangle $c\,d\,e$ is made up of as many triangles as is required to include all pieces of apparatus and the line between the generator and the receiver over which the power current flows in series.

If no attempt were now made to hold the voltage constant, a line drawn from O to e would represent the generator voltage required at unity power factor of load; at a power factor of 95 per cent it would be represented by a line from O to f'''; at 85 per cent by $O\,f'$, and for constant kv-a. of load by $O\,r$, etc. For other loads than full load the quantities are referred to the respective load lines. By causing a quadrature leading current to flow over the reactances, a voltage drop may be compensated for, and by quadrature lagging currents, voltage rises may be compensated for. A synchronous condenser will perform such service when placed in parallel with the load; that is, it acts as a variable condenser for excitations above normal and as a variable reactor for excitations below normal.

If one were sure of the exact numerical value of the load power factor for any load, then it might be of some value to know with mathematical accuracy the particular quadrature currents needed for each load condition.

A very small change in power factor, however, will demand an enormous change in condenser capacity, by far outstripping any small error in the determination of the Ferranti effect represented by the small triangle $a\,b\,c$.

To the left in the figure, the current diagram is drawn so that a good view is had of the manner in which the current and voltage vectors change position with change in load. It is seen how the quadrature currents from the synchronous condenser subtract from or add to the everpresent charging current. At $O\,l$ the quadrature condenser subtracts from the charging current at maximum; then as the load comes on gradually it becomes less until at p the condenser is idling, after which, upon further increase in load, the quadrature current reverses and adds itself to the charging current.

The charging current is shown as a chord of an arc of a circle, more proper perhaps is the circle itself a true representation of the charging current. By a simple geometrical construction, which is obvious, the center of the circle can be found, when it is remembered that except for losses the charging current is in quadrature with the voltage at any point of the line. It is therefor also in quadrature with the voltage at the ends of the line, and hence at right angles to the voltage vectors of the receiver and generator at the various loads.

The arc $l\,n\,p$, etc. is struck from a center m found by locating angle B and making $m\,n$ equal to $o\,b$.

It may, under circumstances, be of advantage to have a drop or a rise in voltage over any particular section of a long line, controlled by condensers at intervals. In such event the diagram at once gives information of what takes place. There may then be a shift to the 110 per cent arc or the 90 per cent arc, or to a curve which would coincide with the 100 per cent arc at no load and with the 110 per cent arc at full load, or vice versa. This is accomplished by adjustment of the potential to the voltage regulator.

The charging current is a function of the impressed voltage. If the voltage is not uniform but changes along the line, the charging current per unit length of line also changes. For a constant voltage system the charging current is therefore constant per unit length of line, and no error is introduced by so considering it.

Ivar Herlitz: The question, so often raised among engineers, whether the hyperbolic theory or some other theory should be used in the calculation of transmission lines seems to me to be rather meaningless. It is established beyond question that the constants in the equations for a uniform transmission line are expressed by hyperbolic functions of certain complex quantities; other expressions for these constants are approximations of the hyperbolic expressions, and it is an easy matter to estimate, for lines of different length, the accuracy obtainable with the various approximate expressions, and then from the demands of the problem decide what method to use. The constants for more general cases, where the transformers are considered together with the line, can be calculated according to Mr. Dwight's paper, or by a similar method described by me in a paper to be published.

The treatment of the equations, after the constants have been determined, depends upon the nature of the problem to be solved. When it is desired to calculate the complete performance of a given line, a circular diagram, for instance of one of the types described in the papers by Dwight and Holladay, may be drawn. In my paper just mentioned I have presented formulas from which the complete performance can be plotted in the form of a few curves giving the loss in active as well as reactive power, and voltage drop for any load condition. For certain other problems I have with advantage used a diagram based on the following principles.

Redrawing Fig. 1 of Mr. Holladay's paper so that the line

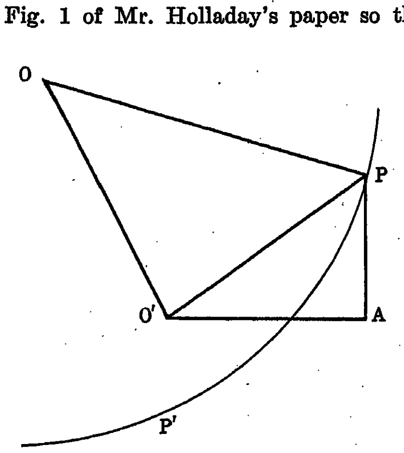

FIG. 3

$O'A$ becomes standard phase, the diagram shown in Fig. 3 is obtained. Here $O'A$ is proportional to the active power, AP to the reactive power. The circle PP' is the locus for P for fixed values of the voltages. The center of the circle always lies on the line OO', forming an angle with $O'A$ that is constant for a given line. Its position on this line depends on the voltages, and the radius is equal to the sending end voltage. If, however, the values of all vectors in the diagram are divided by V_s, the radius of the circle becomes constant = 1, and if the circle is drawn on a separate sheet of transparent paper it may, by means of scales properly arranged, easily be located with respect to a system of coordinate axes to represent any desired case for any line. One diagram can be used for all lines, and it can easily be provided with scales for convenient determination of all desired quantities. The readings have to be multiplied by certain proportionality factors depending on the constants of the line. A similar circle can be drawn representing the conditions at the sending end, and corresponding points on the two circles are found by means of the angular displacement between the voltages, which is equal to the angle $O'OP$ plus a certain fixed angle, as can be seen from Fig. 1 of Mr. Holladay's paper.

D. I. Cone: I want to call your attention to the comparison of these two diagrams, one in Mr. Dwight's paper, and the other in Mr. Holladay's paper. You get a pretty full diagram presented by Mr. Holladay and the corresponding one discussed by Mr. Barfoed is the physical picture given, which is more powerfully expressive than when you get away from the physical picture, as it seems to me Mr. Dwight is doing on the diagram itself. That is all right for a man who is continually dealing with the problem but for others the whole picture is wanted.

A word about when to use these approximations. In my own work I am sometimes dealing with 50 cycles, and again with 500 cycles or 26,000 cycles, and I have found that it was very helpful to consider what fraction of a wave length of line they are dealing with, and on open-wire lines the velocity of transmission always works out pretty close to 180,000 miles per second. If you have a 60-cycle line, you have 3000 miles for one wave length, and if you are working on a line 150 miles long, that is one twentieth of a wave line—pretty short; but if you set it now to 600 cycles, the line 150 miles long, it becomes half a wave length, which is a very different proposition. In dealing with short lines (I think we can safely define the short line as on the order of one-twentieth of a wave length) we can feel safe in using the approximation. If your line approaches anything at all to a quarter of a wave length, watch out. You had better then recognize the fact that at this time due to the work of Dr. Kennelly and others the hyperbolic functions are practically as easy to use as any of these approximations.

About the effect of irregularities in the line, a recent interesting case came up in connection with the Portland-San Francisco telephone lines being adapted to the carrier transmission between five and 3000 cycles. A quite serious irregularity was found in the voltage current relations on the Portland end. It was found to be due simply to the fact that the spacing was 30 inches between the wires in the City of Portland instead of 18 inches, as on the rest of the line, due to the municipal requirements for climbing spaces. It made a serious irregularity in the sending end of the voltage-current relation which has to be corrected by special means.

F. G. Baum: (by letter): In a paper giving "Some Constants for Transmission Lines" before the A. I. E. E. in 1900 (See pp. 412-422, TRANS. May 18, 1900), I showed a method of calculating transmission lines using complex quantities, which showed for the first time the conditions for any load and any power factor. The error for the loaded and unloaded line was shown to be very small for lines less than 200 miles long. And the only error results from the assumption that the charging current is uniform for each line section.

Now, it is admitted that to transmit power over very long distances we must have synchronous condensers at certain intervals to maintain a *constant voltage system* as shown in my paper on "Voltage Regulation and Insulation for Large-Power Long-Distance Transmission Systems." A. I. E. E., 1921. If we do this then it follows that the charging current is also a constant. And if the charging current is uniform, then there is no need for the hyperbolic calculations.

If we are not to hold the line voltage constant, then I admit we need the hyperbolic method of calculations. But why use a method of calculation for an impractical system?

Diagrams 2 and 3 of my paper referred to are *absolutely* accurate. Diagram 4 is accurate enough for all practical purposes. Diagram 5 was given to show the general problem visually. An error in making the diagram accounts for the discrepancy pointed out by Mr. H. B. Dwight and which I acknowledged to him.

In my method we calculate not a 500 or 1000-mile line but calculate the sections between condensers. The errors resulting could never be measured on the completed line by any instrument used in operating the system. The results are shown visually for all conditions of loading.

H. L. Melvin: We who are actively engaged in transmission line design have our pet way of making calculations, I am sure. Whether we use a simple calculation, a graphical chart or an exact solution, depends entirely upon the problem, and it is really our own good judgment which tells us just which solution to use. Furthermore, I believe most of us know how to use any of the methods which have been devised by the technicians. These methods which we have are really a combination of our own study originality and the ideas of others. Personally I like to use the Perrine-Baum graphical chart simply because it gives you a very nice picture of the actual performance of the transmission line. I simply take a piece of cross-section paper and determine upon the kilowatt scales, use one wire values and make a chart somewhat similar to that devised by Professor Carpenter and presented, I believe, at Los Angeles in 1919. It is a Perrine-Baum chart modified, from which you can get practically all the information you want, voltages, per cent voltage regulation, kilowatts, kilowatt-amperes, power factor and synchronous condenser capacity for power factor correction. On the kv-a. circles the I^2R transmission line loss can be placed. The point where the loss in the synchronous condenser increases faster than the I^2R loss in the line decreases can also be determined. That point is approximately the economic or most efficient point at which to operate the transmission line. If you have a problem which requires a more exact solution, the values of resistance and reactance can be modified by the use of hyperbolic functions, and what Dr. Kennelly calls the equivalent values, derived. These values can then be used for making the chart. If you have a still more complicated problem, go through the exact solution. In any event I would make a chart to give a picture of the line, so that good judgment can be used in the design. Pictures mean a great deal to me, if I can see before me just exactly what is going on, I feel that I am better prepared to use good judgment in the proper design. The accuracies of calculation usually exceed by far the original assumptions and necessity in practical application. Temperature change in an ordinary transmission line will introduce more error than the difference between the exact and approximate solution.

Do not misunderstand me, I am not attempting to minimize theory and exact solutions. I have been through them and I feel that I understand them, and they certainly have their value, and unless you do know them you do not know when you can use an approximate solution, or when you have to use an exact solution. The exact solutions are of course absolutely essential on the larger problems. Some of the papers which have come out in recent years are more or less duplicates of papers that have preceded them. I have in mind the sag tension proposition. There were papers after papers on sag tension, different methods of calculation and so on—exact methods and approximate methods. The exact method might tell you to put seven and one-tenth foot sag in the conductor, the approximate solution might say seven feet. If the lineman, gets it within ten per cent, you are lucky.

If you study or go back through the papers that have been written on transmission line regulation and the sag tension problems you will find about every five or six years some one has practically copied an idea of some one before him. We should be careful to give due credit when that is done.

Again I say, practically every one of us have our own pet schemes and could possibly devise some originally and perhaps claim something special for our way of calculating. All these papers are of value if we study them. What we know and use, really are a combination of the other fellow's ideas, coupled with our own.

H. B. Dwight: It has come to be a rule followed by a good many engineers that, in calculating a transmission line at commercial frequencies, if the charging current or capacitance is worth while considering at all, it is worth while calculating its effect by the hyperbolic method. For instance, the old split-condenser method gives rise to an unknown amount of error, and it is better to remove the uncertainty and at the same time effect a standardization of method of calculation, by using the hyperbolic method, which takes practically the same amount of labor as the other.

When a method is advocated which is explicitly not based on the hyperbolic method, it is not sufficient to examine whether its theory appears accurate or nearly accurate, but it is necessary to use the proposed method with a definite example and see if it gives correct results. For this, the criterion by which it must be judged is the hyperbolic method.

Thus, in the last paragraph of Mr. Barfoed's discussion it is stated that "in a constant voltage system the charging current is constant per unit length of line, and no error is introduced by so considering it," but he does not mention any problem which he has worked out as a check of the correctness of his theory for practical purposes, and therefore his statement remains open to doubt until he puts it to the test in the manner described.

So also, referring to the same or a similar method of treating charging current, F. G. Baum says in his discussion that in a constant voltage system the charging current is a constant, "and if the charging current is uniform, then there is no need for the hyperbolic calculations." Now the charging current may be roughly uniform, but the only way to test the above statement is by its results.

Mr. Baum states that the large errors which I pointed out in diagram 5 of his 1921 paper are due to an error in making the diagram, but he does not say, as one might reasonably expect, that he had re-drawn the diagram and found what the errors due to his method really are.

However, he states that "diagram 4 of the same paper is accurate enough for all practical purposes." Now diagram 4 gives complete electrical data of a transmission line of two sections, each 150 miles long, and it is possible to check the results, which are as follows:

RATING OF SYNCHRONOUS CONDENSERS

Synchronous condenser station	Baum's Method	Hyperbolic Method
$S\,C_3$	9,000 kv-a.	22,600 kv-a.
$S\,C_2$	18,000 kv-a.	17,190 kv-a.

If an engineer built a synchronous condenser station for 9000 kv-a. and it was found after load was put on that 22,600 kv-a. of condensers were really required, he would have difficulty in convincing his superiors that his calculations were accurate enough for all practical purposes.

If a method of calculation different from the hyperbolic method is put forward, the advocate of the method should himself first, give clear instructions for using it; second, use it to solve a practical problem; and third, solve the same problem by correct standard methods and show a comparison between his results and the correct results.

C. H. Holladay: There seems to be but two points of discussion, both of which arise whenever a theoretically exact method of calculating a problem is presented. The first is—whether an approximate method is sufficiently exact to use on long power transmission lines. The second, a correlary to the first, is whether the hyperbolic method of calculation justifies its use.

As an answer to the first question, Fig. 4 shows the hyperbolic diagram of Fig. 3, over which is drawn the ordinary approximate diagram obtained by lumping the capacity at the center of the line. It is evident that the error involved by the approximate method is slight, except in the determination of synchronous condenser capacity. The minimum error which occurs at full load is 8.6 per cent.

It is, therefore, apparent that for lines up to 12,000 cycle miles in length, no serious error is involved in disregarding the effect of disturbed constants. For lines of greater length, however, hyperbolic functions become of increasing importance.

I would like to question the statement made by Mr. Baum, that diagrams two and three, of his paper in the Institute JOURNAL for August, 1921, are *absolutely* correct. As I understand it, Mr. Baum states that if the terminal voltages of a line are kept equal by means of a synchronous condenser, the voltage at intermediate points will be equal to the terminal voltages. This, of course, is not true. On the line discussed above, the voltage at the middle point will go all the way from 224,000 volts at no load, to 219,000 volts at 100,000-kw. load, while the terminal voltages are kept at 220,000 volts. This, of course, would prevent the charging current from being uniform.

In performing a number of both exact and approximate power line calculations, I can see no difference between the two methods, in the labor involved, providing, of course, that tables or charts of hyperbolic functions are available.

There are a number of problems, however, which cannot be handled without hyperbolic functions, and I can see no reason for using two different methods for making a complete set of calculations, when they can be made with the same labor and greater accuracy by using one method throughout.

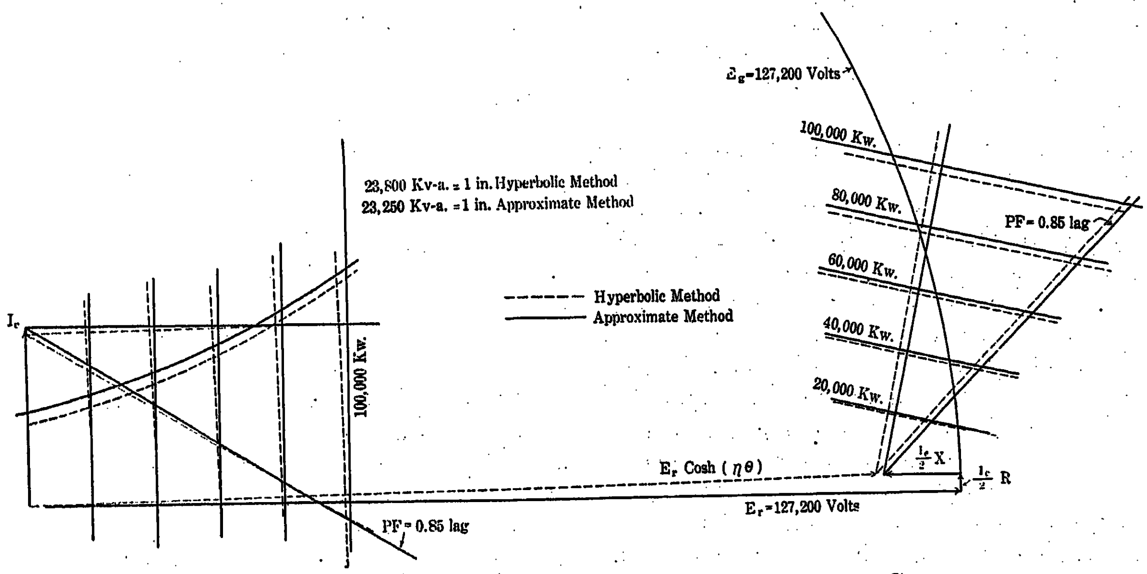

FIG. 4—COMPARISON OF HYPERBOLIC AND APPROXIMATE METHODS OF CALCULATION.

In closing, I wish to state that the purpose of my paper has been to outline a systematic method of procedure for the solution of the two fundamental equations of a transmission line. The form of the resultant diagram follows directly from the equations. Mr. Barfoed should feel great satisfaction in its simularity to his diagram, as it shows that, aside from a slight error due to distributed constants, it is fundamentally correct.

Developments in Telephotography

BY D. W. ISAKSON
Associate, A. I. E. E.
Utah Power & Light Company, Ogden, Utah.

Transmitting photographs, drawings, maps, etc., by wire or wireless is a problem to which a solution is near at hand, and the present paper is given anticipating the addition of this to our already long list of applied sciences. A brief history is given of the early beginnings, and some of the modern methods discussed; among the latter being Korn's and Belin's. The Leishman systems are discussed at length because the author has been particularly interested in their development and has been in intimate contact with both inventor and inventions.

In the present paper it is hoped that interest of the American engineer may be stimulated in this subject to the end that a successful solution might rightfully be attributed to American genius.

THE art of transmitting an optical image to a distance by means of an electric circuit, though we may trace its early beginnings back some seventy years or more, has hardly yet derived results which warrant its commercial application. The entire field today is confined practically to some three or four distinct systems all of which have produced excellent experimental results. And though it has not yet come to any widespread practical application, we may safely anticipate an early solution of the existing problems. Since this art may soon take its place with telephony, telegraphy, etc. as an applied science, the author believes that the present paper will be of interest to those who have followed, or have contributed to the development of this art, and in the following text will endeavor to describe briefly its history and outline briefly the fundamental principles of each important development. The Leishman Code System will be dwelt upon at greater length because of the more general use it has come into in America.

As stated in the preceding paragraph, *i. e.* the art of transmitting an optical image, the subject divides itself into two general heads; the first, of which may be termed television. This indicates the operation of reproducing upon the apparatus of the receiving station an animate object or image coming within the focus of the transmitting apparatus. Under the second head, which may be generally termed telephotography, and which consists in the reproduction upon receiving apparatus, of an ordinary or especially prepared photograph sent out as electrical impulses or suitable signals from the transmitting station. Though several, including Rignoux, Fournier, and A. Campbell Swinton, have suggested possible solutions the former remains as yet entirely chimerical, and in this paper discussion will be confined solely to the development of the telegraphic transmission of photographs.

The field for application of a system for telegraphing pictures economically is fairly obvious. Its use in warfare, in the speedy transmission of photos, maps, etc. should insure its early adoption by governments; the dispatch with which photographs and finger prints of wanted criminals could be transmitted to all the haunts of civilization would make it an invaluable instrument in the hands of the police in the discouragement of crime; and the growing demand for illustrated news argues well for its commercial development from the investors point of view. We find it, then, from every viewpoint, a much desired invention and one with a great mission to perform. Yet unlike other inventions equally needed, it has been nearly three-fourths of a century in coming to a practical state of development. Very naturally we may wonder at the reason for such slow progress, but very likely after a thorough study of the situation we should be unable to attribute a tardy success to any single one of a number of possible reasons. For we find it an intricate problem, involving complex combinations of the physics of light and of electricity and of the mechanics of motion, etc., and of peculiar properties of elements, compounds and substances which have differed widely from time to time as various investigators have attacked the problem. The chief difficulties that have been encountered by such investigators may be brought out in the following brief description of their individual processes and apparata, and thereafter we may draw conclusions as to their bearing upon the development of the science. From this, also, we may derive an adequate idea of the intrinsic value of the work of early experimenters, as their principles may affect or facilitate the work of subsequent investigators.

In ordinary telegraphy we find it quite impossible to transmit simultaneously the entire contents of a printed page. But by a simple process of splitting it up, first into lines then each line into the words that compose it and further, each word into its constituent letters, we may, by means of suitable signals, and by transmitting one letter at a time, reproduce the entire contents of the printed page to a distant station. The process in telegraphing a photographic image is fundamentally the same. Only one minute portion of the composite photograph can be transmitted at a given instant. These minute portions are arranged mechanically into lines and are read by suitable mechanical means. The apparatus therefore must necessarily consist of, first, a means for dividing the photograph into extremely small component parts; second, a means for interpreting the varying degrees of shading of each component part into varying intensities of electric current; third, a means whereby the variation in the electric current can again be interpreted at the receiving station into light and shade variation corresponding both in

Presented at the Pacific Coast Convention of the A. I. E. E., Vancouver, B. C., August 8-11, 1922.

intensity and in relative position with that of the original photograph. In practise, the third fundamental involves a fourth, that of maintaining exact synchronism in the mechanical motion of the sending and receiving apparatus. Having in mind these fundamental requirements which are common to all methods, we may proceed in a description of the varying ways in which they have been carried out.

As early as 1847 Bakewell constructed an apparatus whereby he was enabled to transmit telegraphically, drawings, handwriting and pen sketches over a distance of several miles. Though this cannot strictly be considered a system for sending photographs—photography at that date not being in a sufficient state of development to lend of its application in such a new and untried field—we may consider it the beginning, since upon the principles of this scheme have subsequent experimenters worked. It consisted essentially of two metal cylinders (one at the sending and one at the receiving station) which revolved synchronously under a stylus contacting upon the surface of each. The stylus was mounted upon a threaded shaft geared to the shaft of the cylinder. In operation the stylus was thus

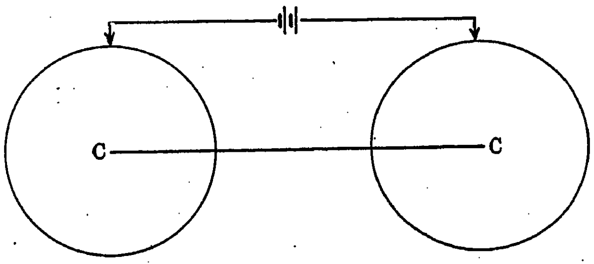

Fig. 1

caused to move laterally as the cylinder revolved and to trace a spiral path upon its surface. The subject sketch drawn in insulating ink upon a sheet of tinfoil was mounted upon the first cylinder. A sheet of chemically prepared paper was mounted on the second. The circuit was completed as in Fig. 1. With the current interrupted by the passage of a line of the insulating ink under the stylus, the electrolytic action of the current upon the paper at the receiving station receives a corresponding interruption. With the cylinders in perfect synchronism and the stylus having traversed the entire length of its screw shaft, the lines constituting the original drawing are reproduced upon the chemically prepared paper at the receiving end. To maintain synchronism a series of impulses was transmitted at regular intervals which electromagnetically actuated the clockwork which furnished the motive power for the apparatus. The difficulties in maintaining synchronism, distortion caused by the capacity and inductance of long cables, and other difficulties encountered caused an early abandonment of the scheme.

For many years thereafter no noteworthy results were obtained although several schemes were suggested. In 1859, an Italian priest, Abbe Casseli, had a model of his famous pan telegraph built. Casseli's apparatus, which was both original and ingenious, consisted of a swinging pendulum to which was fastened an arm carrying the stylus. The stylus was caused to trace a line over the surface of a plate which was shifted laterally the width of one line with each oscillation of the pendulum. The receiving pendulum was electrically actuated by a series of impulses caused by the closing of contacts by the transmitting pendulum with each oscillation. With this arrangement absolute synchronism was very easily maintained. The subject sketch was drawn with shellac ink upon the copper plate of the transmitting machine, and a paper prepared in a solution of ferricyanide was placed upon the plate of the receiving machine. Thereafter the actual reproduction was very similar to that of Bakewell, previously described. With this method, excellent results in transmitting handwriting, drawings, etc. were obtained at a comparatively high rate of speed. Perfect synchronism was easily maintained, but we find the field for such an instrument very limited as compared with the cost of construction and operation of stations, and consequently it, too, failed to be utilized commercially.

DeMeyer (1869), D'Arlincourt, Gras and other Frenchmen experimented on similar lines, but with no noteworthy results. In a process suggested by Amstutz we find probably the first concerted attempt to telegraph a photograph. In his process the photographic negative is printed upon a gelatinous prepared paper rendered light sensitive by the addition of bichromate of soda. The emulsion properly prepared has the property of becoming soluble in warm water after exposure to actinic light. The paper prepared with a thick coating of the emulsion is printed in the regular manner and further developed in warm water. The positive thus prepared will have an irregular surface representing the high lights by depressions or hollows and the shadows by hills or prominences. This positive replaced the tinfoil of Bakewell's process upon the transmitting cylinder. A stylus actuated a sort of microphone over its surface with the result that the current in the telegraphic circuit, instead of being periodically interrupted, was caused to vary in its strength, representing a light portion by a weak current and a dark portion by a strong current, since the diaphragm, while the stylus is passing over a prominence, is caused to compress the carbon grains, thus decreasing their resistance. The current in the line will then be theoretically proportionate to the shading of the original photograph at the point touched at any instant by the stylus. To translate such current variations into the black and white of a photograph, Amstutz proposed to use the received current in the direct engravure of a single-line half-tone. To accomplish this, the received current was to regulate, by means of electromagnets, the cutting depth of a *V*-shaped stylus upon a copper plate wound around the receiving cylinder.

Quite obviously such a receiving apparatus is out of

the question, since a current strong enough to perform so much work would necessitate a voltage for its transmission quite beyond the capacity of any transmitting device that could possibly be constructed. Thus, through lack of a receiving device, Amstutz failed. His transmitting device was later, however, to figure in the more or less successful scheme of Belin, which will be described in its due order.

In 1873, while conducting some experiments in which selenium was used as a resistance, Willoughby Smith was annoyed by the peculiar instability of his resistance and upon investigation found that selenium possessed the peculiar property of varying its electrical conductivity with the intensity of the light to which it was exposed. With the announcement of this discovery, several attempts were made to utilize these properties in various ways. Notable among these may be mentioned the cell constructed by Prof. Bell which played the principal role in the operation of his famous photophone. It was Shelford Bidwell who first suggested its use in the problem of phototelegraphy. He conducted

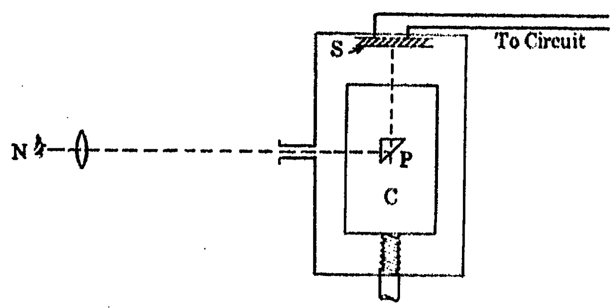

FIG. 2

some very interesting experiments in thus applying it, as did also Perry and Ayrton.

It remained, however, for Prof. Korn[1] of Munich actually to transmit and receive the first photograph by this means (probably the first to telegraph photographs by any means). His fundamental apparatus is depicted in Fig. 2, where C is a glass cylinder rotating upon a threaded shaft within a dark box and upon which is mounted the subject photograph printed on a transparent celluloid film. The prism P is so placed within the cylinder as to reflect the Nernst beam, which is focused through an aperture in the dark box, upon the selenium cell S, situated at one end of the box. Thus, having passed through the film, the light received by the selenium cell will obviously be a function of density variations in the photographic film as the cylinder rotates and moves laterally. And since the conductivity of the cell is functional with the light which acts upon it, the current in the telegraphic circuit will be at a given instant, directly proportional to the density of the silver deposit upon the film at the particular point through which the light beam instantaneously passes.

Theoretically, such a process encounters no difficulties. In practise, however, the characteristic recovery lag of selenium must be dealt with. If an abscissa represents the time and an ordinate the current, then the conductivity in a cell suddenly exposed to a light of given intensity for a time LO, may be represented by the curve in Fig. 3. Grantham[2] found by experiment that the resistance actually increased for an instant on exposure. Characteristic lag may be great enough in some instances to last over a period of several seconds, depending upon the purity of the selenium used, upon the construction of the cell, and in a measure

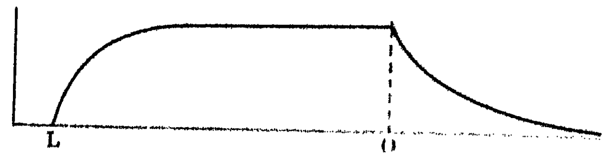

FIG. 3

upon the temperature under which the cell may be functioning, since its maximum sensitivity has been found to be at 0 deg. cent. Thus it will be seen that with the cylinder rotating at its lowest possible practiable speed, the detail of the original photograph will be lost to such an extent as to give an unrecognizable reproduction at the receiving station. Korn overcame this objectionable feature to a great extent by means of his compensation method. This comprises a bridge arrangement with a selenium cell in each arm. S is in a separate dark box and is acted upon by the light from the photograph. S' is in a separate dark box and is

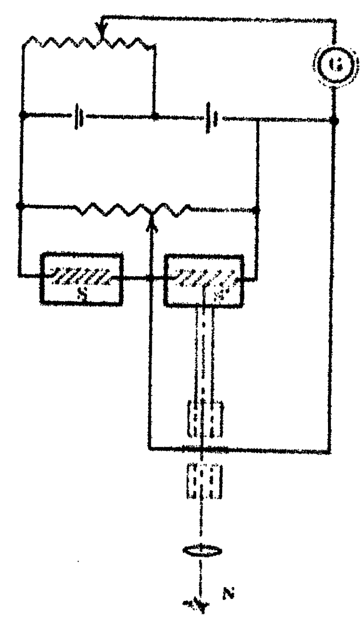

FIG. 4

acted upon by the light from a Nernst lamp. The Nernst beam is intercepted by a shutter electrically operated by the galvanometer G of a modified Einthoven type. With the passage of current in the circuit, the silver wire bearing the shutter is displaced, permitting a portion of the Nernst beam to fall upon S. With this arrangement Korn claims to have improved the sensitivity of the selenium circuit and to

1. T. T. Bakers "Telegraphic Transmission of Photographs."

2. Grantham, *Physical Review*.

have obtained an effect represented by the curve in Fig. 5. At the receiving end, the Nernst beam was focused upon a sensitized paper. Here again the beam was intercepted by the electrically operated shutter. The displacement of the silver wire bearing the shutter in the galvanometer field is theoretically proportional to the current which flows through it. Thus the light which falls upon the sentitized paper on the receiving cylinder will be proportional to the current in the circuit. To maintain synchronism, an impulse each revolution caused both machines to stop and reset to a

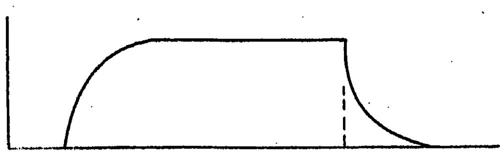

Fig. 5

predetermined starting point. With this apparatus Korn created considerable interest and its application in the journalistic field was attempted in several of the larger cities of Europe. In the extreme delicacy of the mechanism is found probably its greatest fault. Then, too, with difficulties encountered in maintaining synchronism, and the comparatively low sensitivity of the selenium cells, Korns selenium system was doomed to go the way of its predecessors.

Korn also realized its limitations, for he soon turned his genius to a system free from the inherent drawbacks of selenium. His next labors brought forth his tel-

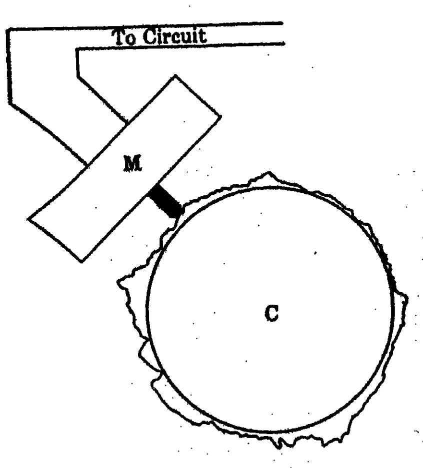

Fig. 6A

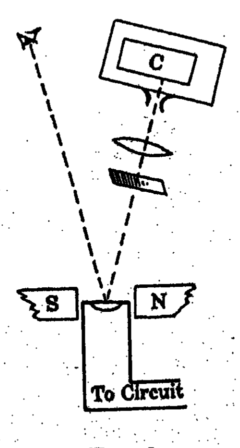

Fig. 6B

autograph. This consisted essentially of a combination of a metal drum and the use of his galvanometer receiving machine.

Of late M. Edouard Belin has come into the limelight of the telephotographic field and has created considerable interest in his telesteriograph, which he very recently brought to America to demonstrate. So much has been written in the daily press, in the technical and semitechnical periodicals of the country of M. Belin's apparatus, that its description must still be fresh in the minds of those to whose attention the present paper may come. It will be necessary here, then, only briefly to review the elemental principles involved in his apparatus.

As has been indicated above, Belin's process for transmitting utilizes the "relief" photograph as developed by Amstutz, and the sending apparatus is essentially the same as that above described. The scheme is depicted in Fig. 6A. At the receiving end, a Duddell type oscillograph is caused to reflect a beam of actinic light (the angle of incidence being proportional to the current in the galvanometric circuit) over a graduated screen containing, to all practical purposes, all the light variations from transparency to opacity (Fig. 6B). The light, thus varied in its intensity from passage through the screen, is focussed by means of a suitable lens through a small aperture in a dark box in which the cylinder carrying a sensitized paper or films revolves and moves latterly upon a threaded shaft. With the passage of a prominence under the stylus at the transmitting cylinder, the mirror of the oscillograph will be caused to reflect the light beam to the transparent end of the screen, and to the dark end

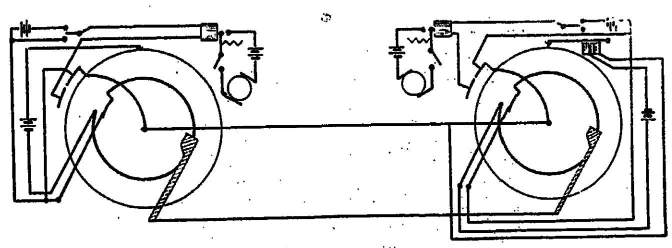

Fig. 7

with the passage of a depression under the transmitting stylus. Under development, the sensitized paper or film will represent a faithful reproduction of the original, providing of course that absolute synchronism be maintained between the sending and receiving machines. Some excellent results have been obtained with these instruments and we may hope much from M. Belin's scheme. The French government has been experimenting recently and it is generally understood that some unannounced developments have been made. In warfare, in the criminalistic field and similar applications, its utility seems practicable in the present state of development. In the journalistic field, however, the expenses which its operation entails in the sending of a single photograph make its practical application necessarily very limited.

Possibly the only systems for telegraphing pictures that have been developed in America and that have attained any notable success in the commercial field are those of L. J. Leishman. The first of his two systems was brought into experimental use by the government during the recent war.

His first system, called "screen process" because the preparation of the subject photograph is similar to the process used in preparing newspaper half tones, is meritorious in that it has done much to eliminate complex and complicated apparatus of previous methods. In this method the subject photograph is

printed through fine mesh screen, (the purpose of which is to separate the picture into its minute component parts) upon a copper plate coated with a solution of glue and bichromate of ammonia. The positive is developed in warm water and the glue solution is washed away in proportion to the light having acted upon it. The developed positive presents a surface of dots of varying sizes, areas of small or no dots representing the high lights and vice versa. For half tone work the plate of course much be etched which

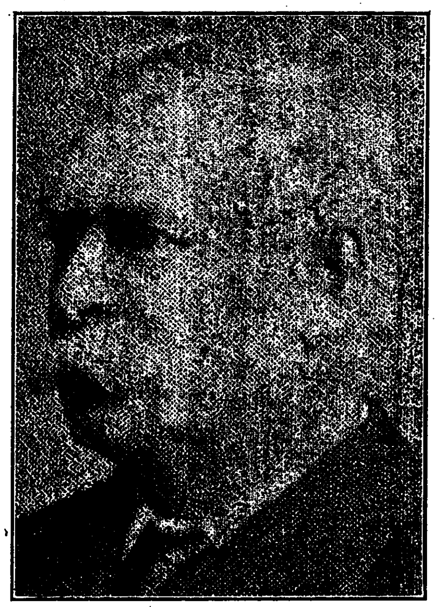

Fig. 8—Photograph of the Mayor of Los Angeles as Received by Telegraph

changes the plate again into a negative for printing purposes. With the glue only on the plate however, it represents a positive and it is in this state that it is used for picture telegraphy. The plate is formed into a cylinder and slipped on to the cylinder of the sending machine where a stylus traveling upon its surface and closing the telegraphic circuit, sends out electric impulses varying in length as to the distance between dots. Here we are brought face to face with a reincarnation of Bakewell's metal cylinder having on its surface drawings and writings done in insulating ink and rotating under the contacting stylus, and we may be struck with thought that it isnt such a very far cry from those early attempts of 1847 to the present-day attempts to solve the same problem. The similarity in the two methods ceases, however, with the sending cylinder and the contacting stylus. At the receiving station the impulses as sent by the sending machine are interpreted into the various tones of the original photograph by a means as simple as it is ingenious. The current in the telegraphic circuit passes through two electromagnets actuating an armature bearing a sapphire stylus at its end. Fig. 7. As the impulses from the sending apparatus pass through the electromagnets the stylus is brought to bear upon the receiving cylinder which has around it an ordinary piece of white paper over which has been placed a sheet of carbon paper. With each impulse then, a mark is made on the white paper and as the cylinder revolves synchronously with the sending cylinder the photograph is gradually built up. Fig. 8 represents a photograph received by this method.

In this system a novel and superior method of synchronizing is used. Korn, Belin and others have synchronized by momentarily stopping one or both of the revolving cylinders. In the newly developed method both cylinders are permitted to revolve continuously. This is accomplished by means of the relays controlling the motor circuit. Batteries actuating the relays are so connected that their current flow is neutralized when the machines are in synchronism. If one machine leads, current flows through the relay controlling its motor circuit and the motor is slowed down in proportion to the lead attained by the machine. It will readily be seen that this is a factor toward faster transmission, and very nearly absolute synchronism is maintained.

Interruptions to the circuit take place at an average speed of 250 times per second; a fact that renders its use on ordinary telegraph lines impossible, since the relays in general use are of a low-speed type. This objection may of course be overcome by vacuum tube relays. Mr. Leishman, however, unsatisfied with this, has turned his genius to what promises to be a long step forward for this science.

In the new process, Leishman utilizes the photoelectric cell in place of selenium, as used by Korn, in surmounting the inherent difficulties that limit its application. Selenium cells have been used during the

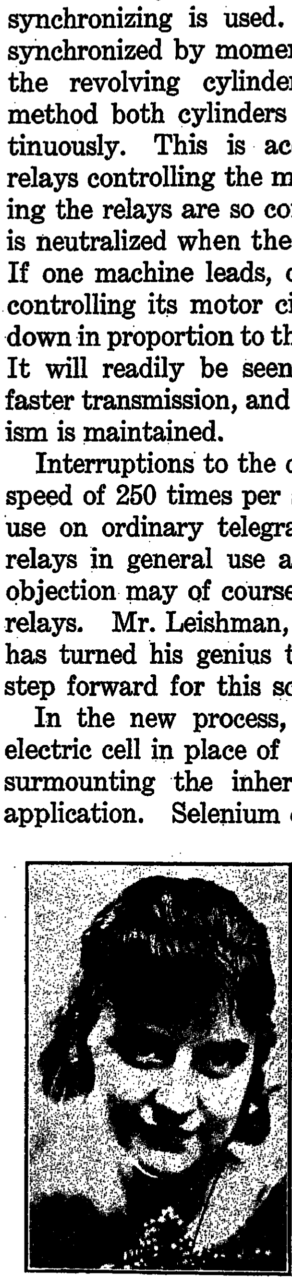

Fig. 8a—From an Actual Photograph which is to be Sent over the Wires

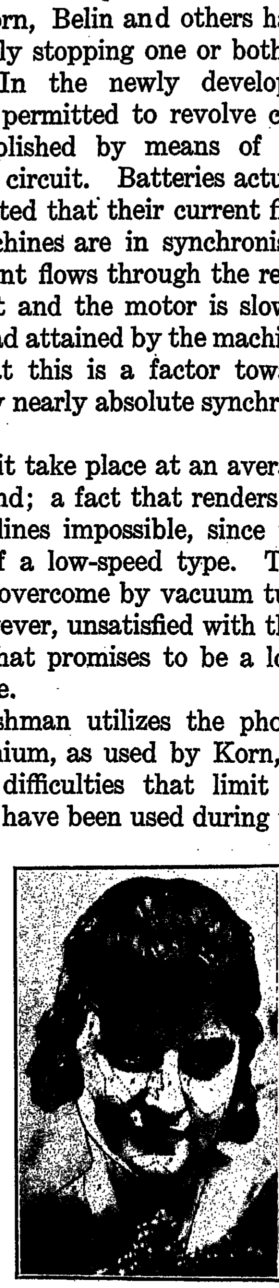

Fig. 8b—Photograph with Features Outlined and Shadows Divided into Five Degrees of Shade

last ten years in astronomical measurement of ight from stars and planets, but it has been discarded in this work owing to the time necessary for recuperation after exposure and to its susceptibility to climatic influences. Highly satisfactory, in fact we might say perfect, results have been obtained in this work in recent years by the use of the gas photo-electric cell as developed by Kunz. This cell recuperates instantaneously, is not susceptible to climatic conditions and

has the light sensitiveness of the human eye. With this system, a film on a rotating glass cylinder is used.

For receiving a picture transmitted by this process, Leishman has used a means that will entirely eliminate gravity, friction and mechanical inertia, factors which tend materially to limit the speed of transmission. An electromagnet carrying the current of the telegraphic circuit is caused to rotate in the plane of

a polarized beam of light. The degree of rotation is a function of the current in the circuit and the intensity of the light passing the second Nichol prism will depend on the degree of rotation. This method for varying the intensity of the light beam was first suggested by Rignoux and Fournier. This method necessitates the use of the film on the receiving cylinder through which the light beam is carried. This method pro-

duces a pure half-tone picture upon the receiving film.

We have seen that picture transmission consists essentially in building up a photograph at the receiving station by placing correctly component parts of the original and by giving each the proper degree of shading. Thus far the systems we have studied have accomplished this by mechanical means only and only a minute portion is transmitted at any instant. In a code system developed by Lieshman we find a deviation from previous practises and though it involves no new application of pure or applied science we may find it of interest in that it is novel and ingenious and has possibly found a wider commercial use than any other process thus far brought out. In this system a photograph is first split up into component parts; this first step differing from previous methods in that large areas comprising one single shade throughout comprise these parts. In Fig. 8b this first step is illustrated.

Being arranged primarily for rapid distribution of current photographs and illustrations for newspaper work this new system concerns itself with only five gradations of shade, further gradations being un-

Fig. 8g

The code system was perfected with the needs of a newspaper in mind. A newspaper uses 60 line screen in making its cuts, and therefore neither the original or reproduction would have the clearness or detail shown in these cuts of 100 line screen. The fine screen was used here to make them look as near like the actual pictures as possible, but on account of the detail shown by the fine screen the original and reproduction—A and F—do not look as much alike as they would if printed in a newspaper.

Not only is this due to the screen itself, but to the fact that detail that will not show clearly in a newspaper cut is *purposely* eliminated, as it is foolish to unnecessarily lengthen a photogram to include details that will not produce in a newspaper picture even if the original itself were used. To show that the code system more nearly meets newspaper needs than the previous cuts would indicate, A and F are herewith reproduced as they would appear in a newspaper—in 60 line screen.

necessary from the fact that only that number appear in the ordinary 60-screen newspaper cut. Each shade may be designated by a letter. In practise X indicates white; F light grey; I medium grey; K dark grey; and M indicates black. For outlining the areas of one solid shade a continuous line is used when its borders are abrupt and distinct, and a dotted line when two degrees of shade blend. After the picture has been divided in this way it is ready for the coding process. The apparatus consists of a drawing board with a scale across the top denoting the abscissa and an ordinary T square with a similar scale along its edges marking off the ordinates, (Fig. 9). The scale is divided into 18 prime divisions and each prime division into 18 subdivisions. For designating these divisions, letters are used instead of numbers for two reasons; first, there are nine digits, which with the cypher, make only 10 possible characters that can be used, while the alphabet

affords 26. With letters, therefore, any division and subdivision may be designated by only two characters; second, telegraph companies send five letters in code as one work but for numbers each digit is charged for at the word rate. Since in the scale designed only 18 letters are necessary, those most easily confused in telegraphing are omitted.

With the coding board any determined point on a picture, as fixed by a first coding board, may be accurately placed, relative to other points, by a second.

This is very similar to the familiar way of locating towns and cities on maps where longitude may be indicated by figures and the latitude by letters or vice versa. This for instance, were it desired to locate the town of Podunk in a certain map we find in the key

Telegraph rules permit five letters to a word in code messages and four are used in locating each point along a line. The remaining letter is used to indicate the various processes to the receiving operator; thus:

Letter *S* indicates beginning of a line
" *D* " end of line
" *A* " end of straight line
" *Q* " cusp
" *W* " end of straight dotted lines } shades
" *U* " cusp dotted } to blend
" *X* " white
" *F* " light grey
" *I* " medium grey
" *K* " dark grey
" *M* " black

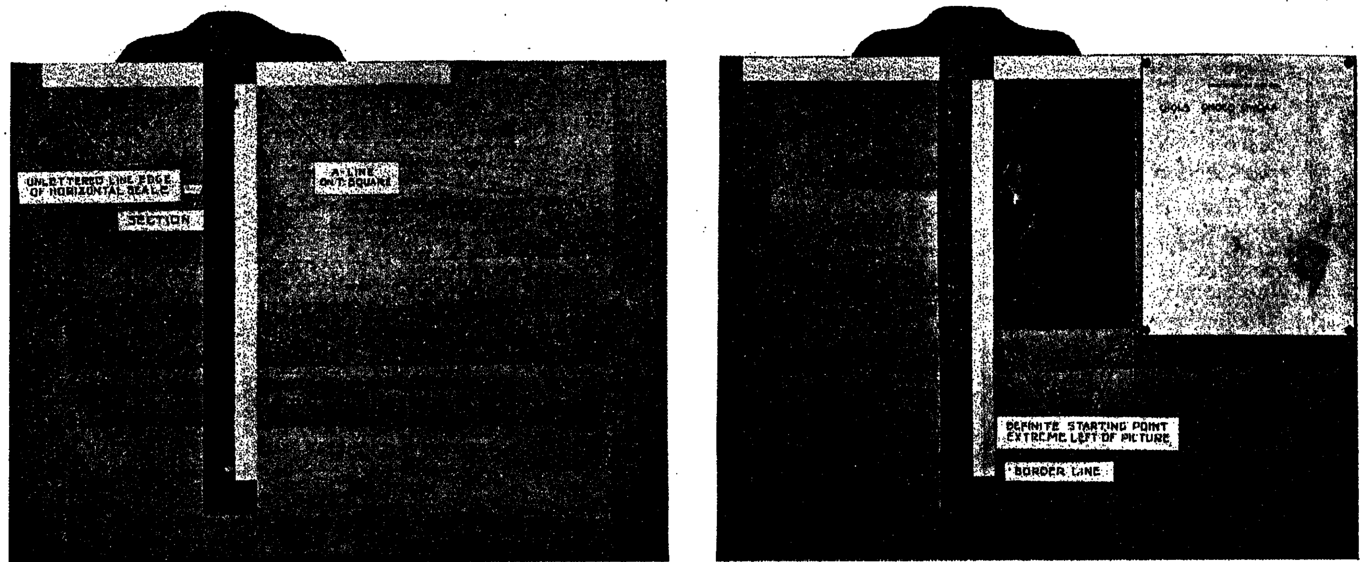

Fig. 9—Coding Board

opposite the name of Podunk the characters *R*-6. By this we know that the town is in proximity of the point where longitude 6 intersects latitude *R*.

Obviously in picture transmission utmost accuracy is necessary in properly fixing points and it is therefore necessary to use an infinitely great number of ordinates and abscissas. It follows therefore, that more characters are required to express the exact location of points. It is accomplished by using four letters; the first indicates the prime division on the vertical scale and the second the particular ordinate coming within that division. The third tells which of the prime divisions on the horizontal scale contains the abscissas indicated by the fourth letter. As an instance, *L G V I* indicates the co-ordinate of ordinate *G* in prime division *L* on the vertical scale and abscissa *I* in prime division *V* on the horizontal scale.

The lines circumscribing the various shades are divided having in mind the following two geometrical propositions; first, that two points determine a straight line and, second, that three points determine a circle. In coding a straight line the *T*-square is placed with the scale edge of the *T*-square on the first point. Both scales are then read and the *T*-square placed on the second point and scales read.

Letters indicating shading are given when the circumscribing line is completed, *i. e.* brought back to the point of beginning.

A finished picture is shown in the illustration, Fig. 10. This was reproduced from the code by an operator who had never seen the original. With this system hundreds of photographs are being sent through the Leishman Telegraph Picture Service Company to progressive newspapers in all parts of the country and though its scope is necessarily limited, due to an inability to code and reproduce photographs containing any great amount of detail economically, yet it seems that the field remains sufficiently broad to warrant its development.

Inasmuch as the code system is not electric, except as concerns telegraph instruments, and does not introduce any new principle of physics or mechanics into the field of applied science it may, perhaps, not be of great interest, considered from a purely technical standpoint. Yet, inasmuch as it has been more or less successfully used in replacing more intricate systems the author thinks he is justified in discussing it in the present paper. A photogram, as it has been termed by the inventor, may be relayed any number of times, lends itself to wireless as well as wire telegraphy and is never subject to static and magnetic disturbances

nor to the inherent evils of long telegraph and telephone lines; viz., capacitance, inductance, etc.

From the preceding description we may rightly conclude picture telegraphy is as yet far from the zenith of its possibilities. A broad field for investigation and experimentation in the application of new and untried laws and phenomena of chemistry, physics, etc.; as promulgated from time to time from the realm of pure science is unfolded to the engineer of tomorrow. Assuredly we may anticipate a great advance in this art during the next decade and we may be hopeful even

of a practical solution to the problem of seeing over a wire or by wireless, in fact, some of the foremost European scientists are even now devoting their energies to this end.

Discussion

R. J. C. Wood: Isn't the picture as received shown at Fig. 8 (D). I think that is actually what the receiving end gets over the wire and any exercise of imagination, as Mr. Hillebrand says, refers to (F). It would seem to me that these boundaries are determined by the co-ordinates of points along them, all around the boundary. That being so you then get these contour lines as shown on Fig. 8 (E). They are filled in with the particular shade according to one of the letters in the code corresponding to that boundary. You then get the Fig. 8 (E) as the final result received at the receiving end. The illustrator knows that nobody looks exactly like (D) and he makes it look a little better, like (8-F). Tele-photography means to a photographer taking very far distance scenes with a lens of long focus. Is this term telephotography standard in this sense of transmitting photographs to a distance by wire? The term is already fairly well assigned to the photographic science, and it would seem to me that some such title as photo-transmission or an equivalent would describe the process better than telephotography.

D. I. Cone: In that connection I note that the artist states "Under the second head which may be generally termed telephotography"—from which I gather that he is not satisfied that his word covers the subject. There are in the paper a number of references to the difficulties that have been encountered by workers on account of the inherent characteristics of the wire line. It seems to me that this is a hang over from earlier days when the transmission of signals over long electrical lines was less understood than it is now. As an example he states, "Interruptions to the circuit take place at an average speed of 250 times per second, a fact that renders its use on ordinary telegraph lines impossible since the relays in general use are of a low-speed type." That, while entirely true, is becoming less and less a limit, in fact it simply suggests that since he wants to use frequencies of the order of two or three hundred cycles per second he needs the telephone line as opposed to the ordinary telegraph circuit, or, what is equivalent to the same thing, the more recently developed carrier telegraph circuit which by merely modifying the terminal apparatus to handle higher frequencies is capable of caring for the high frequency on which his voids hinge. The earlier methods described in the paper can be said to have other difficulties at the present time entirely in the transmitting and receiving apparatus, and the question of troubles due to inductance and capacity on the line may be dismissed; and they say it is a bugaboo which can be most thoroughly taken into account to any degree of refinement that is necessary merely by spending a certain amount of money on it.

D. W. Isakson: As regards a name for the science of transmitting photographs over electric circuits I can only say that in this paper I have reverted to the term generally used and accepted by the technical and semitechnical press. An analysis of the word justifies its application. But as Mr. Wood points out it at present designates a division of photographic art and its inappropriateness therefore is not to be argued. It is to be expected that with the future development of the art appropriate nomenclature will be invented.

In the synopsis of this paper I have made the assertion that the solution to this problem of telegraphing pictures is near at hand. I have given no space to suggestions as to how this is to be accomplished. That the vacuum tube and carrier wave will play important roles in the development of picture telegraphy I have not the least doubt. In fact I am convinced that only by application of the carrier wave can it be made practicable, excepting perhaps radio. In this I have myself made some interesting experiments and hope to announce results in near future. Now as to Mr. Cone's suggestion of using telephone lines as a means of avoiding the difficulties encountered with low-speed relays, let me remind him of the telephone companies strict rules regarding the connection of foreign apparatus to its circuits. Neither is the low speed relay the insurmountable obstacle to success. It will be noted that in the Belin process and Lieshman's second system no interruptions take place. Here the current is continuous but varying in intensity. For this the vacuum tube relay has been used. The prohibitive cost of the arrangement with telephone and telegraph companies render both these systems impracticable from a purely economical standpoint. If by carrier wave we can send five or six photographs simultaneously and for the cost of, say two (allowing for added cost of apparatus) then we shall have taken a long stride toward ultimate success.

Recent Conclusions Pertaining to Electrical Precipitation

BY WALTER A. SCHMIDT
Member, A. I. E. E.
Western Precipitation Company, Los Angeles, California

Investigations into the phenomena of electrical precipitation of suspended particles from gases during recent years have resulted in some important conclusions. The purpose of this paper is to present these conclusions briefly, without entering into a detailed discussion of the actual equations used in designing precipitators, and of calculations embodying their use.

DURING the past few years considerable progress has been made in establishing an understanding of the relationship between the various factors entering into the phenomena of electrical precipitation of suspended particles from gases, and it is the purpose of this paper to set forth briefly some of the more important conclusions.

In the commercial application of the electrical precipitation process, as practised during the past ten years, many puzzling phenomena were encountered for which satisfactory explanations were entirely lacking. In fact, some of these phenomena appeared to be anomalies. As an example of such an apparent anomaly, we may take the relationship between precipitation efficiency and current flow. It had been early recognized that percentage of precipitation increased as the voltage approached the arcing point, and that the electrical discharge or current flow increased simultaneously and in a more or less definitely related manner. An apparent plausible conclusion was that precipitation efficiency was directly dependent upon current flow, and a review of the early work shows that much time and effort were expended in attempting to increase the corona discharge in certain commercial plants where precipitation results were lower than had been anticipated. Later, certain commercial problems were encountered where the very poorest results were obtained with the highest current flow, that is, with the most intense corona discharge. In fact, in one installation where the problem consisted of collecting thoroughly dry colemanite dust, at a California borax plant, the current could apparently be raised indefinitely without bringing about any appreciable precipitation results. The capacity of the electrical equipment at that plant was limited to 10 kw., but this total energy could be dissipated with ease in a 40-pipe precipitator without effecting any useful results.

For the purpose of this paper it will be unnecessary to enter into a discussion of the theory and practise of electrical precipitation, as these subjects have been thoroughly covered in published articles. For those who are not familiar with the subject, a selected bibliography is appended. Furthermore, R. B. Rathbun and G. H. Horne are presenting papers at this same meeting of the A. I. E. E., which review the subject briefly. For the purpose of this discussion, it is sufficient to say that electrical precipitation is accomplished by passing the fume-laden gas through a unidirectional electrostatic field in which a corona discharge is maintained. In practise, a precipitator consists of a multiplicity of opposing electrode units, one group being of such configuration as to facilitate corona discharge, the other group being of such form as to minimize or prevent discharge therefrom. The former are usually referred to as discharge electrodes, the latter as collecting electrodes. Discharge electrodes may consist of wires, chains, edged strips, serrated edges, or any

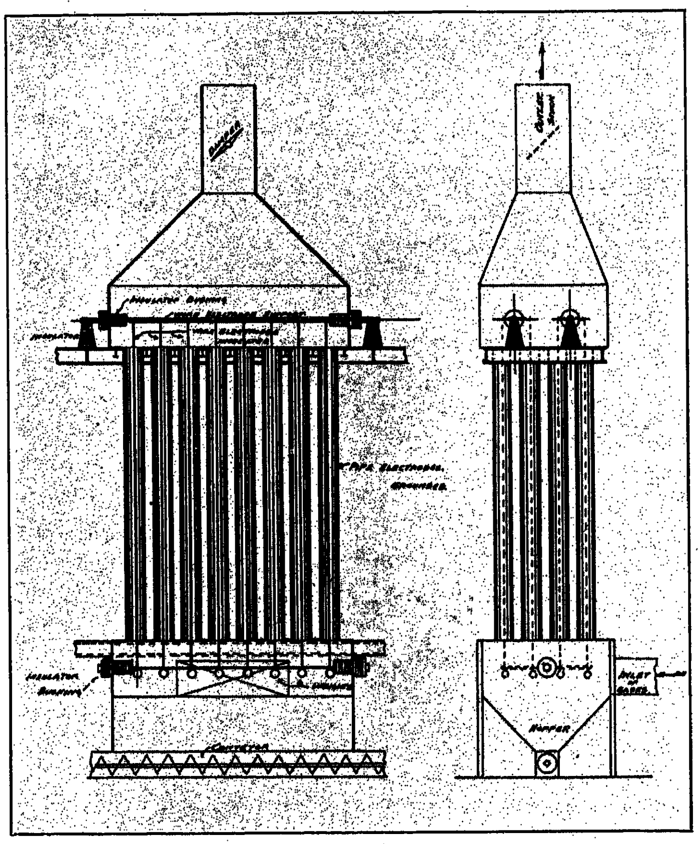

FIG. 1—SCHEMATIC DRAWING OF A PIPE TREATER

other form of conductor that will establish a sufficiently high potential gradient at or near its surface to cause corona discharge. Collecting electrodes may consist of plates, pipes, screens, closely grouped wires, or any other form or arrangement of conductors that will establish low field concentration and thus minimize or prevent corona discharge therefrom. Usually the collecting electrode system is of much greater weight than the discharge electrode system, and consequently is electrically grounded. The discharge electrode

Presented at the Pacific Coast Convention of the A. I. E. E., Vancouver, B. C., August 8-11, 1922.

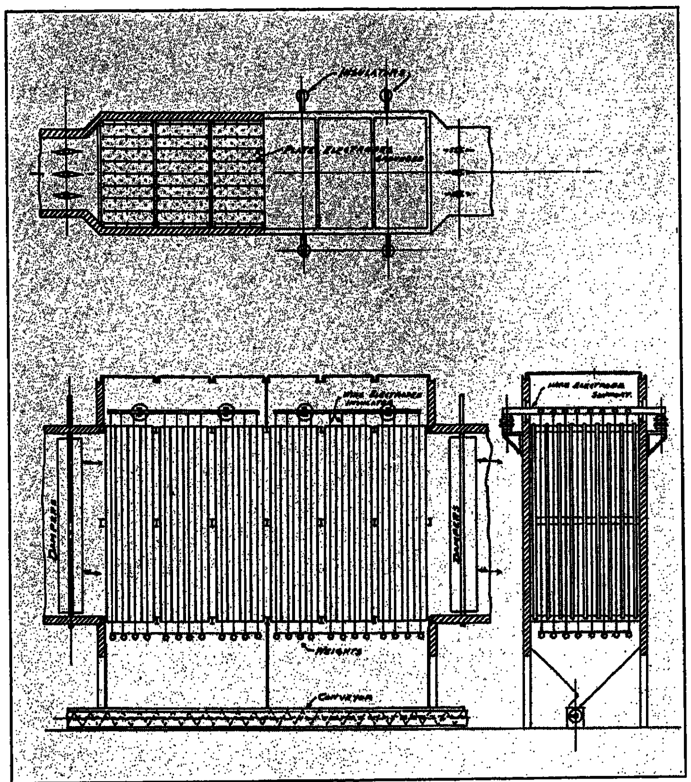

FIG. 2—SCHEMATIC DRAWING OF A PLATE TREATER

FIG. 3—PIPE TREATER INSTALLATION

system is mounted upon insulators and is usually charged negatively with respect to ground. The potential difference maintained between electrodes depends upon the electrode spacing and other circumstances, and ranges in different installations from 20,000 volts to 100,000 volts. Unidirectional current is supplied by rectifying high-tension alternating current. The precipitator has been given the name of treater, and the type of collecting electrodes designates the type of treater, as, for example, pipe treater, plate treater, screen treater, etc. The principle of precipitation is in each case the same, the choice of treater depending on circumstances dictated by engineering considerations. Fig. 1 is a schematic drawing of a pipe treater; Fig. 2 is a similar schematic drawing of a plate treater; Fig. 3 is an illustration of a pipe treater installation; Fig. 4 gives a view of a plate treater; Fig. 5 shows a typical electrical control room, and Fig. 6 a typical wiring diagram.

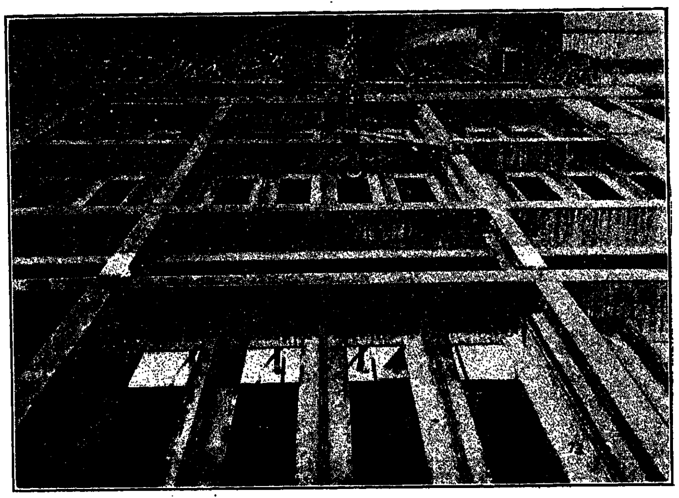

FIG. 4—VIEW INTO A PLATE TREATER

FIG. 5—TYPICAL ELECTRICAL CONTROL ROOM

EFFECT OF DEPOSITS

As already stated, it is sufficient for the purpose of this discussion, to consider that the fume-laden gas is passed through a unidirectional electrostatic field in

which a corona discharge is maintained. However, it must be emphasized that this unidirectional discharge should emanate only from the discharge electrode and travel to the collecting electrode. We shall see that when this condition, which we can call normal, is disturbed, control of precipitation is lost and severe practical difficulties result.

For simplicity we can limit our immediate discussion to a small section of a pipe treater, that is, a short length of pipe, electrically grounded with a negatively charged wire placed along the axis of the pipe. When the voltage is raised above the critical potential, a corona discharge is established, the gas immediately around the wire becomes ionized, and the resultant ions travel either to the collecting electrode or to the discharge electrode, depending on whether they are negative or positive. However, those negative ions which once leave the zone of ionization, travel toward

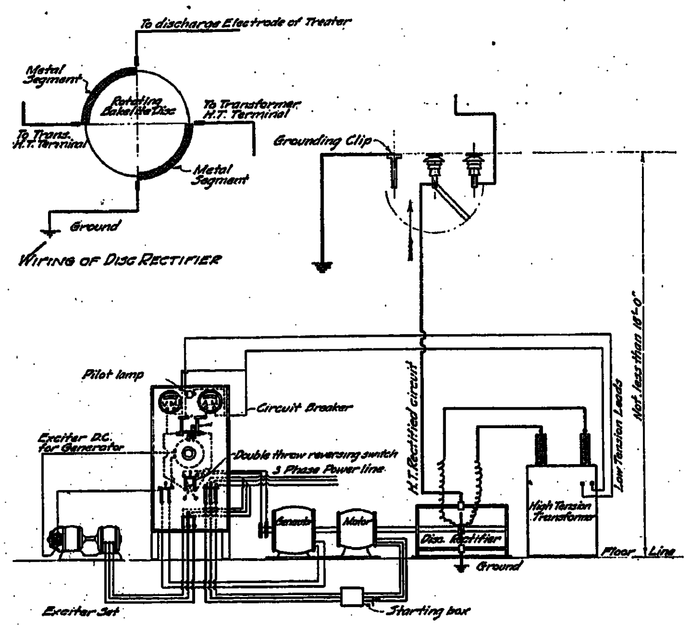

Fig. 6—Typical Wiring Diagram

the collecting electrode and give up their charge to this grounded electrode. Should the gas in the tube carry suspended liquid or solid particles, such particles as come within the zone of ionization may become either negatively or positively charged and thus be either repelled from or drawn to the discharge electrode, while those particles which remain outside of the zone of ionization, become negatively charged and are forced over to the collecting electrode. In practise it is found that a certain amount of the precipitated material is always collected upon the discharge electrode, but by far the greater part of the precipitate is always collected on the grounded collecting electrode.

However, as soon as material commences to collect upon the electrodes, conditions in the precipitator change. To refer again to our short tube: It was stated that the ions traveling to the collecting electrode must give up their charge to this grounded electrode. If this were not accomplished, a banked charge would result and discharge would cease. The same is true with charged particles of mist, dust or fume, when they are deposited upon the electrodes. If they do not give up their charge, one of two things must result; either the material will build up a continuous impervious dielectric and accumulate an electric charge upon its surface until discharge ceases, or the material will build up as a porous or discontinuous dielectric, which also will accumulate a charge upon its surface, but with quite different results. As this is a type of deposit which frequently must be dealt with in practise, it deserves special consideration and we will return to it in a moment. The continuous impervious dielectric is rarely, if ever, encountered in practise, and the fully conducting deposit which readily gives up its charge is only infrequently encountered, except in the case of mist precipitation, as for example, sulfuric acid mist. The usual deposit obtained when precipitating dust or fume, is but poorly conducting, due, in part, to poor conductive properties of the material, and, in part, to the poor contact between the precipitated particles themselves. As this is a common type of deposit, and as the handling thereof has presented many serious difficulties, we will be justified in discussing at some length its properties as well as its effects.

E. R. Wolcott has shown (*Physical Review*, N. S., Vol. XII, No. 4, October, 1918) that when a discontinuous dielectric covers an electrode, it acts in all respects as though the electrode had sharp projections at the points of discontinuity of the dielectric; that is, it establishes a point discharge. In other words, it establishes a discharge at the point of discontinuity, of a nature similar to the discharge that would result if the dielectric were replaced by projecting conducting points. It follows that such discontinuous dielectric, when placed upon an electrode, causes a lowering of the arcing voltage. A porous non-conducting deposit acts very similarly and apparently for the following reasons. Such a deposit consists of minute particles separated by equally minute gas spaces. As the solid particles and the gas will have different dielectric properties the electric field will be concentrated at the points of contact or approximate contact of the solid particles. As the charge accumulated at the surface of the deposit increases, and the field through the deposit increases, the field intensity at these points of local field concentration will rise sufficiently to cause ionization of the gas within the interstices in the deposit. Once this condition is established, the deposit becomes an ionizer or source of discharge, with most disastrous results so far as precipitation is concerned. In the first place, the gas immediately adjacent to the deposit becomes ionized and this results in a decrease in the dielectric strength of the gas between the electrodes and causes a lowering of the arcing voltage, as Wolcott has shown. Secondly, the deposit being an ionizer, causes an increase

in discharge with consequent increase in power consumption. Thirdly, and most important, both electrodes become sources of discharge, and although instruments placed in the electric circuit will indicate a unidirectional current flow, still we will have two opposing discharges of opposite sign, one emanating from each of the two opposing electrodes. Any dust or fume particle placed between these two discharges will be buffeted back and forth, but may fail to be precipitated on the electrodes. In other words, such a deposit will cause three undesirable results, namely, lowering of the arcing voltage, useless dissipation of energy, and interference with normal precipitation. The following results obtained at a lead smelter, illustrate the effects resulting from the formation of such a deposit:

Condition of Deposit	Power Consumption	Precipitation Voltage	Precipitation Efficiency
Non-conducting.......	7.2 K. W.	52,000 volts	74 per cent
Conducting...........	5.0 K. W.	70,000 volts	97 per cent

As was stated early in this discussion, it is essential that the electric discharge shall emanate from the discharge electrode and travel to the collecting electrode if normal precipitation is to be accomplished. When materials are collected which tend to form porous dielectric deposits, it is, therefore, essential that conditions must be so changed as to prevent the formation of such a deposit. This can be done in several ways. The material to be precipitated may be changed through the introduction of substances which will cause the deposit to become conducting, as, for example, the addition of acid mist, carbon smoke, or any other convenient conducting material. Or, the gases may be so changed as to cause a surface leakage over the particles composing the deposit, which is often readily accomplished through the addition of moisture to the gases to increase the humidity thereof. Or, conducting materials may be added directly to the electrodes, as, for example, water or acid. Only a slight conductivity is necessary, as a current density as low as one milliampere per 30 sq. ft. of deposit is not uncommon. We are all familiar with the effect of humidity on the operativeness of electrostatic influence machines, where a slight surface leakage is sufficient to prevent the building up of a charge. A similar leakage is amply sufficient for drawing the charge through the deposit in a precipitator.

It is obvious that some deposits will exhibit much more serious effects than others, depending upon the degree to which they will accumulate a surface charge. In certain cases the discharge from the deposit, or back ionization, as it has been called, is sufficiently heavy to be clearly visible when viewed in the dark. Under such conditions, precipitation virtually ceases, the current flow will mount to many times its normal value, and the arcing voltage may be lowered as much as 50 per cent below its normal value. In other cases the back ionization is very mild and this will be manifested by a correspondingly small decrease in the arcing voltage. In such cases it often will be noticed, with a mixed dust and fume, that the decrease in efficiency will be greater on the fume than on the dust, possibly due to the fact that the relatively heavy dust particles can be shot through the thin reverse discharge caused by the back ionization, while the relatively light and small fume particles are arrested in their course, discharged, then recharged and repelled from the collecting electrode.

From a practical point of view, this can all be summarized by saying that the deposit upon the collecting electrode should, at all times, be kept conducting.

Factors Bearing upon Precipitation Efficiency

A series of investigations recently conducted by E. Anderson and G. H. Horne, has disclosed some interesting and valuable information on the relationship between various factors bearing upon precipitation efficiency. This information can be summarized in a number of conclusions. Of primary importance is the relationship between precipitation efficiency and gas volume. Anderson has shown that the curve expressing this relation follows an exponential equation. Secondly, he has shown that with a given definite gas volume, the precipitation efficiency is a function of the length of discharge electrode and again follows an exponential equation. Thirdly, Anderson and Horne have shown that each combination of gas and fume has certain specific properties when considered from a precipitation viewpoint, and that these properties can be expressed numerically as a constant to be included in the precipitation equation.

The value of these three conclusions cannot be overestimated, as they bring order out of chaos in the mass of puzzling and apparently conflicting data that have been accumulated during the past ten years. All that is necessary now is to determine the value of the precipitation constant that applies to any specific problem, and all other considerations then follow in a perfectly orderly manner, according to definite mathematical relationships. The precipitation constant can be easily determined by experiment, or, where a familiar problem is under consideration, it may be drawn from experience. We will pass over the relationship between different types of electrodes, as discussion of these factors lies outside the scope of this paper, being in the province of the specialized engineer. The choice of type of treater, type and size of electrodes, electrode spacing, operating voltage, etc., are dependent upon engineering considerations, and can be dictated by experience only. The important generalized conclusion which it is desired to emphasize here, is that all types of precipitators behave in a similar manner, the effectiveness of one being expressible in terms of the other, and that after allowance is made

for the type of treater, precipitation efficiency is then expressible in the terms of an exponential equation, which equation involves a precipitation constant expressing the properties of the fume-laden gas under treatment, and which has as its variables the length of discharge electrode and the gas velocity.

The following table shows the close agreement between calculated and observed values for precipitation efficiency:

Type of Treater	Character of Fume	Gas volume cu. ft. per min.	Efficiency Observed per cent	Calculated per cent
Pipe..............	Potash fume	23,000	86	86
Plate..............	Potash fume	18,000	75	71
Pipe..............	Cement dust	150,000	94	92
Pipe..............	Metallic chloride	15,000	97	98.8
Pipe..............	Lead fume	102,000	82	85
Plate..............	Bismuth fume	5,000	90	92
Transverse screen	Potash fume	1,000	73	75

Considering the wide variation in both the character of fume and the gas volumes handled, the agreement between calculated and observed efficiency values is quite satisfactory.

With this definite knowledge at our disposal, it is now possible to calculate the optimum size of a precipitator for any specific commercial installation where the most economical recovery of valuable dust or fume is under consideration. A. A. Schmidt has developed a formula to be used for this purpose, which equation is of the form

$$x = a\left(\frac{\log \dfrac{b}{c \log d}}{\log d}\right)$$

In this equation a is the gas volume to be treated, b is a function of the unit cost of the precipitator, the rate of interest and depreciation and cost of labor and power. The value of the solids carried by the gases is represented by c, d is a function of the specific precipitation rate for the fume or dust considered, and x is the optimum size of the precipitator.

It should be emphasized that the equations pertaining to precipitation efficiency apply only while normal precipitation is being performed. If a porous dielectric deposit is accumulated upon the electrodes and back ionization is established, normal precipitation is obviously interfered with and these equations can no longer be applied.

It should also be emphasized that the precipitation constant is in itself a variable and that its value is only constant for a specific set of fume and gas conditions, and shifts with changes in gas composition, temperature, fume composition, fume concentration, physical state of subdivision of dust or fume, etc.

To make these last statements clear, it might advantageously be said that it is not only the average value of the precipitation constant that is of interest in designing a commercial installation, but consideration must also be given to the limits through which the value of this constant will fluctuate with variations in factory operations. For example, in treating the gases from a single copper converter, different precipitation constants apply at different stages in the converting operations. If the matte fed to the converter contains appreciable quantities of lead and zinc, the gases arising from the first part of the blast will carry a lead and zinc fume, while during the latter part of the blast the gases will carry essentially fine copper pellets or dust mixed with some copper fume. Also, a constantly rising temperature must be dealt with. Furthermore, as lead and zinc fumes have the faculty of forming deposits which easily lead to back ionization, care must be taken to insure at all times the deposition of a conducting deposit. In designing a plant to take care of such a problem, a precipitation constant must be chosen which will represent the most difficult conditions to be encountered under the varying operating conditions. The example chosen is, of course, an extreme case, and the engineer is rarely called upon to design a plant to operate on such a varying load. Usually the precipitation constant will vary within rather close limits, and ordinarily these limits can be readily determined before design of precipitator is undertaken.

Anderson and Horne, in their investigation, have again confirmed earlier determinations upon the effect of voltage. It is now clearly established that precipitation efficiency rises rapidly as the voltage increases, and that for best results, the voltage on a precipitator should be kept as near the arcing point as is consistent with smooth operation. As voltage has a direct bearing upon precipitation efficiency, the question will be asked as to why this variable has been ignored in the previous discussion. This is because commercial installations are always operated at the maximum stress permissible with smooth operation, and consequently the voltage variable can be disregarded.

The purpose of this paper is merely to present some of the conclusions which have been drawn from recent investigations, and to make these available to the engineer. A detailed discussion of the actual equations used in designing precipitators, and calculations embodying their use, have been purposely omitted because, after all, the choice of precipitator types and the analysis of the factors entering into the phenomenon of precipitation, can be properly accomplished only by the experienced specialized engineer, and his ability to do this is part of his stock in trade. However it is hoped that present-day conclusions have been sufficiently clearly and fully set forth to show that the former puzzling and perplexing data and apparent anomalies have been coordinated into a consistent whole, and that, after all, the phenomenon of precipitation is consistent as well as relatively simple in its essential fundamentals.

Summary

1. Many types of fume and dust when deposited on the electrodes comprising an electrical precipitator form porous dielectric deposits.

2. Such deposits establish back-ionization and will cause three undesirable results, namely, lowering of the arcing voltage, useless dissipation of energy, and interference with normal precipitation.

3. To prevent the formation of such deposits, conditions must be so changed as to insure the deposition of an electrically conducting deposit. This can be accomplished in several ways.

4. The relationship between precipitation efficiency and gas volume can be expressed by an exponential equation.

5. For a definite gas volume, precipitation efficiency is a function of the length of discharge electrode and also follows an exponential equation.

6. Each combination of gas and fume has certain specific properties when considered from a precipitation viewpoint, and these properties can be expressed numerically as a constant to be included in the precipitation equation.

7. All types of precipitators behave in a similar manner, the effectiveness of one being expressible in terms of the other.

8. After allowance is made for the type of treater, precipitation efficiency is then expressible in terms of an exponential equation, which equation involves a precipitation constant expressing the properties of the fume-laden gas under treatment, and which has as its variables the length of discharge electrode and the gas velocity.

9. With this definite information available, the optimum size of precipitators can be calculated.

10. The equations pertaining to precipitation efficiency only apply while normal precipitation is being performed and do not apply when the deposit on the electrodes establishes back-ionization.

11. Precipitation efficiency rises rapidly as the voltage increases and commercial installations should be operated at the maximum stress permissible with smooth operation.

12. The precipitation equations and calculations embodying their use are omitted for reasons set forth.

Electrical Engineering Features of the Electrical Precipitation Process

G. H. HORNE

Associate, A. I. E. E.

Western Precipitation Company, Los Angeles, Cal.

Review of the Subject.—*In the beginning, the Cottrell Process of Electrical Precipitation was greatly handicapped by the fact that there did not exist standard electrical equipment which could be used to develop the necessary potentials under the severe conditions imposed by the mechanical rectifier, used for rectifying the high-potential alternating current. The transformers used were a constant source of trouble and annoyance. This condition delayed the rapid accumulation of accurate data pertaining to precipitation phenomena, since those engaged in the work were kept busy in merely maintaining a source of power.*

It was not long, however, before the electrical manufacturing companies were interested in the problems involved, and better transformers were produced. These transformers have now been developed to a degree which is very nearly the equal of the ordinary power transformers of the same voltage ratings. For several years there was a demand for higher and higher voltage ratings, owing to the belief that through the use of very high potentials and consequent large electrode spacing the size and cost of precipitators could be greatly reduced. Potentials as high as 250,000 volts were experimented with, but such high voltages proved to be impractical.

Transformers as now standardized are in two voltage ranges, one with a maximum voltage of 75,000 volts having taps in the low tension to deliver 50, 60, 65 and 70 kilovolts, the other having a maximum voltage rating of 100,000 volts with taps in the low tension to deliver 50, 62½, 75 and 87½ kilovolts. These transformers are manufactured in 10, 15 and 25 kv-a. capacity.

CONTENTS

Source of Power

In all plants in commercial operation today the low-tension current is supplied to the transformer in accordance with one of two systems. These are known as the synchronous motor system and the motor-generator system, and are shown by the wiring diagrams, Figs. 1 and 2 respectively.

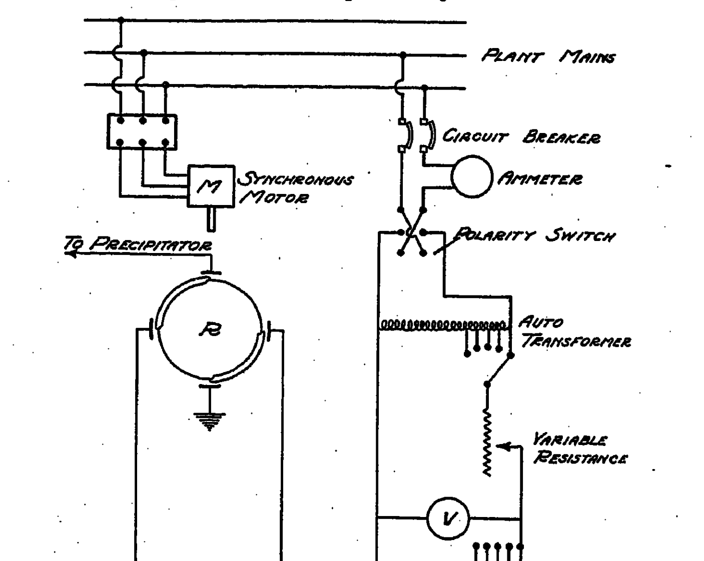

Fig. 1—Wiring Diagram—Synchronous Motor System

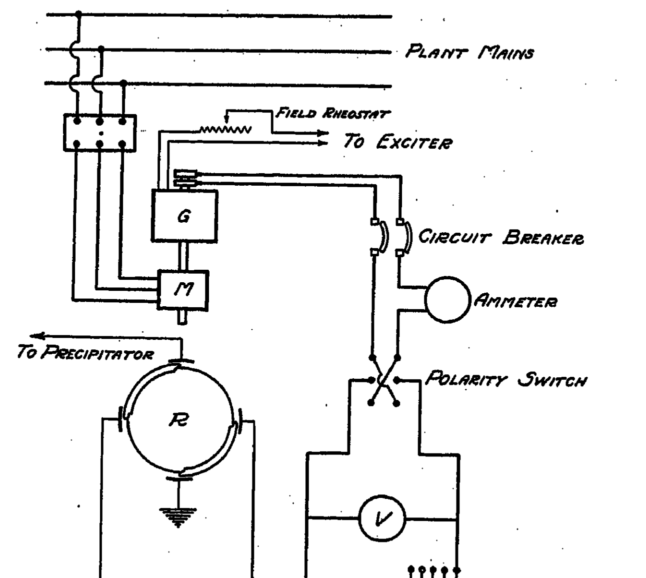

Fig. 2—Wiring Diagram—Motor-Generator System

In the synchronous motor system, the power is supplied to the transformer from one phase of the regular factory three-phase main. The mechanical rectifier is driven by a synchronous motor from which this system derives its name. This motor is usually a three-phase synchronous motor and is self-starting. It consists of a standard four-pole induction motor in a 3 horse power frame, the rotor of which has been slotted or under cut at four places in its circumference to emphasize the poles. As built, the best types of these motors possess the ability to pull into synchronism on voltages as much as 30 per cent below normal, and will deliver approximately two h. p. without slip. The greatest advantage of this system is its low cost. Where this system is employed, care must be taken in starting up to apply negative polarity to the electrode system. This is indicated by a spark gap at the rectifier and

Presented at the Pacific Coast Convention of the A. I. E. E., Vancouver, B. C., August 8-11, 1922.

controlled by a polarity switch. The voltage regulation is usually accomplished by a variable resistance in connection with taps in the low tension of the transformer winding, although in some cases auto transformers or induction regulators or any combination of these are in use. As stated above, in this system the transformer is connected directly to the plant mains and this has been the source of much discussion in connection with disturbances in the precipitation circuits being reflected back on these mains, but tests which are borne out by experience show that any such disturbances do not manifest themselves in external circuits.

In the motor-generator system a motor is used to drive a single-phase four-pole generator which supplies

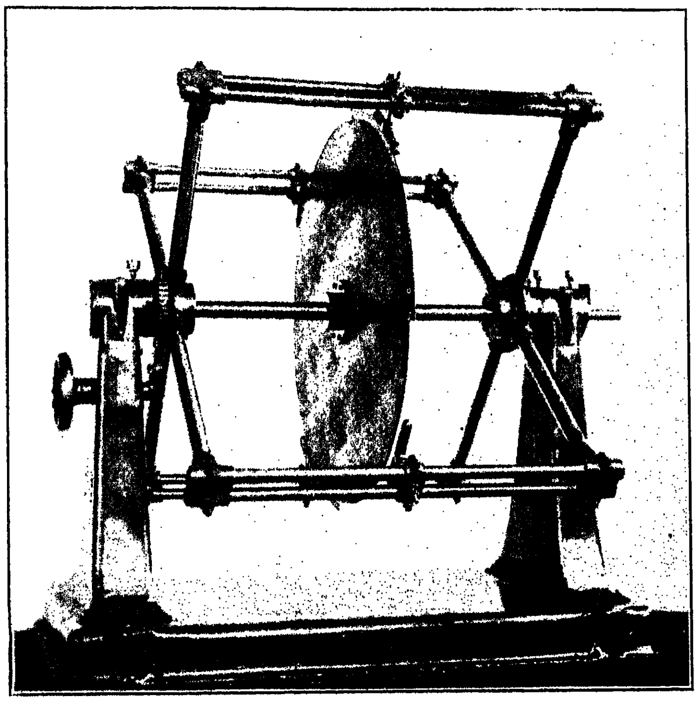

Fig. 3—Mechanical Rectifier

power through the switchboard to the low-tension windings of the transformer, and this motor is also coupled to the rectifier. As the generator and rectifier are mechanically connected, the latter is always in synchronism with the current which it is rectifying. In this system the voltage regulation is secured by means of the generator field rheostat in connection with the taps in the low-tension winding of the transformer. There is no electrical connection between the precipitation circuits and the factory mains, and this eliminates all possibility of disturbances passing from one to the other.

A third system has been proposed which, however, has never been used. In this the transformer would be eliminated and power taken directly from existing high-tension power lines through proper protection and switching devices, and the current rectified by a synchronous motor-driven rectifier. This system will probably never come into actual use as it is doubtful if any company would care to connect a high-tension line to this class of service.

There is no marked difference in the precipitation results obtained from either of the two systems in use, as the same voltage can be maintained on the precipitator by either system, and insofar as power supply is concerned, precipitator voltage is the important factor bearing upon precipitation efficiency.

Methods of Rectification

As indicated above, it is necessary to supply the discharge electrode system with unidirectional current in order to obtain maximum precipitation efficiency. This does not mean that a regular direct current is necessary. In fact, it has so far not been definitely proved that direct current possesses any inherent advantage over the pulsating unidirectional current obtained through the use of the mechanical rectifier.

A typical mechanical rectifier is illustrated in Fig. 3. It consists of a bakelite disk to the periphery of which are attached two quadrant metal strips opposite each other, these constituting the moving conductors. The four stationary shoes are so mounted that they may be rotated about the disk through 90 deg. by means of a hand wheel, pinion and gear segment. The length of the stationary shoes and the length of the moving conductors determine the length of contact on the wave, and the position of the shoes about the disk, as adjusted by the hand wheel, determines the portion of the wave rectified. On the rectifier illustrated, the shoes cover approximately 25 per cent of the wave. Mechanical rectifiers of this general type are the only rectifiers which have so far proved successful in commercial operation, and, as a result, are the only kind in use at this time. While they are far from perfect in many respects, they do possess the advantage of substantial construction and simplicity of operation requiring a minimum of attention. In other words, they embody features of reliability not yet attained in other types. The greatest single objection to them is that the high-tension circuit is made and broken in air, generating high-frequency oscillations, which place abnormal electrical strains on the transformer. Apparently these oscillations do not markedly affect the efficiency of precipitation, at least no tests have shown any appreciable lowering of efficiency from this cause. Another objection to the mechanical rectifier is that it is noisy in operation due to the arc which is drawn out at the trailing end of the rotating segments. However, the noise as well as the oscillations may be fairly well damped out by the use of proper resistance in the high-tension circuits. A further objection to the mechanical rectifier is its low efficiency due to the air gap which must be broken down at each of the stationary shoes. There is an unavoidable voltage drop over the rectifier and it has not been found possible to eliminate this, owing to the high peripheral speed of the disk, which makes metallic contacting impractical.

Another type of rectifier is the kenotron, which is a

vacuum tube conducting current in one direction only by means of electronic emission from an incandescent electrode. This type of rectifier has many promising features as it does not possess a number of the disadvantages of the mechanical rectifier. However, such rectifiers have the disadvantage of being fragile and consequently require much care in handling. Moreover they do not stand short circuits and must be protected by a system of automatic relays since short circuits in the precipitator may be of frequent occurrence. The current-carrying capacity of such a rectifier is limited by the rate at which electrons are liberated from the incandescent filament. The life of such a rectifier is limited, but with the kenotron this has now been extended to approximately 2500 hours. As yet, no large commercial precipitation installations have been made with kenotrons as the sole means of rectification. Investigations are now under way at one of the larger smelters in the United States in which comparative studies are being made of the kenotron and the mechanical rectifier with the object of determining their respective merits over long periods of operation.

A third method of rectification is by means of the air blast rectifier. This method has not been carried beyond the experimental stage as it was found to possess all of the disadvantages of the mechanical rectifier in an aggravated form. This rectifier consists of a discharge point facing a plate. The pointed rod is located so as to project from a tube through which compressed air is blown around the point toward the plate. This apparatus acts as an electric valve, allowing only the positive discharge to flow across the gap to the plate. The only advantage which rhe air blast rectifier possesses is cheapness.

Direct Current

So far as is known, there has been only one serious attempt made to produce a direct-current generator for precipitation work. This was made several years ago by the Girvin Electrical Development Company of Philadelphia, working in conjunction with the Research Corporation of New York. Several machines were built of about 10-kw. capacity which delivered current at 50,000 volts. Also one 75,000-volt generator was built. Fig. 4 shows the commutator of one of these generators. These machines were of the vertical type, belt-driven, with a rotating field and provided with intermediate commutating poles. The armature coils were submerged in oil. The case carrying this oil being partly located in the magnetic field, was made of bakelite. The individual coils of the armature were brought up to a commutator which consisted of a number of disks one of which served as a commutator for each armature coil. The disks were interconnected so as to add the voltages of all coils and deliver the power to a single high-tension lead. The other end of the system was grounded. These machines were 33 inches in diameter and 62 inches high, making a very compact unit when the capacity and voltage rating are considered.

Comparative tests made between one of these generators and a mechanical rectifier indicated that the generator gave slightly better results, so far as precipitation efficiency is concerned, but the superiority was not sufficiently great to warrant further development work.

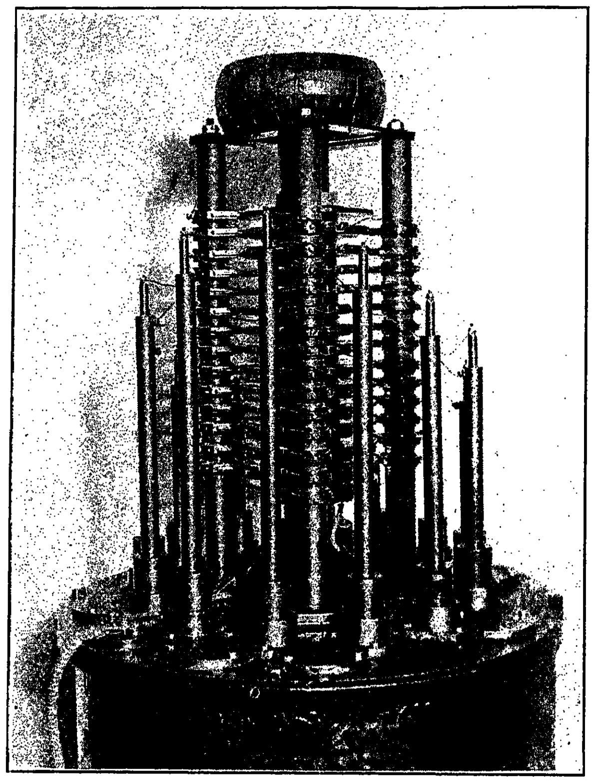

Fig. 4—Commutator of D-C. 50,000-Volt Girvin Generator

Relation between Precipitation and Impressed Voltage

In the foregoing discussion the main features of the apparatus and methods used in producing a source of power for electrical precipitation work have been discussed.

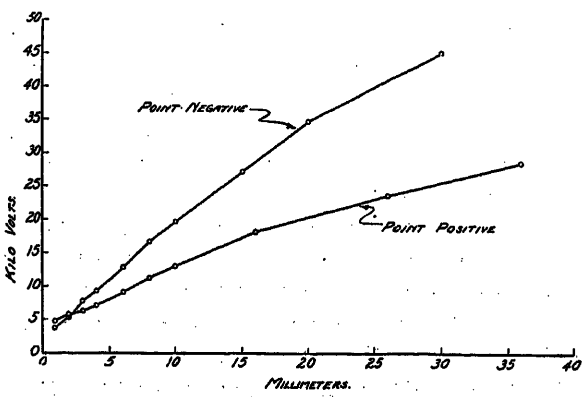

Fig. 5—Arcing Voltage between Point and Sphere at Short Distances

It is interesting to note some of the relations between voltage and precipitation efficiency.

The measurement of voltage by means of the needle point spark gap, is well-known. If one of the needles is replaced by a smooth, clean flat plate, we have what is analogous to a precipitator, the needle point corres-

ponding to the discharge electrode and the plate to the collecting electrode. With such a "point to plate" arrangement, laboratory studies may be made of some of the fundamental factors involved in electrical precipitation. It can be shown that rupture, or complete electrical breakdown, of the air between the point and plate for most spacing will take place at widely different voltages, depending on whether the point is positive or negative. This is shown by the two curves of Fig. 5. It will be noted that the curves cross at about 2 mm. and that at shorter distances the arcing voltage is greater when the point is positive, while for all spacings above 2 mm. the arcing voltage is greater when the point is negative. This is one reason why the use of negative polarity on the discharge electrodes in electrical precipitation is preferable. A second reason for using negative polarity is that usually the precipitation efficiency is higher even with equal impressed voltages.

In a precipitator, under actual working conditions, the difference in the arcing voltage between positive and negative polarity is not so great as found in the

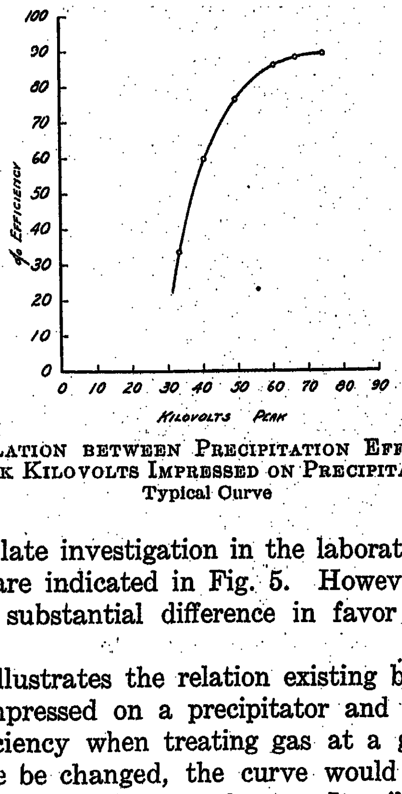

FIG. 6—RELATION BETWEEN PRECIPITATION EFFICIENCY AND PEAK KILOVOLTS IMPRESSED ON PRECIPITATOR
Typical Curve

point to plate investigation in the laboratory, results of which are indicated in Fig. 5. However, there is usually a substantial difference in favor of negative polarity.

Fig. 6 illustrates the relation existing between the voltage impressed on a precipitator and its precipitation efficiency when treating gas at a given rate. If this rate be changed, the curve would be shifted above or below the curve shown. It will be noted that this curve flattens out toward the top and the higher voltages are not accompanied by a corresponding increase in efficiency. The highest point shown on the curve in Fig. 6 is 2000 volts under the normal arcing voltage of the precipitator on which the tests were made. This curve, therefore, shows the fallacy of the belief which has often been expressed in the past, namely, that the last few volts, just under the arcing voltage, are particularly effective.

The fundamental differences between the positive and negative discharge as they affect precipitation, are not well understood. A visual difference is observed in the corona of the two. The positive corona manifests itself in rather long shifting brushes, while the negative is of a steady, bright beadlike character. From such an observation it may be concluded that with positive discharge the gas is ionized to a greater distance from the conductor than with the negative discharge. On the basis of this assumption, it is not surprising that the

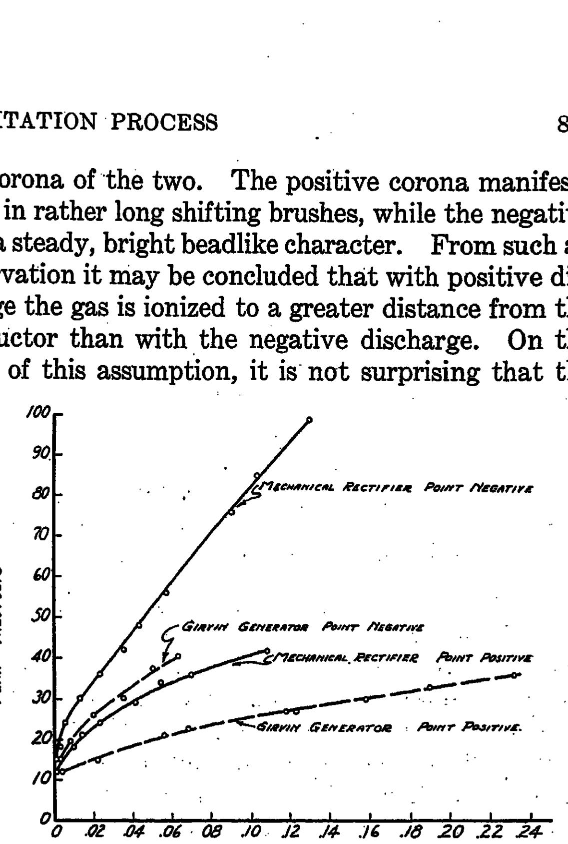

FIG. 7—RELATION OF SUCTION CAUSED BY ELECTRIC DISCHARGE, TO PEAK KILOVOLTS
Point mounted 6 cm. above grounded plate

arcing distance for a given voltage is greater when the point is positive than when it is negative.

In connection herewith, some study has been made of the electric windage established about a discharging point. This was done by using the point to plate method described above, with the exception that in this case the pointed rod was hollow, the discharge

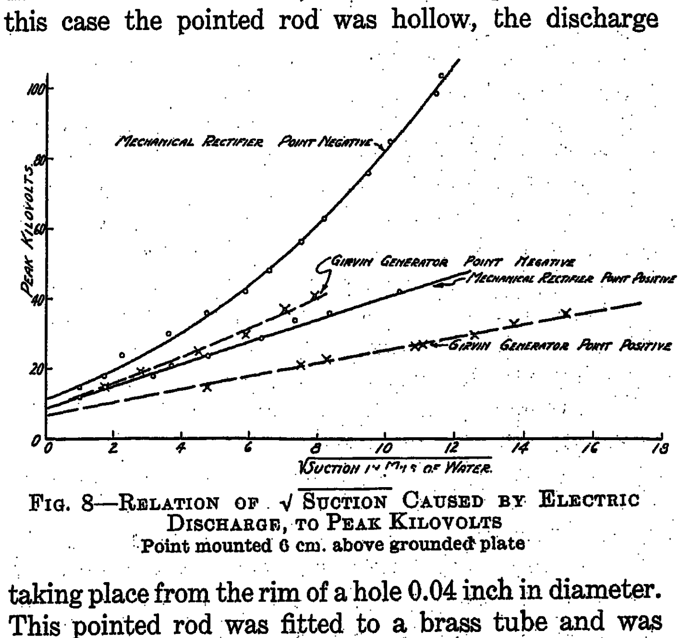

FIG. 8—RELATION OF $\sqrt{\text{SUCTION}}$ CAUSED BY ELECTRIC DISCHARGE, TO PEAK KILOVOLTS
Point mounted 6 cm. above grounded plate

taking place from the rim of a hole 0.04 inch in diameter. This pointed rod was fitted to a brass tube and was connected to a draft gage by means of rubber tubing. Fig. 7 shows curves of the results obtained with a constant spacing of 6 cm. between the point and plate. The curves marked "Girvin" are those obtained with the 50,000-volt generator previously described. The other two curves were obtained by using a mechanical rectifier. It will be noted that in all cases, the suction created about the point is several times greater when

the point is positive than when it is negative. From some further calculations and curves which are shown in Fig. 8, it seems that the suction established around the positive point follows a quadratic law so that the square root of the suction is proportional to the voltage. The suction created by the negative point, however, apparently does not follow the same law. From these results one might be led to conclude that this difference in windage may have something to do with the difference in the arcing voltage, but this does not seem to be the case for with the air blast rectifier, an artificial draft about the negative point does not lower its arcing voltage, but, in fact, slightly increases it.

Power Consumption

The power consumption of a precipitator, having clean electrodes and ordinary air as the dielectric medium, appears to follow the laws of dielectric phenomena discussed by F. W. Peek, Jr., in his "Dielectric Phenomena in High-Voltage Engineering." On the other hand, the power consumption in a normally operating precipitator having the electrodes covered with deposits of fume or dust, and having furnace gases as the dielectric, is influenced by a number of factors which have not as yet been fully investigated.

Gases arising from combustion or other chemical reactions may be highly ionized, and the current flow will consequently be increased unless means are employed to remove the ions before the gases reach the precipitator. Then, too, the temperatures of the gases may be as high as 600 deg. cent., and this in itself may cause variations over and above those which would be expected from the corresponding reduction in the gas density. The nature of the deposits on the electrodes has a distinct bearing upon the power consumption of the precipitator. Thus there may be deposits on the collecting electrode which act as insulating coverings, and therefore simply act to reduce the gradient at the discharge electrode, and consequently also reduce the current flow. Likewise when the discharge electrode becomes partly covered with such a deposit, the current flow is reduced, although in this case the reduction is brought about by a decrease in the effective length of the discharge electrode.

Furthermore, deposits may form on the collecting electrode constituting discontinuous dielectrics, which may so greatly modify and increase the ordinary potential gradient near the surface of this electrode as to cause ionization to set in at this electrode also. An effect is thus produced which so far as power consumption is concerned, is equivalent to an increase in the length of the discharge electrode.

Although few data have been accumulated on the quantitative effect of such deposits on the power consumption, the effects of such deposits on the arcing voltage and on precipitation have been discussed in the literature[1] on the subject.

1. E. R. Wolcott, *Physical Review*, N. S. Vol. XII, No. 4, October, 1918, and E. Anderson, *Chemical and Metallurgical Engineering*, Vol. XXVI, No. 4, January 25, 1922.

The following table will serve to show how much deposits may modify the ordinary operating conditions. This table was made up from data obtained by E. R. Wolcott and the writer, and shows the effect of such deposits on the arcing voltage between a point and a plate, six centimeters apart:

Material on plate		Arcing voltage kv. peak
Plate clean	point negative	120
Mica	" "	50
Sulphur	" "	50
Glass wool	" "	50
Varnished cambric	" "	70
Filter paper	" "	90
Writing paper	" "	118
Writing paper crumpled	" "	90
Edge of glass plate	" "	65
Asbestos	" "	100
Plate clean	" positive	45

From this table it is seen that the greatest effect produced by any of the materials is not as pronounced as that caused by reversing the polarity of the point.

Fig. 9—Corona Formed Around Hole in Mica Sheet Placed upon Positive Plate

Apparently a minimum arcing voltage is reached with the point positive, and the effect of deposits on the plate under a negative point is to lower the arcing voltage to a value which approaches that when the point is positive. So far as is known, no material has been found which reduces the arcing voltage with the point negative to a value as low as that which applies when the point is positive. On the other hand, no materials have been found which lower the arcing voltage when the point is positive. In fact, it has been shown that a point may be substituted for the plate when the plate is negative without lowering the arcing voltage.

The effect of a discontinuous dielectric is illustrated in Fig. 9, which is from a photograph of the corona formed at the positive plate, by a thin sheet of mica having a small hole. Naturally, the current flow and power consumption must be tremendously affected by

conditions such as these, and the problem of obtaining consistent data from different installations is very difficult.

However, there are installations where the above mentioned disturbing influences are a minimum. Data from such installations indicate that Peek's fundamental equation for corona loss does apply, at least approximately. This equation is:

$$P = C^2 (e - e_0)^2$$

For the purposes of precipitation calculations, let
P = power required in watts
e = voltage impressed on treater in kilovolts peak
e_0 = the critical disruptive voltage in kilovolts peak
C = a factor representing the slope of a line resulting from plotting $\sqrt{P}$ against e

The following are representative tabulations of the power data obtained when 112 pipes 8 inches internal diameter by 13 feet 0 inches long were energized at various voltages. While the pipes used in these tests were of wood, they possessed good conducting qualities since the material collected was a mist of salt solution, and the pipes were, therefore, moist and impregnated with salt:

The columns headed "Losses" represent the losses between the input to the transformer and the input to the precipitator. These losses were established in the same manner that is used to determine iron and copper losses in transformers, *i. e.*, by establishing one curve of losses when the precipitator is disconnected with various voltages impressed on the transformer, rectifier and high-tension lines, and another such curve for the $I^2 R$ losses when the precipitator line is grounded, and the transformer current varied. With these losses established for the particular electrical equipment used, it is possible then to calculate the net power input to the precipitator from the instrument readings in the low-tension circuit. This is given in the column headed "Watts net to treater." Under the general heading "Sq. rt. watts," the heading "H. T." is the square root of the power in watts as calculated from the high-tension current ("M. A.") and the r. m. s. kilovolts. The heading "L. T. Gross" is the square root of the generator output in watts. The heading "L. T. Net" refers to the square root of the "Watts net to treater." The first table gives the values obtained when the pipes contained still air at 70 deg. fahr. The second table

gives the values obtained when the treater was operating on a mist-laden gas at the temperatures and velocity indicated.

Fig. 10 shows two lines plotted from the above data, one for air and one for mist-laden gas. In this case the square root of the generator output (input to transformer) in watts (column marked "L. T. Gross") is plotted against the voltage impressed on the precipitator in kilovolts peak.

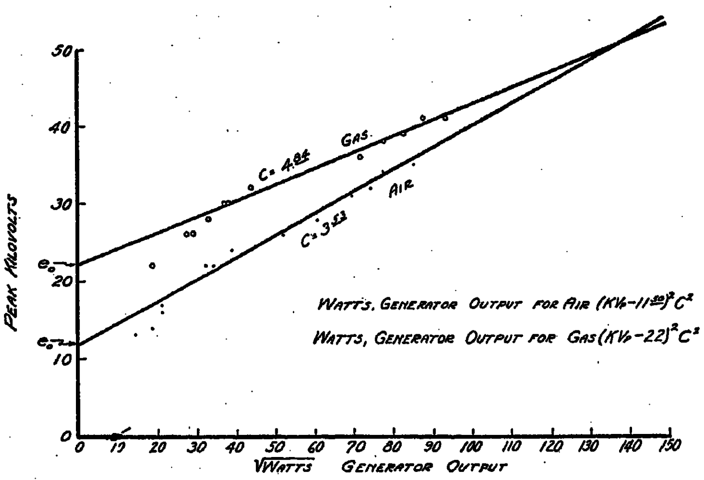

FIG. 10—POWER DATA PLOTTED—PIPE PRECIPITATOR

It is possible to use the generator output in this way as well as the net input to the treater, because the losses are principally made up of $I^2 R$ losses in the transformer and at the rectifier. At least the evidence of the curves indicates that there is little error introduced by so doing. The peak voltage has been used instead of the r. m. s. because of the comparative ease of obtaining readings in terms of peak voltage.

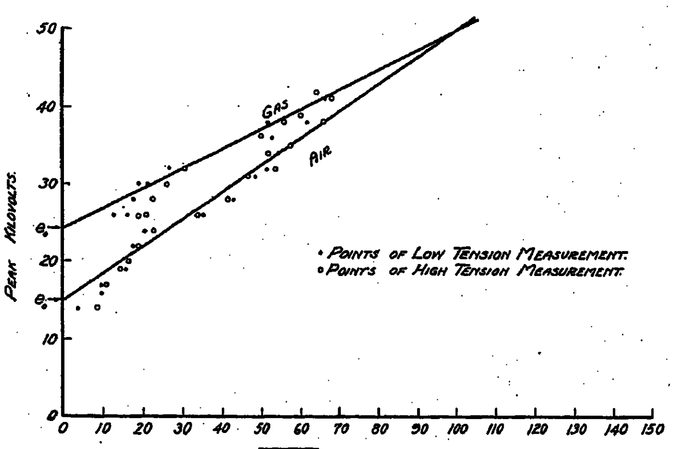

FIG. 11—POWER DATA PLOTTED—PIPE PRECIPITATOR

From an inspection of these curves, the differences in the values of e_0, and of C, the slope of the lines will be noted. It will also be seen that the power for the "air" curve is greater than for the "gas" curve, up to a voltage of approximately 50 kv., where the curves intersect.

Fig. 11 shows similar curves plotted against the square root of the net power input to the treater. The values of the power as obtained from the low-tension readings are seen to be in fair agreement with those obtained directly from the high-tension instruments. These curves also show the same relative values of e_0 and C as in Fig. 10.

It is, of course, impossible to draw any general conclusions from the data here presented, except that it appears the power consumption does follow the quadratic law given by Peek, and that this law is applicable to electrical precipitation. However, it should be said that certain experimental data indicate that the fume or dust carried in suspension in the gases may affect the electric discharge and may decrease the power consumption. From the increase in the value of e_0 for "gas" over that for "air," shown in the curves, it might further be concluded that fume also may cause a considerable increase in the corona starting voltage.

The foregoing data and discussion show that Peek's expression for corona loss may be used as a means of interpreting electrical precipitation power data.

SUMMARY

1. Power is supplied to precipitation plants by two systems, viz., the synchronous motor system and the motor-generator system.

2. The high-tension unidirectional current employed is obtained by rectifying the current from the high tension of a single-phase transformer.

3. Various types of rectifiers have been employed, including the kenotron, the air blast rectifier and the mechanical rectifier, the latter having so far given the most all around satisfaction.

4. Direct current at high potential has, so far, not shown any inherent advantage over the pulsating unidirectional current obtained from the mechanical rectifier.

5. The arcing voltage between a point and plate, which is analogous to a precipitator, is determined by the polarity of the point. At spacings in the neighborhood of 5 cm. between the point and plate, the arcing voltage for the point negative is roughly double the arcing voltage with the point positive.

6. At the same impressed voltage, the negative polarity is more effective in precipitation than the positive. Consequently the discharge system of a precipitator is maintained at a negative potential with respect to the collecting members.

7. The amount of windage or draft created about a discharging point in the "point to plate" arrangement is also determined by the polarity of the point.

8. Certain materials when placed on a plate under a negative point in the "point to plate" arrangement possess the ability to lower the arcing voltage to a value nearly equal to that caused by reversing the polarity of the point.

9. Peek's fundamental equation for corona loss apparently may be used to express the power consumption of precipitators.

Discussion

For discussion of this paper see page 826.

Electrical Precipitation of Solids From Smelter Gases

BY ROSS B. RATHBUN

Associate A. I. E. E.

American Smelting & Refining Company, Salt Lake City

Review of the Subject.—*The fundamental principles of the process in its simplest form are set forth. It is shown why the Cottrell process during recent years has in a large measure supplanted the bag-house and dust chamber in treating smelter gases.*

The commonly accepted theory concerning the manner in which the dust particles is charged and precipitated is given. It is pointed out that the thing most important to the operating man is how the particles may be enabled to give up their charge to the electrodes under all conditions, rather than the manner in which they receive it.

The various types of treaters in common use are described and discussed. The advantages of straight line treaters over those in which the gases are by-passed are emphasized.

It is shown that the gas is ionized much more efficiently for a given power consumption and the construction simplified and reduced by arranging the electrodes in the flue so that their electric fields are in series with each other. It is shown that this is accomplished by causing the gas to flow parallel to the electrostatic lines instead of at right angles to them, as in all other types.

The factors of lead and copper metallurgy are given which control the amount of sulphuric acid and water vapor in the gases. It is also pointed out that these things are a measure of the successful operation when treating smelter gases.

The physical rather than the chemical structure of the dust in suspension is shown to be the all-important matter. Several theories are given as to why flue dust is so much easier precipitated than fume. A number of photo-micrographs are given to illustrate the difference in physical structure between fume and dust.

Two methods are featured of obtaining sufficient conductivity in a dry precipitated coating to permit the electric charge to leak through it to the electrode. The theory of selective absorption is advanced as an explanation of how aqueous vapor added to the gas stream functions in this respect. The method of adding very finely atomized sulphuric acid is shown to be the most practical, it not having certain disadvantages of the water and its higher boiling point permitting a wider field of application. Its action is shown to be due to the fine acid particles being precipitated with the dust particles thereby imparting conductive film to the particles by diffusion.

The amount of free sulphuric acid in grams per 1000 cu. ft. of gas which permits a good precipitation on gas without conditioning is given from tests made on a large installation.

The theory of back ionization and phenomena of discontinuous dielectric are discussed.

Electrical matters are shown to be secondary to treater design and to the conditioning gas. All that can be expected of electrical equipment is to stress the space between electrodes to the economical limit. Local conditions must govern choice of electrical equipment.

The tendency to regard electrical phenomena, such as surging which as a rule accompanies poor precipitation as causes rather than effects, is cited. Effects of conditioning gas in reducing surges is shown.

Internal reactance in transformer best suited to precipitation work is discussed, also possibility of exceeding the practical limit and wasting power on treatable gas by carrying voltage up to the point of disruption; necessity of knowing electrical values in the treater, and these are best obtained with milliammeter and electrostatic voltmeter; finally, the subject of proportioning the plant investment between electrical equipment and treater is covered.

CONTENTS

INTRODUCTION

IN presenting this paper on the application of this process to smelter gases it is with the view of lending practical assistance to the engineer engaged in the smelting industry and furnishing useful information to others interested in the process.

The subject will be covered from the viewpoint of the engineer whose watchword must always be "return on the investment" rather than that of the physicist. However, consideration will be given to such theoretical matters as seem to have a practical bearing.

For the information of those not familiar with the metallurgy of copper and lead a short review will be made of that portion of the subject affecting the adaptation of the Cottrel process.

The present scope and diversified applications of the process preclude a complete discussion in this paper, but the general principles are sufficiently covered to insure an understanding of their application to smelter gases. The essentials are stressed and the non-essentials pointed out. Among the things featured are economy of treater design and methods of treating gases carrying solids difficult to precipitate, the solution of which will materially extend the scope of the process in the metallurgical field.

DESCRIPTION

The process which the genius and foresightedness of Dr. F. G. Cottrell gave to the world in 1908, out of what had been previously considered an interesting phenomenon, is essentially as follows:

A gas, or air stream, carrying solids or liquids in suspension, is subjected to the influence of a strong electric field produced by unidirectional current of high potential for the purpose of charging these particles and throwing them out of the gas stream. The gas is passed through the space between suitable electrodes and this space is made part of a high-potential circuit by placing it in series with the high-potential winding of a step-up transformer. Rectification is accomplished by a revolving switch, driven in synchronism, in series with the electrodes and high-potential winding of the transformer. The current is pul-

Presented at the Pacific Coast Convention of the A. I. E. E., Vancouver, B. C., August 8-11, 1922.

sating in character, but this is only incidental as the same results of precipitation may be produced by any source of high potential direct current.

The electrodes are usually referred to as "passive" and "active" since only the cathode serves as a charging electrode. This is effected by making it of relatively small surface compared with the anode so as to make a steep potential gradient near its surface. The passive electrode with its relatively large surface serves as the principle collecting electrode because most of the dust is driven to it. For purposes of safety the anode is made the grounded side of the system.

A few words as to the commonly accepted theoretical conception concerning the manner in which the dust particle is charged and precipitated: This is accomplished through the ionization of the gas which carries the particles in suspension. It is assumed that the negative ion or electron is the ionizing agent and that the velocity of the electron stream is sufficient to ionize the gas mo'ecules by collision in a relatively small zone near the discharge electrode where the potential gradient is steepest. This stream of electrons in making its way toward the opposite electrode is assumed to charge the minute dust particles in passing by contacting or attaching to the particles. The latter having acquired a negative charge, and being in a strong electrostatic field, are attracted by the positive pole and hurled against it with considerable force, where they give up their negative charge to this electrode and cling to it by adhesion.

There are many iinteresting speculations, such as the possibility of some of the particles being charged by electrostatic induction; the effect of the electric wind caused by the electron stream, in aiding precipitation, and the indication and that some of the particles must be charged positively on account of the deposit which is always found on the discharge electrode; but these things are beyond the scope of the paper.

We need not be concerned with the phenomena of just how the particle is charged, but we are with how it may be enabled to give up its charge to the electrodes under all conditions. The inability of the charge to penetrate the insulating coat of dry precipitated fume causes precipitation to cease just as an insulating diaphragm does when placed between the anode and the cathode in an electrolytic cell. The problem in metallurgical work is to overcome this difficulty.

Application of the Process to Smelting

In its application to the smelting industry the process differs from other applications in several ways, but especially in the matter of size. Installations are as a rule, based on treating from 100,000 to 1,000,000 cu. ft. per minute. Other installations treating 25,000 cu. ft. per minute, such as at brass foundries and detinning plants, are considered a good size. Another important difference is the varying conductivity of smelter gas as compared with other gases. The matter so precipitated varies from a dry basic fume or dust to one containing enough dilute sulphuric acid to make it difficult to remove the deposit from the electrodes.

Electric precipitation was used primarily for the purpose of abating a nuisance by preventing solids from the smelter stacks being carried to the surrounding fields. A greater usefulness was soon found for it in recovering these solids for the values therein.

Twenty-five years ago in the copper smelting industry comparatively little attention was paid to recovering the solids driven off with the gases from the furnaces. The first attempt was made by building longer flue chambers to recover what might be settled out by gravitation and by adherence to the walls. As the industry increased more attention was paid to the very considerable dust losses and these flues were widened considerably for a length of 100 ft. or more to reduce the gas velocity, thereby causing considerable of the heavier suspended solids to drop out. During this time, and in fact prior to it, the system of filtering the gas through woolen bags for the purpose of reclaiming these solids, was in use in lead smelting. This method could not be applied very well to copper smelting due to the fact that the gases were much hotter and usually carried considerable sulphuric acid, these conditions contributing to the rapid deterioration of the bags. At one copper smelter, however, a bag-house was successfully operated by causing the heat from the gases to radiate from a long series of iron pipes, all the free acid being neutralized before reaching the bags by the large amount of zinc oxide present.

The principal disadvantages of bag-houses are the high first cost, together with the maintenance cost of bag renewals, and the very considerable cost of power rquired for forcing the gases through the bags and for producing mechanical draft.

While the long brick settling chambers were quite expensive, especially if equipped with hoppers, they constituted the only practical method of reclaiming the dust lost from copper smelters until the advent of the Cottrell process. Even then it was for a long time considered only an adjunct to the settling chamber. Until recently many of those best informed considered that the process was applicable exclusively to the field where the gases carried enough sulphuric acid, due to the sulphur in the charge, to render them conductive, and that all dry gases could be treated only by the bag-house. As will be shown later, the process is now being extended to dry gases also, by means of conditioning such gases.

Although quite expensive when constructed of steel pipes with hoppers and header flues, the Cottrell plant proved to be a very good investment on account of the large amount of solids recovered which would not settle out by gravity. One serious drawback to this type of treater, which limited its application, was the inevitable loss of draft, partly due to cooling the gases in passing through these pipes but principally due to

the loss in velocity head in passing the gas around so many extra right-angle bends.

Due to recent improvements in treater design smelter construction has been revolutionized by the Cottrell process. Almost any kind of gas can now be treated and long settling chambers are no longer necessary. The chimney may be erected comparatively close to the furnaces and connected with them by a short length of chamber equipped with electrodes which recover all that the long chambers formerly caught plus the larger amount which passed them. This can be done with practically no loss in draft.

Treater Design

The original treater consisted of a tank through which the gas was passed horizontally. The positive electrodes consisted of narrow lead plates placed vertically and edgewise to the gas current. Adjacent rows were staggered with reference to each other. Midway between each pair of plates and insulated from them were hung the negative discharge electrodes, which consisted of lead rods to which were clamped strips of micanite with saw-tooth edges. Later iron was used for both sets of e'ectrodes where the gas to be treated carried little acid.

The pipe treater was developed in 1911 and has been used extensively since. In this treater the gas is by-passed from the main flue through vertical iron pipes from 10 to 15 ft. long and then returned to the flue where it passes on out the chimney. Iron wires of about No. 14 gage, supported by an insulated frame, are stretched through the axis of these pipes and serve as negative or discharge electrodes. Most of the dust is precipitated on the inner surface of the pipes and is shaken from them nto the hopper below by rapping the pipes after the flow of gas through them has been interrupted.

Somewhat similar to this in principal is the box treater, in which the pipes were replaced by vertical corrugated iron walls horizontal to the gas flow. Vertical chains or wires were suspended between these walls and were insulated in a similar manner as in the pipe treater.

The idea of using the corrugated iron walls was later used to better advantage by causing the gas to flow between them horizontally instead of vertically. This permitted installing them in a settling chamber already erected, and being a straight-line treater, the walls could be carried any desired length, whereas in the box treater the height of the walls was limited for structural reasons. In this installation the discharge electrodes consisted of 3/8-in. iron pipes suspended parallel to the gas flow midway between the walls. Such a large surface does not permit steep enough potential gradient for the efficient ionization of the gas.

A short time previous to the development of the straight-line treater just discussed another type of straight-line treater was developed, which is known as the "screen treater." The object desired in this treater is to apply the principal of ionizing the gas in the most efficient manner and thereby reduce the power consumed, which is the principal fixed cost of a large plant. Probably more important than this to the plant manager is the very considerable reduction in first cost on account of the fact that chambers already in existence can be utilized and that in its construction a minimum of material and labor are required. Since these things have been accomplished so successfully on a large scale both in this type and in its successor known as the "wire treater," which is really a simplified screen treater, it seems worthy of some discussion from theoretical and practical standpoints.

In the pipe treater and various kinds of plate treaters, it is evident that the potential gradient is steep enough to ionize the gas only in a comparatively small area near the surface of the discharge electrode permitting a path of relatively large area near the walls of the pipe or plates through which the gas can flow in a straight line in a very weak electric field. In one large pipe treater installation in order to obviate this difficulty and get as high a degree of cleaning of the gas as possible, the gas was passed through three separate plants in series, the mixing action in passing from one plant to the other serving to give all the gas a better chance of being ionized. It was not practicable to increase the length of the pipes in one plant sufficiently to accomplish the same result on account of the amplitude of the swing of the discharge wires in the pipes becoming too great, due to the corona discharge. While this arrangement proved successful it was quite expensive from operating and first cost standpoints. It is quite evident that the same result as obtained with treaters in series can be obtained by putting vertically hung electrodes in series in the same chamber and having the gas flow parallel to the electrostatic discharge instead of at right angles to it as it does in all other types. In order to accomplish this in the best manner the gas must flow through the planes of the passive electrode instead of between them, which is only possible if the passive electrode is in the nature of a screen. Accordingly the treater was constructed by placing a series of parallel screens across a chamber. The discharge electrode consisted of vertical wires supported by an insulated structure and stretched between the pairs of screens. It is evident that these pairs of screens with their discharge wires function as treaters in series. Since the wires in each row are staggered with reference to the other rows, no single gas molecule can find its way through even a short series of these screens without passing close to a discharge wire and through a field sufficiently intense for its ionization. The reason for the relatively small cost of such an arrangement is obvious and requires no discussion. As to its economy of power used, this may be better understood by comparing a screen treater with any other type, say a pipe treater, each having its electrode surfaces proportioned so that the same

watts will be consumed in the two treaters, discharging in air. With the same volume of gas flowing through each, but an excess over the current amount, it is evident that the screen treater will precipitate the most dust on account of the more efficient ionizing of the gas for the power expended; therefore there are less watts consumed per unit weight of dust recovered. Having a minimum amount of surface exposed where radiation can take place, the temperature of the gas is conserved, and having no extra bends, the drop in draft is reduced to a minimum. The drop in draft across such a treater, cleaning gas at a 10-ft.-per-sec. velocity, rarely exceeds 0.1 inch of water and in no case has the precipitate on the screens interfered with operation, regardless of the sticky condition produced by acid. Draft is all important to the smelting man who finds more often than not, that a reduced draft means less ore tonnage smelted. Minimum draft loss is one of the features of this wire treater. Another important advantage is that there are no insulators exposed to the gas with the inevitable current leakage over their surfaces. The insulated structure is suspended at the four corners by members passing through holes in the cover plate. These holes are sealed by insulating lime seals in which crushed burnt lime, which has a high dielectric constant, acts so as to neutralize any acid which may condense on it and at the same time preserve a high dielectric strength. A feature worth noting is the fact that in this type of treater the gas stream always carries any dust that may be blown off toward a collecting electrode. Another advantage is the ease of shaking dust from a small or broken surface as compared to a solid surface.

The wire treater embodies all of the advantages of the screen treater plus the very distinct one of a greatly simplified construction with a much reduced first cost. In effect it amounts to electrifying a small portion of the wires formerly hung in a dust chamber for the purpose of knocking down the small amount of dust which might adhere to them mechanically. As in the screen treater, the length of the treater can be increased at will to obtain any desired degree of cleaning. The amount of dust caught over the length of the treater varies in the form of a logarithmic curve, half of the total being caught in a relatively short length making a very high return on the first portion of the investment. From this it is obvious that a large part of the solids in a gas can be recovered by installing a relatively short section of the treater, the length depending on the degree of clearance desired. In practise it has been found that a treater length of 20 ft. having an active or ionizing length of 10 ft. is sufficient to precipitate practically all the solids from gases flowing at the rate of from 10 to 12 ft. per second.

Metallurgical Considerations

In reference to the metallurgy of copper and lead, this paper is concerned principally with the conditions affecting the amount of water vapor and sulphuric acid in the gases from the various metallurgical units, and with the nature of the solids which the gases carry. It is on these things that the successful operation of the Cottrell plant depends.

As a rule these metals exist in their ores combined with sulphur, although there are some large oxide deposits. Before these ores can be smelted it is necessary to roast off a large amount of this sulphur. This is usually accomplished by multiple hearth roasters in which the ore is fed at the top hearth and is passed down through the succeeding hearths, being stirred or rabbled in transit. The sulphur in the ore usually furnishes the heat for its own roasting, although auxiliary heat is sometimes supplied. The gases from such roasters used for driving off excess sulphur contain more sulphuric acid than the gases from any other metallurgical unit. This acid is caused by the large amount of sulphur dioxide driven off and the fact that in passing up through the various hearths it has considerable contact with whatever catalysts may be present, such as iron oxide. The sulphur trioxide thus formed unites with the water vapor present in the gas and makes sulphuric acid.

There is another type of roaster in common use. It is a straight line roaster in which the fine ore is placed in thin beds on pallets which are drawn slowly through a short fire-box, this action serving to expel a large amount of the sulphur and at the same time to sinter or agglomerate the charge. The gas from this roaster contains very little acid on account of the short time of contact of the gas with the material at the proper temperature as it passes through the thin bed on the pallet. About the only thing contributing to making this gas treatable is the fact that in order to be agglomerated the charge must contain considerable water, often as much as 10 per cent. This water then furnishes enough conductivity to afford precipitation if the temperature is low enough to permit sufficient relative humidity to obtain.

In the case of copper, the roasted material, now known as "calcines", is then dumped into a large reverberatory furnace heated with powdered coal or oil. This type of furnace is quite similar to an open-hearth furnace, the gases leaving it being extremely hot. A large part of the sulphur remaining in the charge unites with the iron and copper in about equal parts to form a physical mixture known as "matte." This is separated from the slag by settling. The gas from this furnace contains very little SO_2 from which conversion to acid is obtained by coming into contact with whatever catalizer may be present on the side walls. In addition, the gas is very hot and there is practically no water in the charge, it being driven off by the roasting. These conditions make it an exceedingly difficult gas to treat.

Sometimes blast furnaces are used instead of reverberatory furnaces. This is often the case if the ore is in large lumps. The same disadvantages apply to

treating these gases with the added disadvantage of a wide temperature variation. This temperature variation depends largely on whether the furnaces happen to be operating with a cold or a hot top.

From the furnace the matte is poured into a converter, which is a relatively small cylindrical furnace, and is rotated on trunions for skimming off the slag. Air is forced in at the bottom and, passing up through the bath, oxidizes the sulphur combined with iron first, on account of the higher affinity of oxygen for such sulphur. Slag is produced by adding silica, and as it rises to the top is skimmed off periodically until only the combined sulphur and copper, known as "white metal" remains. During this slagging period very little acid is made which is available in the treater, and what acid is formed in the gases reacts with the oxides present, and the sulphates formed are not precipitated more readily than the oxides or sulphides of the original charge. The gas from a converter in the slagging stage is perhaps the most difficult of all to treat, as it contains no acid and practically all of the suspended solids are present in the form of fume, that is, material which has been condensed from a volatile state. During the second stage of converting, considerable acid is made due to the oxidizing of the sulphur, and conditions are favorable for good precipitation If there are several converters operating it is well to have their stages arranged so as to have at least one of them on the finishing stage all the time.

While the discussion has been confined principally to copper, the metallurgy of lead is so nearly similar that for our purpose little distinction need be made. It should be pointed out, however, that in lead smelting the reverberatory furnaces are not used, and that the lead is made without the use of converters it being smelted directly in the blast furnace where a reducing atmosphere is maintained.

The suspended solids from these various metallurgical units are sulphides, sulphates and oxides; however, the chemical nature of these solids does not seem to enter into the matter of their precipitation. Their physical nature is all important. It is a comparatively easy matter to precipitate flue dust, that is, material which has not been condensed from a volatile state. Frequently some of the material just as it is charged is present in the gas. This is especially true in the case of the multiple hearth roasters in which the constant stirring causes a considerable amount of the fine particles of the charge to be carried out with the gas currents. The wide application of the flotation process has contributed greatly to this dust loss from the charge, on account of the exceeding fineness of the particles. In fact, if it were not for the Cottrell process the flotation process would not be as great a success as it is, because of these losses.

There are several theories as to why fume does not readily lend itself to precipitation. Of these theories the one usually advanced is that on account of the exceedingly small mass of the particle it is not able to acquire enough electric charge, or enough momentum with the charge it does acquire, to cause it to lodge on a collecting electrode before it is swept by. This theory would seem to be disproved by the fact that these fume particles actually are charged and migrate to the electrode, but experience difficulty in giving up their charge to the electrode after the latter has become covered with a thin coating or film of such material. This is shown by the fact that if a practical method could be devised whereby this film is wiped from the electrodes every few minutes good operation would result. No method of shaking will remove this film sufficiently.

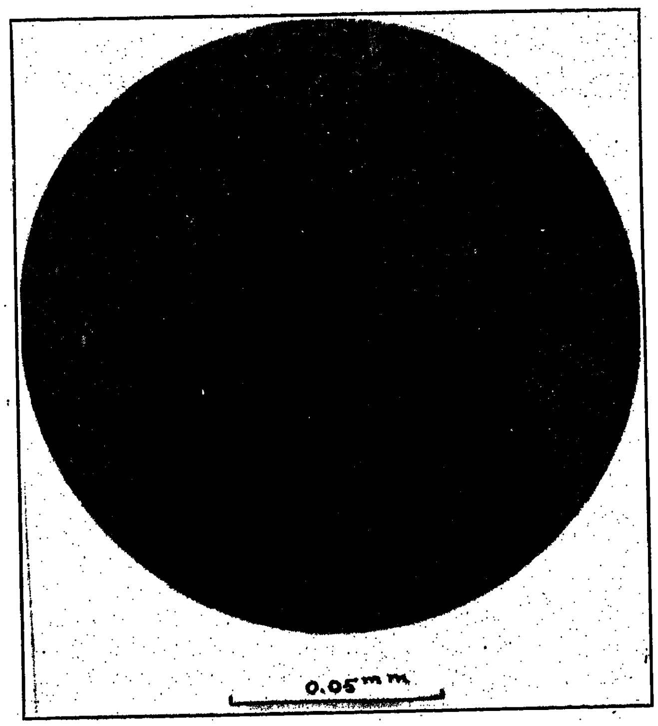

FIG. 1—PHOTO-MICROGRAPH OF CONVERTER FUME MAGNIFIED APPROXIMATELY 560 DIAMETERS
The dark grains are silhouettes of the particles.

There has been some speculation as to the effect of the air occluded in the fume on the electrode. It is a fact that if the fume shaken from the electrodes is beaten or squeezed, enough air will be excluded to make the fume occupy a very much smaller volume than before.

Another theory, which seems the most likely, is that the trouble is due almost entirely to the smooth amorphous state of this coating on the electrodes making it very compact, whereas the flue dust is of a porous nature having small interstices through which the charges may be forced. A good analogy of this is the insulating properties of various kinds of wood. It is known that pine is a relatively poor insulator for high voltages, whereas the same thickness of maple is exceedingly hard to puncture. The difference in

the dielectric strength of these two woods is probably due largely to the difference in porosity. A point lending color to this theory is the fact that if flue dust or other rather coarse material is mixed in with the gas and precipitated with the fume it improves the precipitation of the fume.

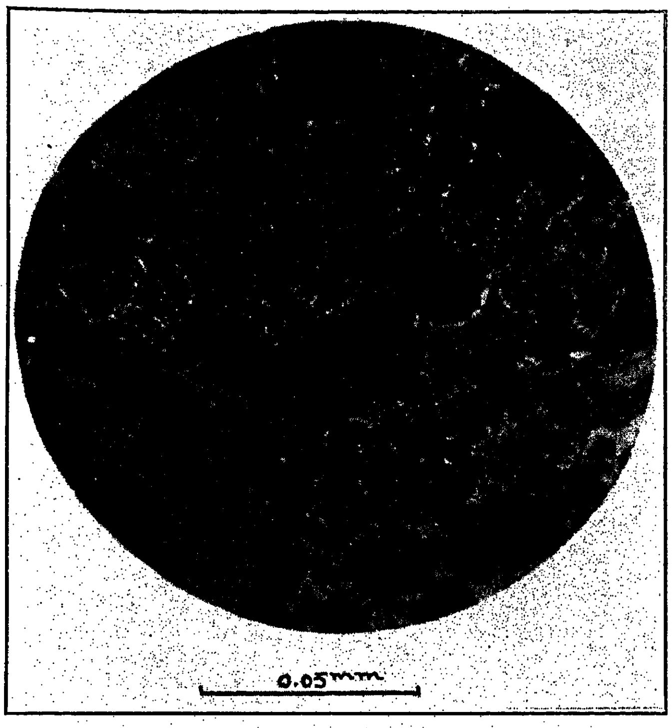

Fig. 2—Photo-micrograph of Roaster Flue Dust Magnified Approximately 560 Diameters
The dark spots are silhouettes of the particles.

The difference in physical structure between fume and flue dust is shown clearly by the photo-micrographs submitted. Figs. 1 and 2 show the particles silhouetted on glass mounts, consequently the dark spots are the grains. Fig. 1 shows the fume particles of high lead content from copper converters which must be conditioned previous to recovery in a Cottrell plant. Fig. 2 shows fine flue dust recovered from roasters which lends itself to treatment very well without conditioning in spite of the fact that it has a very high dielectric strength. This dust without magnification appears to be a dark powder of fineness comparable to that of the fume but when thetwo are magnified approximately 560 diameters, as shown, each particle of flue dust is shown to be about 20 times larger than the fume particle. These flue dust particles are also shown to be irregular in form with rough edges from which an electric charge can readily leak and pass through the interstices of the coating to the electrode. These sharp edges are further indicated by the wavy lines which are pictures of minute spectra caused by fine edges, similar to diffraction gratings, or crystal clevage planes. The fume particles are seen to be almost spherical in form which fact would make the particle tend to hold its charge.

In Figs. 3, 4, and 5 are shown the compact surfaces of converter fume, roaster flue dust and blast furnace flue dust, just as they were taken from the treaters without any attempt to compress them. The compactness of the fume as shown by its enamel amorphous surface as compared with the granular porous structure of the flue dust is clearly seen. The sample of blast furnace flue dust was taken at a time of excellent precipitation. Under high magnification it resembles a mass of coke. Fig. 6 is a photo-micrograph of chemically pure zinc-oxide which is a true fume and is submitted for purposes of comparison. Its general structure is seen to be quite similar to the converter fume. The areas photographed represent a magnification of approximately 43 diameters.

Laying aside theoretical considerations, the important point is a practical solution of the problem of conditioning gases and this will now be discussed.

Conditioning the Gas

By far the most important consideration in the operation of a plant is keeping the gas and the precipitated coat conductive. Conductivity is a relative term. What is considered a perfect insulator for ordinary voltages and currents may become an excellent conductor where only extremely small currents and high voltages are involved.

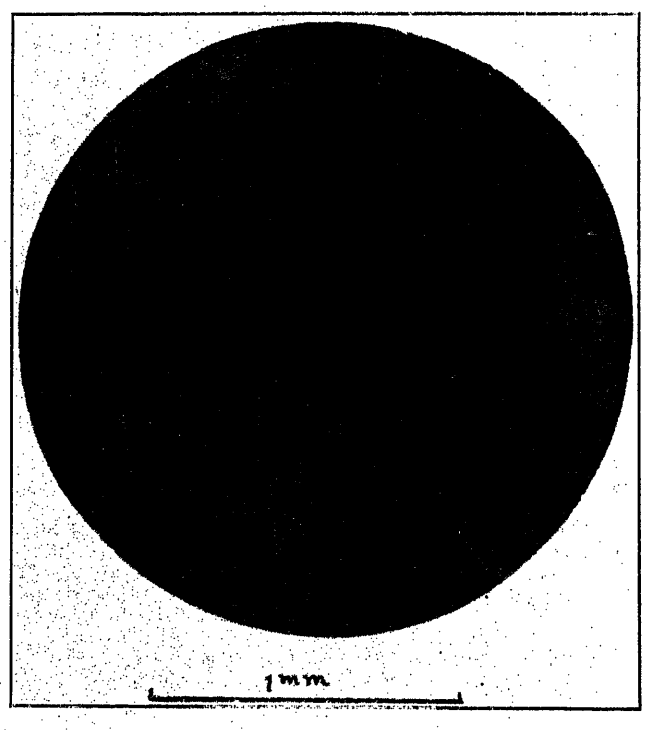

Fig. 3—Photo-micrograph of Surface of Converter Fume Magnified Approximately 43 Diameters

There are two ways in common use of supplying the necessary conductivity if it does not exist; the addition of sufficient aqueous vapor to the gases, or the addition of very fine acid particles. While the results obtained in each case are the same as regards furnishing

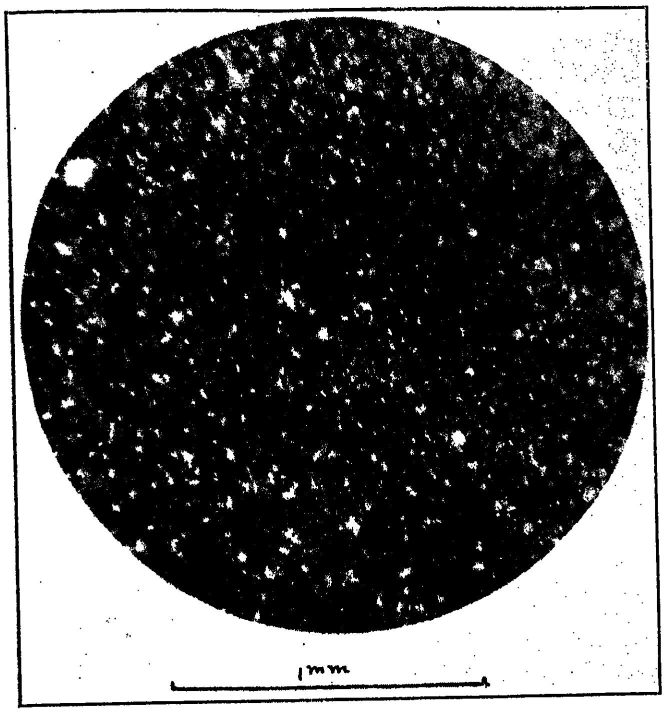

Fig. 4—Photo-micrograph of Surface of Roaster Flue Dust Magnified Approximately 43 Diameters

conductivity for the charge, their methods of functioning are somewhat different.

The selective adsorption theory as an explanation of how relative humidity functions in furnishing conductivity was advanced by the writer in a discussion of a paper presented to the Institute of Mining and

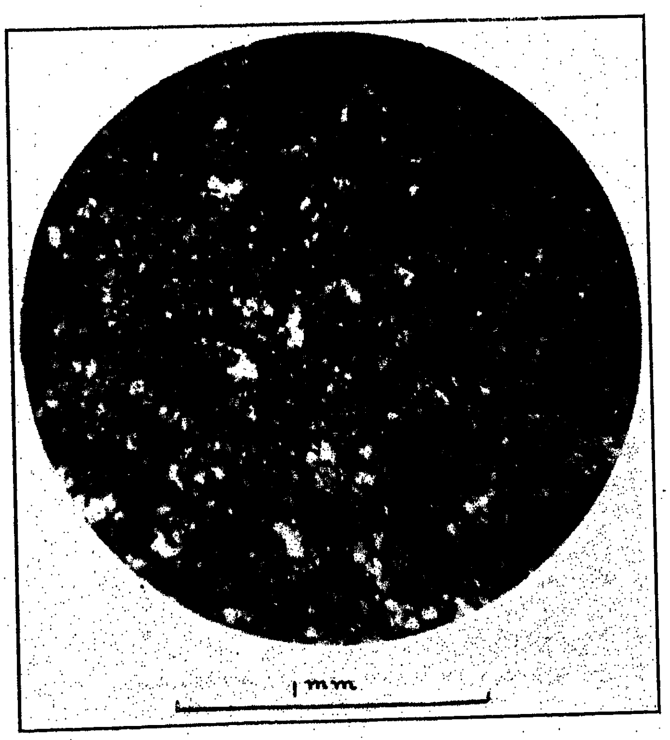

Fig. 5—Photo-micrograph of Surface of Blast Furnace Flue Dust Magnified Approximately 43 Diameters

Metallurgical Engineers in 1919 by Mr. Eschholz on the subject of "Electrostatic Precipitation." It was pointed out that the dry dust particle must take on a film of moisture, for aqueous vapor is known to be taken up by the surface of solids, and that these adsorbed surface films persist at temperatures far above the boiling point of water. The early work of Bunsen in trying to remove the last traces of moisture from powdered glass or the interior of glass tubes was cited.

If the very slight surface adsorbed film is sufficient to conduct off the charge from the glass plates rendering an influence machine almost inoperative on a humid day, it is not hard to understand why the film adsorbed by dry dust particles from air or gas of like humidity should be sufficient to conduct a charge through the

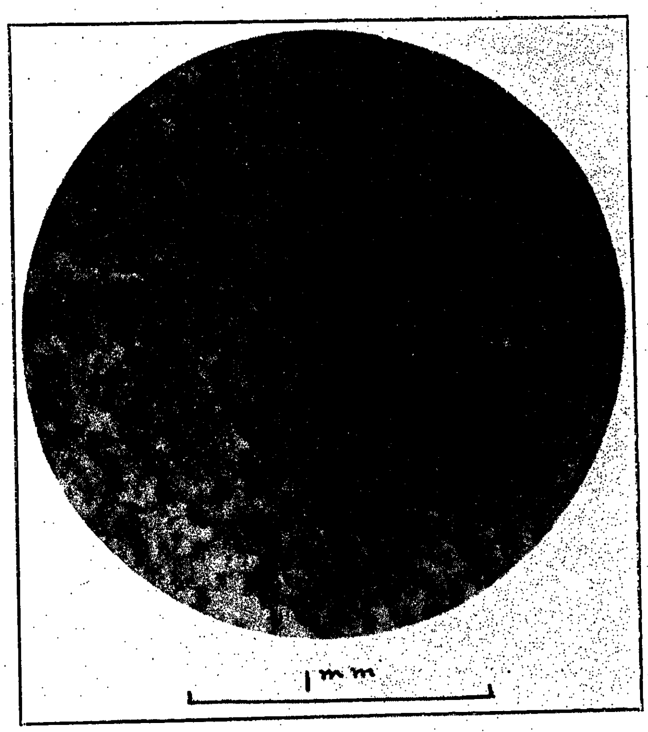

Fig. 6—Photo-micrograph of Surface of Chemically Pure Zinc Oxide Submitted for Comparison

coating to the plate, since the current per unit area is of about the same order as that in the case of the influence machine. As evidence of this 50 milliamperes is a good average current for a treater of 200 pipes six inches in diameter and 12 ft. long. This gives a current density of 0.0135 milliamperes per square foot of electrode area at the pipe. This is to show that aside from the fact that it is a physical impossibility to precipitate droplets of water from a gas below the point of saturation, it is unnecessary, for the aqueous vapor alone is sufficient to conduct off the charge. It has been claimed that the relative humidity itself did not function in conducting away the charge but was only indicative of a condition whereby droplets of water could be precipitated.

Increasing the relative humidity of the gas is usually

accomplished by spraying into the gas a considerable quantity of finely atomized water by the use of suitable sprays at very high water pressure. Since the relative humidity increases faster and faster with a given moisture content as the temperature is lowered below the boiling point it follows that the water sprayed into the gas is more useful in raising the relative humidity due to its cooling effect than by virtue of the water added to the gas.

From a curve showing percentage by weight of water in saturated air, it is seen that at 100 deg. the percentage of water is only 0.14 per cent. At 120 deg. it is 1.07 per cent, rising with increasing rapidity so that at 150 deg. it is 6.34 per cent.

It is interesting to note that in a large installation operating on roaster gases the cooling effect of the gases during winter weather is sufficient to raise the relative humidity of the gas to a good working point due to the water in the furnace charge, although the latter is not changed in percentage.

As regards the limits for good operation, it was shown about five years ago that when the relative humidity of the gas was kept between 40 per cent and 70 per cent the precipitate would not be too dry or too wet for good work and all other connsiderations, such as temperature could be neglected since the temperature factor is reflected in the relative humidity. This reduced the field that could be covered by water treatment to comparatively cold gases only. Two serious objections to this method quickly developed. It was found that the water caused rapid deterioration of the flue system at the sprays, and the humid gases caused corrosion of the steel of the treater due to condensation at points exposed to the influence of the outside air. Perhaps more important was the reduction of the effective draft due to the cooling of the gases. This in several instances reduced the tonnage smelted. In spite of these difficulties this method is still used to a large extent.

Mr. Wolcott[1] has offered some important theoretical considerations on this matter. In citing the well-known fact that the tendency to arc between a plate and a point is greater when the point is positive than when it is negative, he pointed out that experiments showed the arcing voltage was considerably lowered when the plate is covered by some insulating material. This he did by placing various substances on the plate capable of retaining a charge, such as a sheet of paper or mica. The arcing voltage was lowered still further by a hole in the sheet. A glow was seen to emanate from the edges of the hole. Roughening the surfaces had the same effect. Roaster dust containing a large amount of elemental sulphur, when it was sprinkled on the plate, acted in the same manner. In every case these effects disappear when the dielectric on the plate was dampened very slightly or when the atmosphere was quite humid. He accounts for this glow, which under some conditions can be seen in the dark on the passive electrode, by theory of back ionization, and to the phenomenon produced by discontinuous unlike dielectrics in series which in this case are the dust particles in the coat and air in the interstices between them. The charge, which is retained by these particles, is evidently sufficient to ionize the gas adjacent to them. Since the sign of this charge is negative like that on the particles migrating to the passive electrode, the latter will be repelled, somewhat, by the dust already precipitated.

It seems, however, that these phenomena are results of precipitation having ceased, and not the causes. It is evident that the moment the particles can no longer give up their charge it becomes equivalent to an open circuit. We may be concerned more with another result of this back ionization than we are with the lowering of the sparking voltage. The redistribution of the potential gradient, due to the ionization which starts somewhere in the interior of the coat near the surface of the electrode, unquestionably lowers the gradient at the discharge electrode by the amount gained by the passive electrode. In this way it differs from the ideal distribution of the voltage, in which its gradient is as steep as possible near the surface of the discharge electrode, and quite flat at the passive. This is similar to a case cited by Dr. Whitehead in which he found that the corona glow at the wire almost disappeared when an intermediate concentric tube was inserted between it and the outer tube due to the accumulation of ions in the intermediate tube lowering the gradient at the wire.[2]

The method of conditioning with sulphuric acid is much more important than conditioning with water since it extends the scope of the process to dry gases well above the boiling point of water without any material lowering of the temperature and draft. This is due to three of its properties; its relatively high boiling point; its power to absorb water from surrounding gases at temperatures well above the boiling point of water; and to its rapid rate of diffusion over the surface of solids.

Since it remains in a liquid form at ordinary gas temperatures it is evident that the phenomena of selective surface adsorption does not occur as it does in the case of the aqueous vapor. It is more likely that it furnishes its conductivity by being precipitated as minute acid droplets which are well disseminated through the precipitated coating and quickly spreads a film of acid over the surface of adjacent dust particles due to its high rate of diffusion. Probably it is for these reasons that it has been found absolutely necessary to get a high degree of atomization of the acid.

There are several methods of introducing the sulphuric acid into the gases. Of these probably the

1. "Effects of Dielectrics on Sparking Voltage," by E. R. Wolcott, *Physical Review*, N. S. Vol. XII, No. 4, Oct. 1918.

2. "Electric Strength of Air," Whitehead and Brown, A. I. E. E. TRANSACTIONS, Vol. 36, 1917.

better is to fume it off by boiling the acid and introducing the mist into the gases at some point in the flue system where it may become well mixed through the gases before reaching the treater. In one instance the intense heat of the copper converters was taken advantage of for the purpose of conditioning the gases, by introducing the acid at the hood of the converter by means of a spray. The intense heat atomizes the acid to the highest degree. The advantages of this fine dissemination of the acid probably more than offsets the disadvantage caused by cooling the gases from approximately 1000 deg. cent at the converter hood to 150 deg. cent. at the treater, resulting in considerable acid lost in forming sulphates since time is afforded for the reaction at suitable temperatures.

Another method consists of breaking up the acid into a very fine mist by high pressure air sprays and introducing it at a point near the treater so that all of the acid may be available in a free state. One advantage of this method is due to the fact that it permits dilution of the acid before mixing with the gas when required. Concentrated sulphuric acid is a very poor conductor of electricity. It becomes more highly dissociated and hence more conductive electrically as it approaches a concentration of 30 per cent. It is hard to precipitate a very dry mist, such as that fumed off by boiling, unless it has an opportunity of diluting itself by coming in contact with air containing appreciable moisture. In cases where there is practically no moisture in the gas the acid introduced may all be made available in the treater by diluting it before spraying into the gases, at the same time furnishing a greater volume of liquid at a higher degree of conductivity with which to condition the particle. This result can not be obtained in boiling the dilute acid, for in this case the water is driven off first until the acid reaches a high concentration.

Another method of conditioning which conserves the acid is known as "conditioning the electrodes." Good precipitation may be secured from gases carrying a dry basic fume by spraying the interior of the pipe electrodes with a fine mist of sulphuric acid intermittently. The periods between applications vary from one to twenty-four hours, depending on the nature and amount of suspended solids. If there is present much zinc oxide or other material which will quickly take up the acid, more frequent applications are necessary. It seems that the acid sprayed on the walls of the pipe adheres to them absorbing water from the gases, spreading a conductive film over the solids as they are precipitated until the supply is exhausted. Better results are obtained when the inner pipe surface is almost imperceptibly dampened with the mist than when it is thoroughly wetted.

Since the success of precipitation in smelter gases depends largely on the sulphuric acid content of the latter it may be interesting to note just what constitutes the right amount for good working conditions. Data were taken over a considerable period of time to establish this during the operation of a plant securing good results without conditioning the gases. With an average gas volume entering the treater of 470,000 cubic feet per minute at 184 deg. cent. of mixed converter, roaster and furnace gases, the precipitation over the period as noted visually varied from poor to excellent with the sulphuric acid content of the gases, and filtration tests showing that 67.7 per cent of the solids entering the plant over the entire period had been recovered. The average SO_3 entering the treater during this period was 4.9 g. per 1000 cu. ft. of gas (standard conditions), which is equivalent to 6 g. of H_2SO_4. Leaving the treater, there were 3.1 g. SO_3 or 4 g. H_2SO_4, showing that 33 per cent of the acid was precipitated. This gave a free acid content in the dust precipitated of around 1 per cent. A good working rule is, that gas lends itself to treatment readily if it contains enough acid to give a free acid content in the dust recovered of from 1 per cent to 5 per cent. With greater acidity the dust becomes sticky making it difficult to remove the precipitate. It also causes a high treater current and low treater voltage, which means high power consumption with poor precipitation.

Electrical Considerations

There was an early tendency to attribute the frequent fluctuations or erratic behavior of the plant to various electrical phenomena, especially when it was repeatedly seen to accompany poor precipitation. An example of this is when the dryness of the precipitate on the electrodes increases the electrostatic capacity of the treater sufficiently to cause a resonant condition which is manifest in sparking across the protective gap between the terminals of the high potential winding of the transformer. This critical combination is possible since the capacity reactance of the treater is in series with the inductive reactance of the transformer during a portion of each cycle. That the low treater voltage that this necessitates in an effect and not a cause of the poor precipitation, is shown by the fact that when the electrical system is rebalanced by juggling the inductive reactance of the system so that the treater voltage can be forced up to its value for good work, poor clearing of the gases still continues. When the gases are humidified sufficiently the surging condition disappears and good precipitation results, which continues fairly good when the voltage is lowered down to where it was with the resonant condition. The good precipitation was the result of conditioning the dust particle so that it could give up its charge rather than to reducing the surges. The effect of humidifying the gases in reducing the surges is shown quite clearly by the oscillograms in Fig. 7, where the transient in the high-potential wave at the point the contact is broken is seen when the gases were dry to be about three quarters the root-

mean-square value. When they were humidified, this surge is seen to be greatly reduced. During this test, only one half of each wave was utilized for purposes of safety to the oscillograph. It is interesting to note in this connection that lowering the frequency of the impulses in the treater one-half in this manner has no effect on precipitation except as it lowers the resulting treater potential, and this can be partly compensated for by raising the primary voltage a corresponding amount. There are conditions where the power consumption can be cut almost in half in this manner with only a slight diminution in precipitation. As a rule though the values in the dust lost in this way more than offsets the cost of the extra power.

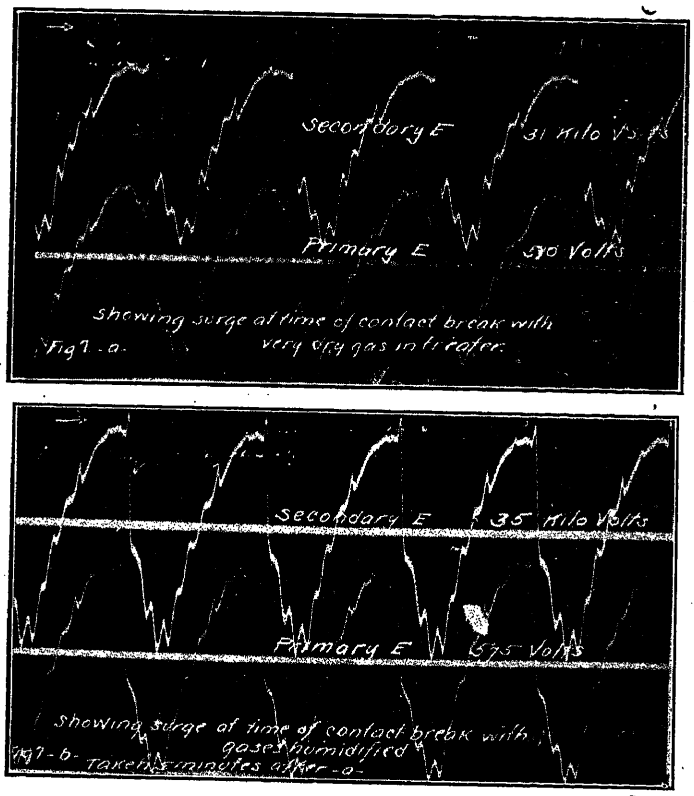

Fig. 7—Oscillograms Showing the Effect on the Surge in the High Potential Wave of Humidifying the Gases

Some of the early generators developed for precipitation work had rather a poor wave form, probably due to tooth ripples. These harmonics had a tendency to increase the effect of the surges and consequently this small defect frequently came in for a good share of the blame for poor work. As a matter of fact, when the gas is in good condition for treatment no difference can be observed in the precipitation from what it is with a perfect sine wave.

There has been considerable discussion as to the best transformer internal reactance. Off-hand one would say that a transformer of high internal reactance is best for the same reason that it is in electric furnace work, so that it can carry a short circuit, which frequently occurs in the treater, without injury. But this is not a real consideration since the revolving contact of the rectifier does not permit a very large current to flow into the treater even on short circuit. Standard power transformers have proved quite satisfactory. One reason for this seems to be that the greater the reactance the more the crest voltage of the wave will be lowered during the portion of the cycle that the rectifier connects the transformer to the treater, making a steeper wave front at time of contact and increasing the surging effects. This lowering of the crest voltage is shown by the oscillogram of the primary voltage wave in Fig. 8. The writer has frequently found that the tendency to surge was reduced by connecting to such a tap in the low-voltage winding as will give a maximum number of turns in series with a corresponding increase in the impressed voltage.

It is now pretty well understood that the electrical side of the process is of less importance than the treater and gas conditions. There is a saying among operating men "get the gas right and electrical troubles may be forgotten." That is the real problem. Electrical matters are relatively unimportant except as they effect the voltage and current of the treater. All that can be required of the electrical system is to stress up the space between electrodes to the economical limit, regardless of the source of the power, the number of electrical sets, or the type of electrical equipment comprising them. As to the current values, it is evident that with a given voltage impressed on the electrodes of a treater the current depends entirely on the conductivity of the space between electrodes and takes care of itself. At least there appears to be no method of varying it except to vary the conductivity of this space by changing the nature of the gas.

There has always been a good deal of uncertainty among engineers regarding the correct number of electrical sets to use for a given treater installation, or, putting it another way, the best proportioning of the investment. There has been a tendency to follow the lead of some other plant without determining if that proportion was best suited for their particular conditions.

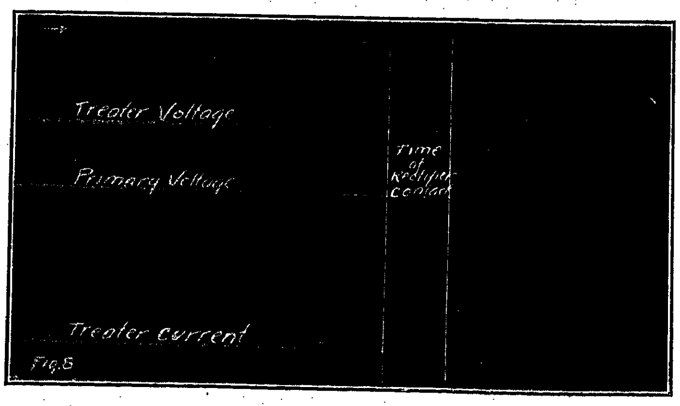

Fig. 8—Oscillogram showing the Time of Rectifier Contact to Primary Voltage Wave, the Treater Voltage Wave, and the Current Wave Impressed on the Treater

Since the main function of the electrical equipment is to keep adequate electrode potential, the investment for any equipment over this is wasted. The curve representing treater voltage, which may be taken as per cent precipitation as obtained from a single set, falls off rather fast beyond a certain limit as the number of electrodes is increased and then flattens out at about 50 per cent of maximum voltage. The problem is to determine the economical limit on this curve, *i e.,* to obtain the most satisfactory balance between the cost of extra machines and power consumed against the extra dust recovered. Since the values in the dust differ at different plants and the rate the treater voltage falls off differs with different types of precipitate, it is evident that no general rule can be laid down and that local conditions should govern. An economic limit for average conditions on a pipe treater was found to be

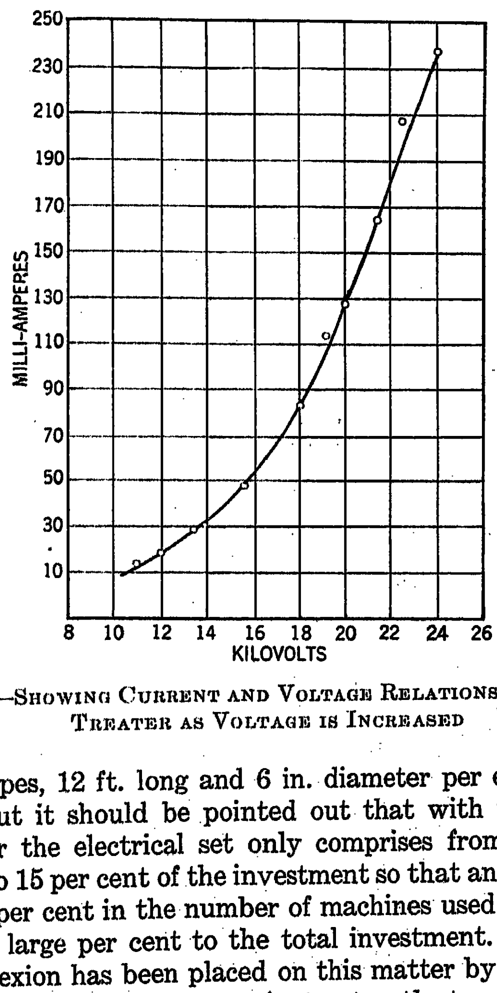

Fig. 9—Showing Current and Voltage Relations on Wire Treater as Voltage is Increased

200 pipes, 12 ft. long and 6 in. diameter per electrical set, but it should be pointed out that with the pipe treater the electrical set only comprises from 10 per cent to 15 per cent of the investment so that an increase of 25 per cent in the number of machines used did not add a large per cent to the total investment. A new complexion has been placed on this matter by the fact that in the more modern wire treaters the treater plant has been cheapened so much that the electrical investment is now as great as the treater investment, which has a tendency to increase the number of electrodes per set.

Electrical sets of 15 kw. capacity have come to be regarded as standard for precipitation work. This is due largely to the rectifier having a poor regulation. The drop in rectified voltage becomes considerable if it is attempted to pass much more than half an ampere over the revolving contacts of the rectifier. The transformer as a rule steps up from 440 volts to 22,000 and 44,000 with intermediate taps. This is suitable for the electrode spacing of six inches usually employed where an electrode potential of 25 kv. is adequate. However 12 in. spacing has been used somewhat, requiring voltage values of twice those given.

Mr. Eschholz has shown in his paper[3] that although the voltage is impressed on the treater in impulses, it has the effect of that from any continuous current source, due to the electrostatic capacity of the treater filling up the spaces between. This fact was established quite early by means of oscillograms (See Fig. 8 in which treater voltage and current waves are shown).

An important point not usually recognized is that due to the cumulative ionizing of the gases as the voltage is raised above a certain limit (explained by Townsends' theory of ionizing by collision) causes the circuit to become more and more conductive so that the last few thousand volts impressed on the electrodes is at the expense of greatly increasing the current flow and hence the power consumed. This is shown very clearly in Fig. 9. While this is a curve showing the current and voltage relations on a wire treater, it may be taken as typical of other types and follows very closely Mr. Peek's curve showing corona loss[4] near the critical voltage for large conductors. In the case in question it is seen that by increasing the voltage from 22 to 24 kv. the kilowatts consumed increased 43 per cent, a useless waste of power since the gases were cleared in this case almost completely at 22 kv. It is evident that considerable power may be wasted if the gases are in a good condition for treatment if the commonly accepted rule of carrying the treater voltage as high as possible is observed. This is a good rule to follow, however, if the gases are so non-conductive that adequate current cannot flow.

It is just as important to know the treater voltage and current values in a Cottrell treater as it is to know the cathode current density and cell potential in electrolytic work, and the best way of obtaining these is to connect a milliammeter in series with the ground side of the treater circuit and to connect a dead beat electrostatic voltmeter which reads root-mean-square values across the electrodes. While the readings obtained may be out a small percentage owing to the intermittent flow of current into the treater, they are at least comparable with each other and serve all practical purposes. It is misleading to try to calculate the treater voltage by multiplying the voltage across the low-tension winding by the ratio of the transformer, on account of the changing ratio of alternating current to direct current at the rectifier with varying conditions. It is

3. "Electrostatic Precipitation," O. H. E. Eschholz, Vol. LX, American Inst. Mining and Metallurgical Engineers *Transactions.*

4. "Dielectric Phenomena in High Voltage Engineering," F. W. Peek, page 144.

also often misleading to use the value of the current flowing in the low-tension winding at different times for comparative purposes, on account of the power factor changing with the nature of the gas in the treater.

As already intimated, the various types of electrical equipment used have received more than their share of consideration. For a time it seemed from the attention the matter received that the success of the process depended on whether the rectifying switch was driven by a small synchronous motor and the current impressed on the step-up transformer taken from the local power system, or whether it should be mounted on the shaft of a motor-generator, the current driving the motor being taken from the power mains and the single-phase current made by the generator impressed on the step-up transformer. In a discussion of Mr. Eschholz' paper already largely cited on this subject the writer pointed out that it was unfortunate that a non-essential should receive so much consideration and that it was really local conditions which should govern as to which system should be adopted, but pointed out a number of reasons why a large smelting company had found it expedient up to that time to install motor-generator rectifiers.

Acknowledgment is made of the cooperation and assistance of the Salt Lake Intermountain Experimental Station of the United States Bureau of Mines in connection with the photo-micrographic study of flue dust. Especial thanks is due Mr. R. E. Head for making the photo-micrographs, and to Mr. C. G. Maier for advice in their study.

Discussion

DISCUSSION ON "RECENT CONCLUSIONS PERTAINING TO ELECTRICAL PRECIPITATION"* (SCHMIDT). "ELECTRICAL ENGINEERING FEATURES OF THE ELECTRICAL PRECIPITATION PROCESS"† (HORNE), AND "ELECTRICAL PRECIPITATION OF SOLIDS FROM SMELTER GASES"‡ (RATHBUN),

Vancouver, B. C., August 11, 1922

C. E. Skinner: It is rather curious that this process, developed primarily to abate a nuisance should become so valuable economically. I have been familiar with some attempts in the Pittsburgh district to abate the smoke nuisance by the Mellen Institute of Industrial Research. They made a smoke survey of Pittsburgh, and a study of this survey shows how desirable it is to abate this nuisance in the Pittsburgh district. However, the values recovered are not such as to justify the cost from the commercial standpoint, and consequently very little has been done.

E. P. Dillon: Mr. Schmidt's paper is very opportune, as it presents clearly an explanation of phenomena which have for many years been an obstacle to precipitation engineers in their efforts successfully to handle certain kinds and conditions of gases that do not lend themselves readily to effective clean-up in Cottrell precipitation treaters.

It is shown that the suspended fume or dust carried in practically any gas may readily be precipitated by proper conditioning of the gas, and while in the case of certain gases there is an apparent anomaly in the relationship between precipitation efficiency and current flow, when such gases are properly conditioned the expected normal relation obtains between precipitation efficiency and current flow.

In substantiation of the theory that a non-conductive deposit on the receiving electrode retards if not entirely stops precipitation, numerous observations have been made, and in a particular instance where the material to be precipitated was ground button dust, it was found that with perfectly clean plates the precipitation was for a short period practically perfect, but after a deposit had collected on the plate precipitation ceased, and in this same problem it was possible, by properly conditioning the gas with the idea of making the deposit conducting, to maintain continuous precipitation.

Mr. Schmidt's analysis of the economics of "treater" design is extremely important, since it is the engineer's function to so design and proportion plants as to show to the user the maximum return on the investment, and knowing the conditions, the designer, by Mr. Schmidt's method, may readily so proportion his plant as to accomplish thus result. With the data obtained from wide research and extensive experience now available to engineers, it is possible to design "treaters" for practically any problems of cleaning gas that will in practical operation obtain a predetermined percentage of recovery or clean-up. It is obvious, therefore, that the proportioning of the "treater" for the percentage of recovery to be obtained will depend to a very large extent on the economics of the problem to be solved, and it is indeed fortunate that engineers are now equipped with information permitting them to take cognizance of the economic elements in designing a "treater" for a given problem.

The necessity of properly conditioning gases has been brought home to precipitation engineers in the problem of precipitating zinc oxide perhaps more forcibly than in any other operation. The recovery of this material, whether pure or impure, by means of precipitation from gases not properly conditioned is extremely difficult. With the increasing knowledge and experience of conditioning gases, it is now considered entirely feasible successfully and economically to treat gases carrying zinc oxide, removing therefrom the fume at any pre-determined and desired efficiency. Gases of this character have been successfully handled in numerous commercial installations, as well as various test problems, with gas volumes from 5000 to 20,000 cu. ft. per min. at temperatures of treatment up to 700 deg. fahr. the fume content of these gases so treated being as high as four to five grains per cu. ft. of gas at standard conditions. In general, the conditioning of these gases has been accomplished by the addition of steam or water, and it is an interesting fact that when so conditioned that effective precipitation resulted, it was found that the precipitate was in a dry form, as required for commercial conditions.

In most of the earlier electrical precipitation installations the treaters were of the open type discharging into the atmosphere, or if closed were so designed merely for the purpose of conducting the gases to stacks. Recent developments, however, have brought about designs of gas tight treaters where the gas is used after being cleaned in the treater, and such gas tight "treaters" have been used in some instances for the cleaning of explosive gases. Numerous installations of the gas tight treaters are now in commercial operation, giving very satisfactory results and evidencing material progress in applying electrical precipitation to an ever widening field of gas cleaning.

Referring to Mr. Rathbun's paper. In the earlier stages of the practical application of the electrical precipitation processes they were considered applicable only to the recovery of sulphuric acid mist, and, as Mr. Rathbun states, for some time later they were thought of as a means only for abating a nuisance. The variety of the applications of the processes to gas cleaning problems has extended to such a point that now practically any fume or dust recovery problem is susceptible of solution by these processes. In fact, the metallurgist and chemist is now free to develop processes disregarding fume losses, even going so far as to create

fume losses in process operations, since the Cottrell processes may be relied upon for efficient economical recovery of such losses.

The description of the wire type "treater" is extremely interesting, particularly in view of the fact that it is based on actual experience, and it is undoubtedly a valuable contribution to the subject of precipitation. Draft losses are an ever present problem to the precipitation engineer, and constant efforts are being directed to minimize such losses in modern designs. Modern installations are so designed that the draft losses will not exceed 0.25 in., and in a wide variety of installations it is found that the draft loss is much less than this, ranging from 0.15 in. to 0.10 in.

The presence of sulphuric acid in some form in the gas is certainly a great aid to precipitation, and the idea suggested by Mr. Rathbun of adding sulphuric acid by various methods to the gases, with the attendant favorable results, indicates a material advance in the art of precipitation. In many plants, however, sulphuric acid is not available for such use, and it has been found in a wide variety of operations that eminently satisfactory conditioning of the gases can be obtained by the proper introduction of water or steam, and this result has been obtained in numerous instances with gases at high temperatures of treatment with a resulting dry precipitate, thereby indicating that in some problems at least the use of steam or water for conditioning is not confined to cold gases only.

As Mr. Rathbun says, the electrical equipment for precipitation has been very well worked out and developed, and we agree entirely with the statement that "the electrical side of the process is of less importance than the treater and gas conditioning. In selecting the number of electrical sets for a given installation, there is room for careful thought on the part of the engineer to so proportion the electrical equipment as to insure a reasonable flexibility and at the same time avoid unduly burdening the installation with an increased investment, keeping in mind the necessity, however, of having available a sufficient number of sets to obtain the desired precipitation efficiency. The general trend of treater design seems to indicate a tendency at this time toward the lower voltages. The selection by Mr. Rathbun of 15-kw. sets as standard checks with general practise, although in some smaller installations sets of smaller capacity are used, but it is generally conceded by precipitation engineers that large capacities such as 50 kv-a. or over are not desirable and are rarely if ever used.

The operating voltage of the treater can be predetermined with fair accuracy, but the most effective voltage to be used will vary with changes in gas condition, velocity, etc. and the electrical equipment is so arranged that adjustment of voltage on the treater can readily be made by the operator to obtain best precipitation under existing conditions.

O. H. Eschholz: To the engineer electrostatic precipitation will always serve as an excellent illustration of the successful utilization of advanced scientific knowledge for the development of an important industrial process. While in other electrical systems the presence of corona too frequently is indicative of energy waste or impending failure, in this process it functions as an essential operating agent. Fume, vapor or suspended solids, ionized in the corona surrounding the discharge wire or chain are propelled through an electrostatic field of decreasing potential gradient to finally impinge upon the surface of an adequate receiving electrode. Because of the importance of the corona phenomenon, interest is frequently centered on the character of the treater voltage wave.

On an oscillograph record of treater voltage and current, the peak voltage as measured by sphere gap was 57,000 and the effective voltage, as determined from the oscillogram, was 97 per cent of the peak. The effective mechanical rectifier ground current on this quite large treater was approximately 1 ampere. Numerous oscillograms taken of treater voltage under varying conditions of gas flow and treater capacity gave in most cases effective voltage values exceeding 90 per cent of the peak. This quite flat character of the voltage wave is doubtless responsible for Mr. Horne's observation that the substitution of a high-voltage direct-current generator (Girven) for the mechanical rectifier does not give a substantial increase in precipitation efficiency.

It is of interest to note that the velocity of the charged particles, or heavy ions, is quite low owing to their relatively large mass. This had been estimated[1] for one set of conditions to be of the order of 0.8 in. per sec. Upon disconnecting the supply circuit as a result of this low ion velocity the heater discharge is found comparatively slow. The discharge rate is somewhat greater than would be estimated from the above value of velocity due to the discharge of the treater energy through the oscillograph circuit as well as to the displacement of the ionized gas by the incoming uncharged furnace gases. As a result of the low "ionic drift" considerable energy is stored between electrodes. This energy assists in maintaining treater voltage or serves to quickly reestablish such voltage in the event of a short circuit caused by a break-down between electrodes.

Owing to the slow movement of the charged particles, only those in the immediate path of the arc were discharged, thus permitting the immediate reestablishment of treater voltage when the arc had been ruptured at the contacts of the mechanical rectifier. It is important to note that because of this low ionic drift and the breaker-like action of the mechanical rectifier, the precipitation time lost due to treater shorts is negligible so that it is practicable to operate treaters very close to their critical break-down voltage.

Some consideration should be given to the fact that treater circuits may serve as a source of high-frequency radiations and hence cause "wireless interference." Observations on a small plant have shown that energy stored in the treater proper is radiated from the transmission line, functioning as an antenna, at the natural frequency of the system, as a result of the intermittent corona or arcing occurring in the treater. In the case studied sharp resonance was obtained with the wave meter located at the top of the treater at 150 and 300-meter wave lengths. The sound in the receivers was very similar to the frying noise characteristic of the treater corona. Various expedients may be adopted to reduce the energy of the high-frequency oscillations such as a high resistance in the treater end of the transmission line—a ground wire screen under the antenna—a condenser across treater line and ground at rectifier end or possibly substitution of steel for the usual copper line wire.

J. C. Hale: There are a few points in Mr. Horne's paper which may lead to questioning by those not thoroughly familiar with the subject and it seems desirable to amplify somewhat on certain portions of the paper.

The relative advantages of the synchronous motor and motor-generator set depend largely upon the characteristics of the power supply circuit to which they are to be connected. If the regulation of this circuit is extremely poor it may, as the author has said, be advisable to install a motor-generator set to secure better operation. Sufficiently close voltage regulations to permit entirely satisfactory operation of the present type of synchronous induction motor has been found in practically all the installations which have been made east of the Rocky Mountains. The disadvantage mentioned,—that a synchronous motor requires careful attention on the part of the operator in starting up to secure proper polarity, is in practise unimportant, as the operator can immediately reverse the polarity if necessary by means of the double pole double throw switch shown in the author's wiring diagram, Fig. 1. In most cases the proper polarity can be determined as shown by Mr. Horne in Fig. 5 of the paper. If the wrong polarity is obtained the precipitator will arc over before the voltage can be raised to the proper operating value.

[1]Electrostatic Precipitation, H. H. Eschholz, *Proc.*, A. I. M. & M. Eng., Vol. 60, p. 243.

The disadvantage that the synchronous motor may slip a pole due to momentary low voltage is, of course, important. Actual tests on the latest design of motors now being furnished by the manufacturers show that they will not drop out of step (or slip a pole) unless the voltage is reduced by somewhat more than 20 per cent. If regulation as poor as this is encountered a motor-generator set certainly should be installed. Such poor voltage regulation is, however, rarely encountered.

With reference to the disadvantages of the motor-generator set, there is a further point which applies especially to small power units, (5, 10 or even 15 kv-a.). It has been shown by oscillographs that unless special attention is given to the generator design the voltage wave obtained from a 5-kv-a. or even a 10 or 15-kv-a. gnerator will be very badly distorted by the oscillations set up by the transformer rectifier circuit. These oscillations are of course too small to react upon the wave shape of a large generator such as would be found on a power circuit. It cannot be definitely said just what is the effect of those wave distortions upon the efficiency obtained in the precipitator. It is obvious however that, if there are very high peak voltages they will prevent, by causing an arc over, the maintaining of a sufficiently high average voltage to secure most efficient precipitation.

With reference to Fig. 6, the reader should be carefully warned not to draw an erroneous conclusion from the curve given. The author's conclusion is unquestionably correct, but it should be borne in mind that although the curve given is typical in shape for all precipitation circuits it will differ in each installation in its location with respect to the coordinates. It might be inferred from the curve given that the maximum obtainable efficiency of precipitation is about 90 per cent. Any desirable location with respect to the abscissa can be obtained by a change in the operation or design of the precipitator unit; in other words, any desired efficiency can be obtained by a suitable precipitator design and there are installations in commercial operation which have shown, by actual test, a continued efficiency of 99½ per cent.

Emphasis should be laid on the reliability of the electrical equipment now available for use in connection with the electrical precipitation process. Eight or ten years ago the objection to the mechanical rectifier because of the high-frequency oscillation set up in the high-tension circuits was very serious and a great many transformer failures occurred. Since that time, by careful study of the problem, the manufacturers of electrical equipment have been able to supply suitably designed and constructed transformers and to protect them by means of external resistance or reactance so that the transformer failures very seldom occur at the present time. All of the other apparatus used in obtaining and controlling high-tension unidirectional currents have been from time to time the subject of study and improvement, and, as a result, thoroughly reliable equipment is now obtainable.

Svend Barfoed: I would like to ask Mr. Schmidt one question: In the treatment of smelter fumes I understand that you can remove SO_3 fumes from the gases, as it is in the nature of a solid. I have not read the paper but I wonder if SO_2, which is a true gas, can be so treated that it also could be removed from the gas so that it will not constitute a nuisance.

W. A. Schmidt: I know of no case where SO_3 has been precipitated as such. SO_3 is very difficult to isolate since it combines very readily with any water vapor present. There is usually sufficient moisture present in the gases to immediately form sulphuric acid which is H_2SO_4. If sufficient sulphuric acid is so formed to exceed the saturation point of the gases at the temperature existing then this excess will form a mist of liquid particles of sulphuric acid and be precipitated as acid or combined with other substances present.

The question of the precipitation of SO_2 has often been raised. SO_2 is a gas and this process does not effect any separation of gases. The suggestion has been made to oxidize SO_2 to SO_3 and convert to sulphuric acid, but that has to date proven impractical.

R. J. C. Wood: It may be of interest to tell about the electrical precipitation that we have been getting on the Big Creek lines. We have a very large precipitator there, 200 miles long and 100 feet wide. We noticed when going over the line some couple of years ago that the aluminum cable was perfectly bright up in the higher altitudes, up near the power houses at the Big Creek end. It looked exactly the same as it did when installed, absolutely new, bright and shining. As you got down into the lower altitudes that brilliancy began to fade, and at two or three thousand feet or so it was of a light brown color. By the time we were down in the San Joaquin Valley it was quite dark brown. By the time we got to Eagle Rock, down near Los Angeles, it was dead black. However, crossing the Tejon Mountains, it lost its color again as it ascended the altitudes—apparently some kind of mountain sickness.

I took a piece of that cable from the Eagle Rock end—and examined it, and I thought at first that this was just discoloration of soot and I could brush it off with my hand. I rubbed it with my hand and I got just a little stain on my hand but the deposit did not come off, and I rubbed harder, and I rubbed until I began to get sore, but still did not remove this coating. All I did was to put a very nice black polish on this coating. The wire looked just like black enamel wire. Finally I got the coating off with either dilute acid or dilute caustic soda. The black powder that came off in the solution I examined under the microscope and found that it was made up of grains of translucent material, I suppose little bits of the country, little bits of rock and dust, and interspersed between those grains were very small black points or spots, but the rather astonishing thing was the transparency of the preparation under the microscope. We expected to see large masses of dark black substance, whereas it looked like a piece of ground glass broken up with just a very few black spots on it.

I am assuming that the voltage on the line causes precipitation of particles flying in the air, that up in the higher altitudes there was not sufficient of the black carbonaceous binder to make the particles stick together, that in the lower altitudes where there was a good deal of oil smoke and so on, the binder cemented the clearer particles together, making a hard coating on the wire. Practically you might say that this coat is a microscopic macadam.

I would like to ask Mr. Schmidt also whether by the use of the treater he could cut part of that very tall stack off. The stack as made—and it is an enormous one, 560 feet high, as I understand—was originally made of that height in order to carry the gases and dust to a sufficient height so that they would not fall on the immediately surrounding country, but be carried off to somebody else. Now, if you put in a precipitator and collect these fumes possibly you might be able to save somewhat in the height of this stack.

W. A. Schmidt: In answer to Mr. Wood's question I would say that in certain cases the stack could undoubtedly be decreased in height, and in fact at some places the stack has been replaced entirely by fans; but in the particular case to which Mr. Wood refers, which is the Anaconda Smelter, that is not true. As a matter of fact, the stack is on the top of a hill, quite a good height above the smelter, and the stack is proportioned so as to give the desired draft behind the furnaces to overcome the resistance in the flue system.

I might say one word in connection with the thought that came to my mind when Mr. Wood spoke of the collection of dust on the high-tension transmission line. As I showed in my informal discussion, the effect of a deposit upon a surface when that deposit is composed of porous or discontinuous dielectric is such as to convert the surface into an ionizing medium. It would be very interesting to obtain some measurements on the high-tension transmission lines on the effect of such deposits on the corona losses. It is quite possible that there might be a distinct effect there.

There is one other question which I would like to touch on in connection with Mr. Rathbun's paper. He speaks of the difference in effectiveness of the wire treater. He unfortunately overlooked pointing out that with the type of construction to which he refers it is possible to put a very large amount of discharge electrode in a very small space. The work which Anderson and Horne conducted, and which is discussed in my paper, shows that after all every treater in its effectiveness follows an exponential equation, and we have no evidence at hand indicating that an arrangement such as Mr. Rathbun refers to in his discussion of the wire treater has any greater effectiveness per unit length of discharge electrode. In fact there is some evidence indicating that the effectiveness per unit length is less. But he does obtain a greater length of discharge electrode with the same cubical contents of the treater, and that, of course, has a distinct bearing upon the cost.

C. N. Beebe: As was pointed out, in Mr. Rathbun's paper, the wire screened treater and also the wire treater were capable of being installed in the present existing flue chamber. It is a fact that modern smelters do not hesitate at all to make an expenditure of millions of dollars on a complete new treater plant; with the wire screen or wire type of treater, which is capable of being installed in the short length of existing flue chamber, the same amount of gases can be treated with the treater, costing three per cent. of a million dollars, or $30,000 approximately. This will give you some idea of the saving to the smelting industry of the research work which Mr. Rathbun has accomplished.

W. A. Schmidt: In connection with that statement I wish to call attention to the fact that in all those cases where the installations have cost sums approximating a million dollars new flues were constructed, and in a measure the entire flue system was scrapped and rebuilt. In the case that Mr. Beebe is referring to, the electrical equipment was on hand, and the cost of installation simply covered the insertion of electrodes into the existing flue.

R. B. Rathbun: The period of six months, which has elapsed since the paper on smelter gases was written, has done much at the various plants at which the author has contact to substantiate the views expressed in the paper on the subjects to "treater design" and "conditioning of the gases."

Discussion of the paper seemed to have centered around the development of the new wire treater described briefly under the head of "Treater Design", together with the other types of treaters.

In view of the remarkable record for construction and operating costs being made at present by this treater in the precipitation field it should require no defense.

Mr. Schmidt remarked in his discussion that it was perhaps unfortunate that the fact was not pointed out that with this type of construction it is possible to put a very large amount of discharge electrode in a small space. The advantage of this is obvious. He does, though, go on to infer that the lessened cost is due to its greater length of discharge with the same cubical contents of treater as in the other types. This would make it appear that its advantages lie almost wholly in its ability to dissipate a large amount of electric power in a small space, whereas it is clearly shown in the paper that economy of power over other types was one of its advantages. It was clearly demonstrated that this, and its high efficiency per unit of cost, was due largely to the fact that it provided a large number of electric fields in series in the same chamber and staggered with reference to each other so that every gas molecule must of necessity pass close to a discharge electrode where the potential gradient is steep enough for its ionization. The fact is again pointed out that in other treaters, such as the pipe, a large portion of the gas passes out parallel to and through the weak field adjacent to the passive electrode which is the wall of the pipe.

In the introduction of the paper it was stated that the subject would be covered from the standpoint of the engineer whose watchword must always be "return on the investment." From this viewpoint it seems immaterial whether or not this treater is covered by the exponential equation developed by Horne and Anderson. It is no doubt a very interesting academic point, however. Nor does it seem important if its superiority measured by the standard of the dollar is conceded whether or not the effectiveness of the discharge per unit of length is less than in other types, as intimated by Mr. Schmidt. This statement, by the way, seems misleading when not qualified. It must be remembered that in the wire treater the gas flow is in the direction of the discharge instead of right angles to it, as in other types, making such a comparison difficult.

It is usual to think in terms of the ionized length, or the distance through which a given gas molecule is in the influence of the electrical field. In the wire treater this length is rather less than in other types for a given gas velocity and cleaning of the gas, having as it usually does only 20 electrified spaces of 6 in. each in series, whereas in pipe treaters the gas usually passes through from 12 to 15 ft. of ionized length.

Mr. Dillon has in his discussion noted one of its very important advantages—that of extremely low draft loss, not to exceed 0.25 in. It might be added that for pipe treaters, performing under like conditions, it is often as much as ½ inch. This conservation of draft is partly due to the fact that the wire treater, equipped with insulating lime seals where live members enter, has practically no infiltration of outside air, but it is mainly due to the fact that the gases are not deflected from their straight course from the furnace to the chimney and suffer practically no interference due to friction of the treater interposed in their direct route.

In regard to Mr. Schmidt's qualifying statement to that made by Mr. Beebe regarding costs. It is true, as the former states, that in the instance cited a large part of the saving was due to the use of flue chambers already in use. In a large sense it was the adaptability of such chambers to this system which led to its development. However, instances have been found where the existing flue does not lend itself readily, and in such cases it is found that a short portion may be rebuilt and the straight line principle maintained without seriously affecting the cost.

Regarding "conditioning the gases." Mr. Dillon, in commenting on present methods as described in my paper, felt that in these considerable progress had been made in the art of precipitation. That is true—but it must be realized that the methods of humidifying or acidifying gases difficult to treat are but makeshifts since the former is injurious to flue and treater system at temperatures where water will condense, and the latter is often prohibitive due to the cost of the acid.

An account of some preliminary microscopic work, together with micro-photographs showing the physical properties of fume and flue dust, was submitted in the paper. It was hoped that this would lead to discussion, or pave the way to constructive thought toward the final solution of this important problem.

Technical Committee Annual Reports, 1921-1922

ELECTRICAL MACHINERY COMMITTEE

To the Board of Directors

It has been the aim of the Committee on Electrical Machinery during the past administrative year to extend its usefulness, as heretofore, to a survey of the art through descriptive papers and the arrangement of meetings for their presentation in cooperation with the Meetings and Papers Committee and to assist in the clarification of work in connection with the standardization of temperatures in electrical machinery.

A review of the theory of electrical machinery is opportune from time to time and this Committee has endeavored to follow this idea by inviting a paper on the kinematic reproduction of vector diagrams of induction motors, which was presented by Prof. Karapetoff at the Midwinter Convention. Another paper on "Theoretical Problems in Connection with Induction Motors" was solicited from Mr. B. G. Lamme and was presented at a meeting specially arranged for this purpose at Pittsfield.

The development of large power generating machinery and its application to modern power-house design has been considered in the presentation of important papers on the new development work done at Niagara Falls, on the Canadian side. These papers were presented at the Annual Convention in June, held at Niagara Falls. They describe constructive engineering work of great originality and magnitude.

The problem of the internal heating of coils in alternating current generators, which has been agitated for some considerable time, has received the most careful attention of this committee. At the Pittsfield meeting of the committee held March 16th, the problem itself was fully discussed and it was decided that the designing engineers on the one hand and the operating engineers on the other would present complete experimental data and records at the June Convention. These records were presented by Messrs. Foster, Newbury, and Williamson for the designing engineers, and by Mr. Philip Torchio for the operating engineers.

A most complete discussion of the subject took place, which it is hoped will result in a settlement of this problem by the formulation of rules of standardization, upon which the development work of the art will be based for some time to come.

The efforts of electrical engineers during the past year in connection with the design and construction of electrical machinery have been concentrated very largely upon the subject of greater refinement in the determination of temperatures and upon the development of larger sizes of individual units. This applies particularly to the generators connected to steam turbines and to large water-wheels. The work in the development of the latter, which was so well described by Mr. William M. White in his paper on "Hydraulic Turbine Development" delivered under the auspices of this committee at the June Convention last year, has led to the construction of large hydraulic units at speeds formerly undreamt of. This, of course, was immediately utilized by the electrical engineers for the construction of electric generating units, so that now individual units of capacities of 50,000 kw. are not only being contemplated but actually designed and executed, both for steam turbine connection and water-wheel connection. It is, of course, evident that the latter are very much larger in size on account of their reduced speed.

There is another field in which there is promised great activity and reference is made to the possibilities in the railroad field. It is evident that the condition of the railroads of the country is today such that, unless their present capacity is greatly increased, the railroad system will be unable to do justice to the future of industrial development. It is evident that, through the applications of electrification, the capacity of the terminals, both as regards passenger handling and freight handling, can be enormously increased. This has been shown convincingly in the electrification of the terminels of New York City and Philadelphia, and the sooner the railroads realize the necessity of such work the better it will be for them and for the country at large. Such economic development will naturally carry with it a tremendous stimulus to the entire electrical industry, with the result that the electrical machinery which comes under the scope of this Committee will meet with an area of revival.

The chairman wishes to thank the members of this committee for their active and loyal service rendered failthfully throughout the year.

B. A. Behrend, *Chairman*

PROTECTIVE DEVICES COMMITTEE

Subcommittee Circuit Breakers and Switches—B. C. Jamieson, *Chairman*

To the Board of Directors:

Several papers covering certain features of this subject have been presented before the Institute this year, which we feel will be instrumental in improving this type of equipment. The representatives of the Power Club, N. E. L. A. Electric Apparatus Committee, and your committee have cooperated in attempting to clarify interrupting capacity ratings of oil circuit breakers. The three important features in this rating are:

1. The point at which the duty cycle terminates.
2. The condition of the breaker at the end of the duty cycle.
3. The starting point of the duty cycle, whether open or closed position of the breaker.

These points threw this whole matter back to a stage which required discussion of fundamentals supposed to have been thoroughly understood and agreed upon

previous to the publishing of the Hewlett-Burnham-Mahoney paper.

A fairly definite understanding has been reached on the first two points, *viz.*

1. Duty cycle terminates with the breaker in the open position.
2. The breaker is to be capable of closing and carrying full rated current.

There has been so much misunderstanding and difference of opinion regarding the third point, that it was decided to submit the subject for general discussion at the A. I. E. E. Annual Convention at the time of the presentation of the papers on circuit breakers. However, when these papers were presented, much disappointment was felt by operating engineers because of the small amount of desirable data that they contained. On this account the discussions were not very fruitful and the matter of duty cycle remained in practically the same undefined state as before. The opinion of your committee, however, is that the duty cycle should begin with the breaker in the open position, and the duty cycle consisting of closing the breaker on a short-circuit and the breaker interrupting this current. The multiple shot rating to be made up on the basis of repeating this cycle the desired number of times.

The committee also favored the suggestion of the manufacturers that the old standard so-called two shot rating be retained as a published or reference standard for the normal measure of breaker capacity.

Until the committee can get further assurance that its findings would receive more approval, it hesitates to submit these findings as a final report. The committee, however, hopes that the ultimate disposition of the matter will be on the basis as recommended since the N. E. L. A. findings are based on a reluctance to disturb existing manufacturing standards. If this is their principal objection it would appear that there is good ground for believing that, with this removed, they would favor the same definition of duty cycle as we propose. Certainly, it would make for a safer and more logical standard of protection to have a breaker which is capable of closing in on a short circuit at its first operation and particularly is this so in view of the fact that in all subsequent operations it must be able to do so.

In view of the lack of agreement among the various organizations interested in this matter of duty cycle, it is proposed that during the coming year your subcommittee shall immediately begin work on a comprehensive plan for the guidance of member companies contemplating oil circuit breaker tests, specifying the data which are necessary to certify or amplify the correctness of the present definition of interrupting capacity of oil circuit breakers. It is believed that such a course will eliminate to a large extent duplication in tests and will also serve to remove elements of doubt as to the efficacy of the tests, either of which would of course result in furthering the development and reducing the hazards incident to the test. It will serve also to accomplish a more thorough diffusion of results among the interested companies and unify the manufacturers in the line of development and progress.

This program would perhaps be a little more logical if it had been possible to dispose of the duty cycle matter during this last year. However, it is believed that the subcommittee will be warranted in going ahead anyway with a more intensive scrutiny of the fundamentals which were assumed as correct in order to get a satisfactory working definition of duty cycle.

Subcommittee on Grounding

E. C. Stone, *Chairman*

The subcommittee on Grounding of Systems of the Protective Devices Committee was created at the meeting of the General Committee held in New York on Friday, Oct. 14, 1921. The scope of the Committee was defined as follows:

"It was decided that a subcommittee should be appointed to study the methods of grounding and collect such information as it thinks desirable regarding the amount of neutral resistance and special application of relays to grounded systems. This subcommittee was to cooperate with the subcommittee on Relays in properly stating the latter phase of this problem."

Under date of November 22, 1921, the subcommittee was further instructed by the Chairman of the General Committee to make a study of the Protective Devices which would be considered necessary in connection with the use of 66,000 volt underground cables for bringing transmission lines of such voltage into the sub-stations.

It was decided that the best method of approach to this study would be a questionnaire. Accordingly, the questionnaire, of which a copy is attached herewith, was prepared. The essential points which the questionnaire was designed to cover are as follows:

General practise with reference to operation.
Grounded or ungrounded.
Number of points grounded.
Method of grounding.
Operating experience.
Switching practise.
Types of grounding resistances.
Inductive inter-action with signal circuits.
Relay systems.
Protective devices other than grounding used to take care of surges.

On account of the unpopularity of questionnaires, it was decided that this one should be sent out only by members of the committee to their personal friends in the various operating companies. The results, however, have been very gratifying and indicate that the men on this subcommittee are in close touch with

practically all of the important operating companies in the United States.

It was found that the Electrical Apparatus Committee of the National Electric Light Association was making a study of methods and practise in grounding the neutrals of large generating stations. This study was under the direction of Mr. H. C. Albrecht, who has very kindly cooperated with this subcommittee in every way possible and has made available all of the information which he had collected bearing on the subject.

In collecting the data two major sub-divisions have been made, as follows:

(a) Practise in systems which transmit substantially all of their power at generator voltage.

(b) Practise in systems which step up substantially all of their power to transmission voltages above generator voltage.

In order that this committee might work in close cooperation with the N. E. L. A. committee, Mr. P. H. Chase of Philadelphia was appointed to gather the data and prepare the report on Section A. The report on Section B will be prepared by the chairman of the subcommittee.

Up to the present time, 31 companies have submitted complete answers to the questionnaire sent out. These companies represent a total kv., of 5,002,500 and operate 15,804 miles of transmission lines at voltages from 11,000 up 150,000. Thirteen other companies have submitted the essential facts regarding their grounding practise.

Very wide divergence in practise is indicated. Some systems including many miles of line at very high voltages are apparently operating successfully ungrounded, although the trend is strongly towards a dead grounded neutral for systems operating at 66,000 volts or above. For systems operated at lower voltages, resistances of widely varying ohmic magnitude are used. Practise with reference to switching, type of ground used, and other protective devices is also very divergent and some very unique schemes have come to the committee's notice.

As the collection of data is not yet completed, the report of the subcommittee at this time must be merely a progress report. Because of the wide divergence of present practise, the chairman of your committee feels that the subject is of sufficient interest to warrant holding one or two sessions of one of the main quarterly meetings of the Institute. The data should all be in in time to be presented at any meeting after January 1, 1923. In addition to the report on the data collected on practical operation by the subcommittee, it is also recommended that one or two papers be prepared on the theoretical aspects of the subject. The industry is sadly lacking in definite information as to why transmission systems are grounded or not grounded and what factors determine the method of grounding.

Subcommittee on Lightning Arresters

F. L. Hunt, *Chairman*

The publication of the operating data showing the performance of several types of arresters in a paper by Mr. Roper before the Institute in November, 1919, has apparently acted as a great stimulus to the designers and manufacturers of lightning arresters, as at the present time three new types of arresters are being offered for service tests and there will apparently be at least two additional types offered within another year. In addition the two papers on the subject of Lightning Arrester Protection which were presented at the Mid-winter Convention have created considerable interest.

The development of equipment for testing lightning arresters with large capacity, current and steep wave front has been of great help in classifying the different types of arresters as to the relative protective value against surges.

The tests made by this method and the analytical studies of the engineers of the manufacturing companies appear to confirm the prediction from the published data previously mentioned, namely, that a lightning arrester to be most efficient as a protective device, should have a minimum impedance to flow of surge current so as to permit a very high current to flow at the instant of lightning discharge.

These tests also indicate that it is apparently entirely possible to devise an arrester which will have a maximum potential across its terminals that will be less than the primary bushings and the primary windings of line transformers as now constructed for distribution voltages will withstand. It is confidently expected that arresters meeting this requirement will be produced by one or more manufacturers and available for general use within the next few years. When this result is achieved, then disturbances from lightning will be practically eliminated from our low potential distribution circuits, except in the few cases of defective bushings, insulation damaged by severe overloading, or direct lightning strokes. The total difficulties per annum in a large system from these causes should not exceed one tenth of one per cent of the total number of transformers installed.

With the case of the lightning arresters for transmission voltages, the situation is somewhat different. There appears to have been no radical improvement in such arresters during the last few years, but with the development of the new types of arresters for the distribution voltages and with the recent improvements in the methods of testing lightning arresters, and with the large amount of attention being given by the engineers of the manufacturing companies to the analytical study of the subject of lightning and lightning arresters, it seems quite probable that the serious improvement in lightning arresters for distribution voltages now in progress will be followed very quickly by corresponding improvements in lightning arresters for the higher voltages.

A paper read at the Midwinter Convention brought out what the prevailing practise is in the use of lightning arresters on circuits of 10,000 volts and over, and also brought out the fact that some prominent engineers differ widely in their views about the use of arresters from the majority of opinions.

A paper by Mr. Creighton pointed out the operating characteristics of the arresters in use today and their application to the conditions that have to be taken care of on transmission lines, and made clear the fact that apparatus now being supplied under the name of lightning arresters has characteristics so widely different that a need has arisen for a classification of lightning arresters, so-called, as supplied to the operators.

The subcommittee is now working on a classification of lightning arresters which will make possible a more complete comparison of the types available and give operating engineers a better basis for choosing the arresters to be used on their lines. We believe such a classification should include the following sub-divisions:

1. Path of initial discharge.
   - (a) No gap in series.
   - (b) No resistance in series.
   - (c) Gap in series.
   - (d) Resistance in series.
2. Rate of discharge at over voltage, normal frequency.
   - (a) High rate (specify limits).
   - (b) Intermediate rate (specify limits)
   - (c) Low rate (specify limits)
3. Rate of discharge at over voltage, high frequency
   - (a) High rate (specify limits)
   - (b) Intermediate rate (specify limits)
   - (c) Low rate (specify limits)
4. Flashover potential at normal frequency.
   - (a) 20 per cent (this will include the counter e. m. f. type of arresters)
   - (b) Between 20 per cent above normal potential and 1.5 times normal potential plus 5000 volts. (This will include the types of arresters consisting of a number of spark gaps with a resistance in series.)
   - (c) More than 1.5 times normal potential plus 5000 volts. (This will include the arresters of the single gap type with resistance in series.)
5. Time required to interrupt dynamic current.
   - (a) No dynamic current follows.
   - (b) Less than 2 cycles.
   - (c) Less than 10 cycles.
   - (d) More than 10 cycles.
6. Attention required in service.
   - (a) None. (This will include arresters like the most recent designs for low distribution voltages, and contained in a sealed porcelain case that does not permit of inspection or adjustment.)
   - (b) Not more than once per season. (This will include some arresters of the wooden box type in which the gaps must be cleaned and perhaps renewed or adjusted.)
   - (c) After every heavy discharge.
   - (d) Once a day or oftener.

Subcommittee on Current Limiting Reactors

N. L. POLLARD, *Chairman*

Failures. From information gained by the committee from a number of operating companies that use a considerable number of current limiting reactors, it appears that the manufacturers are gradually overcoming many of the weaknesses inherent in previous designs, so that during the past year there were fewer failures. Several of the failures reported were due to the coil supports being too far apart or the coils not being properly braced. The manufacturers have in most cases remedied these defects and it is hoped that the changes made will entirely eliminate this trouble.

A few failures were evidently caused by the thermal capacity being too small for the service. Both the operating companies and the manufacturers are taking the necessary precautions so as to prevent trouble of this nature in the future.

High-Voltage Reactors. One manufacturer reports the new development of a high-voltage reactor which is applicable to high voltage tie lines. The windings are constructed and insulated in a manner similar to transformers and are immersed in oil and contained in steel tanks.

In order to get a straight line volt-ampere characteristic, the iron cores are omitted and to prevent the flux from passing into the tank and causing excessive losses, a short-circuited winding is placed adjacent to the walls of the tank. In water cooled reactors the copper cooling coils are utilized also for the flux shielding winding.

Outdoor Reactors. One manufacturer reports that one of their first outdoor installations was made in 1916. The performance of these and all others subsequently installed has been satisfactory.

During the past year, another manufacturer has started to build outdoor reactors and it is reported that those that have been installed are operating successfully.

Mechanical Strength of Reactors to Withstand Magnetic Forces. One of the manufacturers of reactors reports exhaustive tests both at large power plants and with a 27,000 kv-a. generator specially built for the purpose of testing electrical apparatus under short-circuit conditions. The tests made with the generator were carried up to the point of destruction of the reactors. These tests clearly demonstrated the short-circuit stresses that the reactors were able to withstand.

Use of Shunting Resistors with Reactors. An exhaustive investigation is being made by one manufacturer of the effect of shunting the reactors with carborundum resistors. It is their opinion that the resistors damp out oscillation and thereby clear the system of disturbances which might build up very high voltages. One large operating company reports the successful operation of about 50 indoor 13,200-volt reactors equipped with resistors.

Losses in Reactors. During the past few years the cost of copper has been low and the cost of electrical energy high. As a result reactors can be economically designed with much lower losses than previously. One of the big advantages is on account of the reactor being able to withstand overloads and short circuits for greater periods of time.

The committee is working on a standard specification for reactors and hopes to have something definite to report before very long.

The committee expects to have three or four papers ready to present at one of the Institute meetings next year. Several of the papers will deal with the design features of reactors from the manufacturer's standpoint and at least one paper will give the experience of an operating company with different types of reactors over a period of eight years.

Subcommittee on Relays

E. A. HESTER, *Chairman*

In accordance with the decision reached at the first Protective Devices Committee Meeting of this year, which was held on October 14, 1921, the Relay subcommittee has been actively engaged in the preparation of a paper utilizing the information collected from the replies to a questionnaire sent out by the previous sub-committee. In order to facilitate this work, an editing committee was appointed consisting of two operating and two manufacturing company representatives. On account of the fact that some of the information contained in this questionnaire was at least a year old it was found necessary to get into communication with most of the reporting companies and request up to date data on the various schemes which were reported. Information was also requested on any schemes which might have been installed since the original reply was made.

In addition to the data obtained from the questionnaire, there were also incorporated in the paper sections on the calculation of short-circuit currents, approved practises in relay application and notes on settings and tests. At the suggestion of some of the members of the Protective Devices Committee a section on methods of keeping records of operation were also included.

The question of cooperation with the Apparatus Committee of the National Electric Light Association in the preparation of a Relay Handbook has also been active. Mr. C. H. Sanderson of the New York Edison Company has been appointed Chairman of the N. E. L. A. Relay subcommittee and is to cooperate with the Chairman of the A. I. E. E. Relay subcommittee in this work. The Chairman of the Apparatus Committee and Protective Devices Committee with the Chairmen of the two subcommittees held a meeting in January and decided to prepare a tentative outline of the handbook as the first step in this work. Such an outline has been prepared and submitted to the various interested persons. On account of the work on the paper the A. I. E. E. Relay subcommittee has not had an opportunity of actively engaging in this work but now it is hoped that with the paper completed, the work may proceed more rapidly. It is intended to have the handbook completed some time this fall.

There are several questions which have been docketed for future study by the Relay subcommittee. These are as follows:

1. Protection of high voltage underground cable.
2. Further study of the use and merits of split conductor cable.
3. Apparatus protection. Former studies have been largely on transmission line relays. It is proposed to make a study of protection of generators, transformers, rotary converters, etc., and possibly to present a paper covering the investigation.
4. Special relay applications, such as those used in automatic and remote controlled stations.
5. Further study in standardization. A former subcommittee proposed a standard nomenclature for relays. This has been adopted by the Standards Committee, and there now seems to be a need for some standard form of symbols to represent various relays in single line schematic and detail diagrams. It is proposed to suggest a list of suitable symbols and if approval can be obtained, to use them in the N. E. L. A.—A. I. E. E. handbook.

H. R. WOODROW, *Chairman*

COMMITTEE ON ELECTROCHEMISTRY AND ELECTROMETALLURGY

To the Board of Directors:

This committee has not been active for some years, due principally to the facts that the subjects falling properly within its scope are more advantageously treated on the chemical and metallurgical sides than on the electrical, and have, therefore, been much more actively dealt with by some of the other engineering societies, notably the American Electrochemical Society and the American Institute of Mining and Metallurgical Engineers. At the outset this situation was discussed with the various members of the committee, of whom five showed an active interest in the work.

This discussion brought out in general that the usefulness of this committee lies principally in stating from time to time the status of the art, with particular reference to the power side, as even those members of the Institute who are furnishing electrical equipment

to electrochemical industries do not seem very familiar with the essentials of the processes in which the power is used. It seems desirable at this time to make a general resumé of the various branches of the industry, giving a detailed statement of power requirements, and it is suggested that a symposium be arranged, a page or two being contributed by each of a number of men specializing in the various processes coming under this heading.

A second possibility for work on the part of this committee covers the subject of electrochemical corrosion to underground structures. This is a subject which has been neglected by the sister societies, due probably to the fact that it is a matter chiefly interesting public utility companies and in a sense parallel to inductive disturbances which fall exclusively within the province of the A. I. E. E.

It so happens, however, that there has been a special joint committee for a number of years working on this subject, a preliminary report of which has been recently published in bound form. It seemed to some of us that a public discussion of this report would be advantageous to all concerned, but this was opposed by the chairman of this special committee and at the present writing the President of the Institute has not come to any conclusion as to the desirability of action, although personally he appears to be in favor of it.

Discussion along the general lines of the conversion of chemical into electrical energy appears to belong, in the opinion of most of this committee, within the province of the Electrochemical Society. This, therefore, eliminates the discussion of the various forms of batteries as such, although leaving open their application, as, for instance, the use of storage batteries in power plants.

Altogether the most promising line of work for next year's committee would appear to be the preparation of the general symposium suggested earlier in this report.

LAWRENCE ADDICKS, *Chairman*

COMMITTEE ON TRANSMISSION AND DISTRIBUTION

To the Board of Directors:

The Committee on Transmission and Distribution submits its report for the year 1921-1922 under the following headings:

1. Report of the Cable Research Committee.
2. General Review of Construction Problems in Overhead Transmission and Distribution.
3. Underground Distribution Practise on Edison D-C. Systems.
4. Testing of Underground Transmission and Distribution Cables.
5. Foreign Practise in Transmission and Distribution Systems.
6. Review of Papers Submitted During the Year.

As in previous years and in line with the action taken by the Board of Directors a year ago, the report of your Committee summarized under the various headings records the historical progress made in the field covered by the committee, and secondly, indicates the direction in which future progress may be expected.

Your chairman desires to make particular reference to the report of the Cable Research Committee, which has been working jointly with the Underground Systems Committee of the National Electric Light Association.

In the matter of overhead transmission and distribution, as well as several of the other subjects in the report, the work was carried on by subcommittees appointed to investigate each particular topic and to confer with other engineering societies to obtain their views and as far as possible, to outline the tendencies in the entire field of transmission and distribution.

The section of the report dealing with foreign practise is the result of a questionnaire sent by Mr. C. T. Wilkinson, an English member of the Committee, to prominent engineers who are in close touch with European transmission and distribution problems.

REPORT OF THE CABLE RESEARCH COMMITTEE

During the past year, one American company has installed some three-conductor cable for operation with a normal working pressure of 33 kv. Other companies are seriously contemplating the installation of single conductor cable for three-phase transmission at 40 kv., 60 kv. and 66 kv. respectively. In the first case, the company is transmitting the energy from a generating station in one of the large cities to their surburban districts. In the other two cases the companies are receiving the current from overhead transmission lines, but on account of the objections to these high voltage lines in the thickly settled portions of moderate sized cities, they are proposing to use underground cable for transmitting the current directly to the distributing substations located in the center of the city. This plan will eliminate the extra step-down transformer substation at the city limits, which would otherwise be necessary. It is also reported that an English manufacturer has taken an order for ten miles of 55,000-volt three-conductor cable for use in Holland and also has completed and has on test a single length of 60,000-volt three-conductor cable.

In connection with these several propositions, it may be well to review our present knowledge and state of the art in this country with a view of determining to what extent the various elements in the design and construction of cables will limit the voltage.

1. Dielectric Losses. On this subject a number of papers has been presented to the Institute in recent years which have included examples showing the reduction in dielectric losses. The leading manufacturers in this country are now prepared to make dielectric loss guarantees on three-conductor cables up to 33 kv. normal working pressure, and on single-conductor cables for somewhat higher pressures. In the cables

having high dielectric loss, the maximum permissible operating temperature is determined by the temperature at which the heating of the cable due to dielectric loss becomes cumulative. For low dielectric loss cables, the limiting temperature is that temperature which will cause permanent deterioration of the impregnated paper insulation.

It is now possible to get lead-covered cable with impregnated paper insulation and with a dielectric loss so low that this feature will not be the determining factor in limiting the voltage.

2. Maximum Permissible Operating Temperature of Impregnated Paper Insulation. The maximum permissible temperature for impregnated paper insulation in lead-covered cables is set forth in the Standards of the Institute as 85 deg. cent., while for similar material in electrical machinery, the limiting temperature is 105 deg. cent. This subject has been discussed in the committees of the Institute for a number of years, and a symposium of papers was presented at the Midwinter Convention in 1921. The views expressed at that time were so widely divergent that the Standards Committee decided that there was no hope of reconciling the conflicting views of the various engineers without additional data. The Research Subcommittee, has, therefore, arranged during the past year for a research investigation on this subject to be conducted by the Massachusetts Institute of Technology under the supervision of the committee. This work has been started and it is expected to continue over a period of about three years. The funds are being contributed by the N. E. L. A. and A. E. I. C.

For single-conductor cables intended for a normal working pressure of 66 kv. between conductors, the pressure to ground would be about 38 kv. and the maximum copper temperature according to the Institute Rules would be 85 deg. minus 38 deg. or 47 deg. cent. While this is about the same as the English practise for armored cables buried directly in the ground, it would be considered rather low in this country for cables to be installed in conduits, and particularly so if there were other loaded cables in the same conduit. Apparently it will be necessary to operate such cables at a very low current density or operate the cables at temperatures materially higher than those permitted by the Institute Rules. A number of the larger American companies however, are now operating their transmission cables as well as their low tension cables at temperatures appreciably above those permitted by the Institute Rules and without signs of depreciation of the insulation. It is suggested that this Institute Rule should be revised upward to correspond with the advances in the art.

3. Maximum Safe Dielectric Stresses. In the past we have apparently confused troubles due primarily to dielectric losses and dielectric stresses. A symposium of papers on this subject was presented at the June Convention. One of these papers indicates quite definitely cable failures due to dielectric stresses are quite rare. In Table I are given data on high voltage cables in this country and in several foreign countries, from which it will be noted that a number of foreign cables are operating at dielectric stresses materially higher than any that are used in this country. This tabulation has been made from data secured from a number of sources; the data regarding the English cables have largely been published in the English technical press and the statements indicated that the 33 kv. cables were being installed for ultimate operation at that pressure, but most of them were being operated at the start at a lower voltage. The best information obtainable however, is that at least one of these cables is now operating 33 kv. The statement is also definitely made that the 33 kv., three-conductor cable in Normandy has been in actual operation since 1914. The single-conductor cable at Barcelona, Spain, has also been in operation at 50 kv. normal working pressure since 1914 without any cable failures except one caused by electrolysis.

TABLE I
DATA ON HIGH-VOLTAGE CABLES

Location	Date	Normal operating voltage	Size of conductor cm.	Thickness of insulation: Conductor	Thickness of insulation: Belt	Maximum dielectric between conductors kv. per cm.	Stress to sheath

No. 1 has sector shaped conductors; all others are round.
Dielectric stresses calculated according to Davis & Simon (Journal A. I. E. E., January 1921).
*Single conductor cables. All others are 3 conductor.
†Not given.

In an Institute paper several years ago the statement was made that when the dielectric stress exceeded 20 kv. per centimeter, ionization would occur. Shortly afterward a paper appeared in the technical press giving a list of cables that had been in operation for a number

of years in this country at materially higher stresses. One of them, the 25,000-volt cable on the St. Croix-St. Paul transmission line, is given in the above table.

Engineers are not in accord as to the maximum permissible dielectric stress nor which particular dielectric stress it is that is the limiting feature in high-tension cable design. Some engineers think that it is the maximum stress next to the conductor, but others think that it is the average stress, that is, the total voltage divided by the thickness of insulation. An English engineer contends that the limiting stress is determined by the stress next to the lead and published some data which appeared to support his theory. With such widely divergent opinions, we are apparently not prepared at this time to set the exact limit of dielectric stress that is permissible, but we can be guided however, by the stresses that are found on cables that have been in successful operation for a number of years. Our information along this line should be considerably extended if in the future we are to design high-voltage cables scientifically with the thickness of insulation properly proportioned to the working voltage.

4. Thickness of Insulation. The Standards of the Institute give recommended thicknesses of rubber insulation for various sizes of conductors and working voltages, but they do not include any such recommendations for impregnated paper or varnished cambric insulation. In 1920 the N. E. L. A. Underground Systems Committee included in its report a tabulation of thicknesses of insulation being used by the larger operating companies throughout this country. These thicknesses varied over a rather wide range, and accordingly the committee secured from the American manufacturers their recommendations for the thickness of impregnated paper insulation for various sizes of conductors and working voltages. These recommended thicknesses are shown in Figure 1. In the same figure are also shown the recommendations of the British Engineering Standards Association, several examples of ordinary English practise, the thicknesses being used by one of the larger American operating companies, and also the thickness being used by one of the leading English companies for 20,000-volt cable.

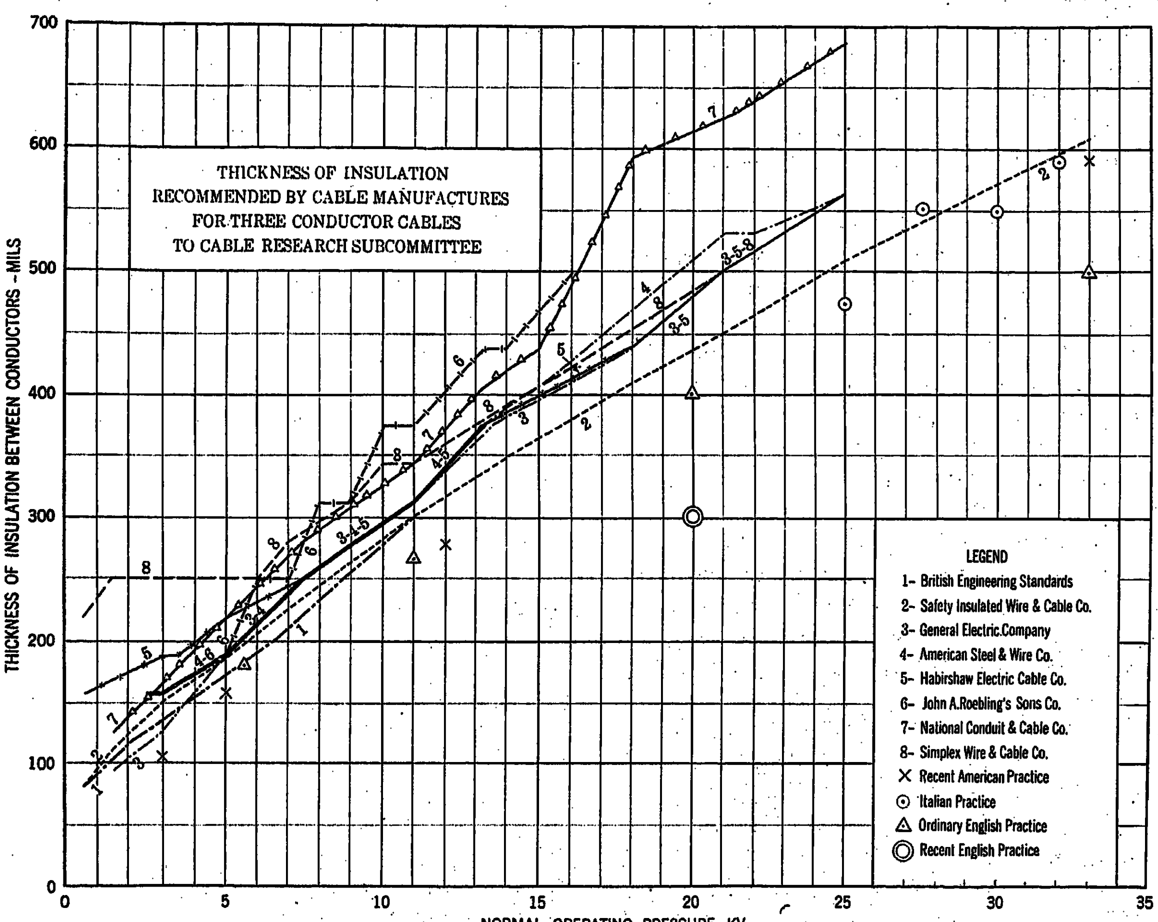

Fig. 1

From this figure it will be noted that ordinary English practise is appreciably below the minimum recommended by any American manufacturer, and also that the recent thickness adopted by one English company for 20,000-volt cable is 25 per cent below their previous practise, and about 30 per cent below ordinary American practise. In Italy the high voltage cables apparently have about the same thicknesses of insulation as are used in this country.

English practise for the installation of underground cables calls for the cables to be made up with steel armor and jute covered and laid directly in the ground. Their conditions for the radiation of heat from the cable are therefore very much better than in the ordinary American practise of cables installed in conduits. According to the best information obtainable the English operating companies carry about the same loads on the various sizes of three-conductor cables as are customary in this country, but because of the improved facilities for radiating the heat, their maximum operating temperature of the copper is about 50 deg. cent. The dielectric losses in their cables are about the same as the best American practise, and at this low temperature, cable failures due to cumulative heating caused by the dielectric losses do not occur. It appears therefore, that when the failures due to dielectric losses are eliminated, that English engineers and operating companies think that they are entirely warranted in reducing the thickness of insulation materially below those that have heretofore been considered necessary.

Two American manufacturers have been operating experimentally, at about double voltage and at room temperature, short lengths of three-conductor cable made from operation at 33 kv. One of these companies reports that after three months continuous operation a case of trouble occurred in one of the cable bells. This trouble was repaired and the cable again placed on test. Cable bell trouble has also been repeatedly experienced in endeavoring to make dielectric strength tests on the same cable, and tests which have been carried up to 212 kv. have been limited by trouble in the cable bell and without causing a failure in the cable. A dielectric strength test of five times normal working pressure is considered by some engineers as a necessary test for their three-conductor cables. If the cable bells are not to be the weak feature of the line, then they should be able to withstand the same test, and if it is impossible to go materially above 200 kv. in a three-conductor cableb ell, then this may place the limit on three-conductor cables at about 40 kv.

5. *Dielectric Strength Test.* The Standards of the Institute mention dielectric strength tests on cables, but cover only the maximum length of the sample to be tested and the limiting temperatures. The rules also specify the test voltage to be applied to full reels of varnished cambric and impregnated paper cables at the factory, but there is nothing in the Rules to give the ratio between the dielectric strength test and the high voltage test applied to full reels. If it is the intention that the Standards of the Institute will prescribe tests which will determine whether or not the cable is satisfactory for the proposed working voltage, then it is submitted that the rules should include a dielectric strength test so as to insure that the cable has a proper factor of assurance.

6. *Impregnation of Paper Insulation.* Some years ago practically all American manufacturers used a vegetable oil base compound for impregnating the paper insulation, and generally these were rosin oil compounds. Cables with paper impregnated with these compounds were entirely satisfactory for the lower working voltages, but in their efforts to reduce the dielectric losses, the leading American manufacturers have gradually changed to a mineral oil base compound. About three years ago the percentage of vegetable compound, as shown by the saponification test, ranged from 0 to 35 per cent, while at the present time the maximum is about 10 per cent.

Practically all manufacturers now use the vacuum process of drying and impregnating, but a number of auxiliary methods are in use by the different manufacturers for the preliminary heating of the insulation for the purpose of removing the moisture. These improved methods of drying and impregnating have served to increase the uniformity of the product as compared with the older open tank methods of impregnation. With the older methods there would occasionally be found a small spot sometimes a few feet long in the center of a length of cable where the paper insulation was entirely devoid of any suspicion of impregnating compound. Such spots of dry paper are not found when the vacuum process of drying and impregnating is used.

Impregnating compounds enter the pores of the paper rather slowly, even under the most favorable conditions. When the cable leaves the factory it generally shows a considerable excess of compound in the interstices of the stranded conductors and between the layers of paper and throughout the fillers. After the cable has been operated at moderate temperatures for a number of years, this excess disappears. Engineers who have investigated such cable and removed the impregnating compound by means of a solvent, report that there is just as much impregnating compound in this impregnated paper that is apparently dry, as there was in the original cable showing the excess compound. It is also alleged that this excess is due to the fact that the paper will absorb only about 90 per cent of the total possible amount of compound during the time that the cable is in the impregnating tanks. It is suggested that with the tendency to higher operating voltages for underground cables it may be found desirable to have some excess compound inside the lead sheath so as to prevent ionization troubles.

One foreign manufacturer is using a thin transforme oil for the impregnating compound and finds that in thi way he can get very low dielectric losses. Som American manufacturers have been aware that very lo losses could be obtained in this manner but have no pushed the use of this compound as they did not con sider that the cable would be entirely satisfactory i other respects. In addition, it is to be noted that th lowest losses reported with the use of this thin tran former oil are not materially below the minimum loss which have been reported by one American manufa

turer with a mineral base compound. It, therefore, appears that the American manufacturers should continue their recent improvements in methods and materials for the impregnation of high voltage cables, and exhaust the possibilities for reducing the dielectric losses by these means before attempting the use of a very thin impregnating compound.

7. *Depreciation of Impregnated Paper Insulation.* In order to determine the maximum permissible temperature for impregnated paper insulation, when subjected to heat alone, and also when subjected to heat and dielectric stresses in combination, it is necessary to devise some laboratory tests which will serve to measure the depreciation of the insulation. This question, while apparently simple, is in reality a very awkward problem. If the cable is to be allowed to remain indefinitely in the position where first installed, then it might not matter for low voltage cables whether the insulation has become somewhat brittle or charred, but changes in the location of substations or the shifting of business, or changes in the methods of distribution frequently require that cables should be removed and reinstalled in another location. In such an event, it would be necessary for the cable to be bent in order to remove it from the manholes and place it on a reel and again to unreel it for installation in a new location. Apparently, therefore, the cable should be able to pass a bending test without serious injury to the insulation.

A careful comparison of many types of cables does not reveal any single property of the paper insulation which will check with the bending test. Of the various tests such as tensile strength, tearing strength and folding endurance, the latter appears to be the most useful as indicating the toughness of the paper. The tests appear to indicate that if the impregnated paper insulation will stand, say, 1000 double folds in the folding endurance test, then the cable will pass the bending test without difficulty, but if the folding endurance is only a few hundred double folds, then this test gives indefinite results, that is, the cable may or may not pass the bending test. Apparently other factors are involved such as for example, the relation of the width of the paper to the diameter to which it is applied, the tension on the paper, and the amount of lap. The latter variable can be eliminated by applying the strips of paper without lap, and several American manufacturers are now making their high voltage cables in this manner.

This subject of depreciation of the impregnated paper insulation is one of the problems now being investigated by the Massachusetts Institute of Technology as a preliminary step in the studies to determine the maximum permissible operating temperatures with and without dielectric stresses, and the committee would welcome discussion or suggestions from engineers who have had experience along these lines.

8. *Sheath Losses in Single-Conductor Cables.* When single-conductor lead covered cables are used for the transmission of heavy alternating currents, the lead sheath acts as a secondary of a current transformer, of which the primary is the main conductor. In order to prevent high voltages between the lead sheaths of the cables, it will be necessary to bond the lead sheaths at frequent intervals probably in every manhole. The resulting sheath currents may reduce the carrying capacity of the cables by 10 or 15 per cent, the amount of the reduction depending upon the spacing of the cables, the thickness of the insulation and the size of the conductor. The losses in the lead sheaths must also be taken into consideration in calculating the efficiency of the transmission as in amount they may be greater than the dielectric losses. The amount of data heretofore published has been insufficient to make accurate calculations of these losses and it is suggested that such additional data as may be available should be published in the JOURNAL.

General Review of Construction Problems in Overhead Transmission and Distribution

The outstanding features of the present status of overhead construction are the continued tendency toward higher voltages, both in transmission and distribution, and the improvements in construction methods as a result of standardization in materials and design.

Supporting Structures. Steel towers continue to be standard practise for extra high voltage transmission lines, especially for the more important trunk circuits. Single circuit flat, single circuit triangular and twin circuit double vertical are the configurations most generally employed, the selection depending on the particular condition to be met. For the very high voltage lines, special designs are required for anchor and transposition towers. The testing to failure of full sized sample towers is often justified in new designs.

Narrow base steel poles continue to be utilized in some sections of the country as substitutes for both steel towers and wood poles. They are especially applicable to high voltage or extra heavy work along city streets.

Special high elastic limit steel has recently been employed in the construction of both towers and narrow base poles with economical results.

Wood poles continue to be used very largely not only for distribution but also for the more moderate voltage transmission lines up to and including 66 kv., and there are in this country a number of excellent examples of wood pole transmission lines at considerably higher voltages. Single wood poles are generally employed for wood pole transmission lines where the voltage is 66 kv. or lower and the spans are under 500 feet; beyond these limits because of the greater clearances and strengths required, it is customary to employ two-pole *A* or *H*-frame construction.

The guying of narrow base steel poles and of wood poles, especially on higher voltage lines, is receiving increased attention, particularly guy insulation, involving as it does a combined mechanical and electrical hazard, has been subject of much careful consideration.

Changes in economic conditions have necessitated changes in wood pole specifications and this year the new tentative specifications of the National Electric Light Association will make their appearance. They differ essentially from the old specifications in providing a larger number of classes from which selections may be made.

With the increased cost of wood poles, butt treatment is receiving the consideration which it deserves. It is now clearly recognized that the open tank treatment is a measure fully warranted economically on the more durable timbers, such as cedar and chestnut; while on those woods which tend to decay above the ground line, a pressure treatment of the entire pole is advisable. Operating companies are realizing that there are no excessive complications involved in the open tank treatment and that the greater length of life fully justifies this treatment in comparison with the relatively inadequate brush treatment.

During the past several years various companies along the southern border have come to realize that much of the pole deterioration which has heretofore been loosely termed "rot", is in fact not a true fungus rot, but is caused by the depredations of insects, particularly termites or white ants. The protection of poles from termites and the saving of poles already attacked offers an interesting field of research in which valuable work may be done.

Insulators. In a general way it can be said that the manufacturers have made good their claims of the past several years that insulators of the latest manufacture are not subject to the rapid depreciation which was the cause of such concern a few years ago. Both in suspension and pin type insulators, perfected methods of design, manufacture and inspection have resulted in a more dependable and substantial product. Research is continuing unabated and we may expect in the not distant future to see even more useful and dependable designs, particularly in the line of high-strength, high-capacity units for extra high-voltage circuits.

The use of static shields to effect the double purpose of equalizing the stress distribution over long strings of suspension insulators and to obviate cascading in case of flashover, is becoming general on extra high-voltage lines.

Various new designs of pins for high-voltage pin type insulators are making their appearance on the market. In particular, the character of thimble is receiving close attention, it being well known that certain types utilized in the past have resulted in high insulator depreciation, and that failures have been incorrectly attributed to insulators which were in reality initiated by the pins.

A standardization of the rating of pin type insulators on a basis of leakage distance, flashover and other physical characteristics, eliminating the nominal voltage rating, appears highly desirable.

Increased attention is being given to insulator selection, as it has become evident to operating companies that in making a selection for any given line, close consideration must be given to climatic and economic conditions. The degree of over-insulation which is advisable or necessary, obviously depends on the relative importance of continuity of service on the particular line in question and the climatic conditions under which it will operate. In particular, the frequency of occurrence of lighting, temperature ranges, both daily and seasonal, humidity, the frequency of cleansing rains and the presence of wind-carried salt spray, dust or the fumes of industrial plants, must be given close consideration. It is only too evident that many of the insulator failures of the past have been due to incorrect selection, to an acceptance of a catalog rating which at best can be only nominal since it ignores the important variables mentioned above.

Engineers who have given the insulator much study believe that the insulator unit for 220 kv. should be larger, so that the number of units may be reduced to about the same number as now used for 100 kv. The following are desirable features for any new insulator design:

1. Length of unit increased to give larger arcover per unit, will use porcelain puncture value to better advantage; and give about 50 per cent more leakage length per given length or string, due to the elimination of one-half the metal connectors.

2. The reduction of the number of units gives much better natural potential distribution and simplifies shield problem.

3. The arrangement of porcelain to metal parts should be such as to reduce air and leakage stresses and eliminate corona.

4. Porcelain surfaces should be arranged to facilitate cleaning by storms and so arranged as to break up the continuity of water streams, which may result from rain, dew or fog.

Conductors. But little change is noted in the line conductor situation. Copper, copper-clad steel, aluminum, steel-cored aluminum and steel continue to be most largely used. For extremely high-voltage lines the nature of the conductor is often determined by limitations of corona.

Increased attention is being given to copper quality. Many companies have found, both for transmission and distribution purposes, that medium hard drawn copper has many of the advantages of hard drawn, without its corresponding disadvantages, and therefore are standardizing on this quality for all overhead purposes.

Close attention is being given to stringing and sagging, various methods using dynamometers or sighting targets, being employed. The attachment of conductors to either pin or suspension type insulators is being given careful consideration. Some form of shim is usually found advisable between conductors and suspension insulator hangers. Full flexibility of suspension strings in all directions at the tower support has

been found desirable, conductor breakage having been noted where the lateral motion was restricted. Sleeves or other mechanical connectors, avoiding the use of solder, long standard on aluminum conductors, are found equally desirable where copper conductors of other than annealed grade are employed.

Miscellaneous Line Hardware. Standardization of line hardware and miscellaneous appliances continues to go forward under the auspices of the National Electric Light Association and much useful work is being done along this line.

Line Sectionalizing and Protective Devices. With increased voltages it is logical that line protective and sectionalizing devices, including fuses, switches and lightning arresters, should receive more careful consideration. Many new and useful devices are constantly appearing on the market, and operating companies now find available a wide selection for any voltage or character of service. Air and oil break switches have improved materially in the last several years. Fuses, particularly for the higher voltages, continue to be a source of difficulty, and some useful research work remains to be done thereon.

Construction Progress. The past year has seen the completion of the highest voltage transmission line to date, this being the 165-kv. line of the Great Western Power Company from Caribou to Valona, California, a distance of 199 miles. Likewise, the year has witnessed the first actual construction of lines to operate ultimately at 220 kv. The Pacific Gas & Electric Company of San Francisco has under construction a 220-kv. line from Pit River Power house No. 1, in Shasta County, to Vaca in the Bay region, a distance of 202 miles.

The Southern California Edison Company has begun the remodeling of its two Big Creek lines, from Big Creek to Eagle Rock, a distance of 241 miles, for 220 kv. operation. These lines are now operating at 150 kv., but the increased power to be transmitted renders the raising of the voltage imperative. It is interesting to note that the Southern California Edison Company has already had in operation, 27 miles of one of the Big Creek lines at 280 kv. and 240 kv. for experimental purposes. This experimental operation was unusually successful, and demonstrated that the addition of a static shield would make feasible, operation at the higher voltage without increased insulation.

Not only do transmission voltages continually show an upward trend, but likewise there is noted a tendency toward increasing the voltage of distribution lines. Increased loads and areas covered have finally made evident the inadequacy of the customary 2300-and 4000-volt circuits for many distribution problems, with the result that 6.6, 11, 13.2 kv. and higher voltages are now entirely standard in many districts for purely distribution purposes. This is a logical outgrowth, first, of the higher voltage agricultural lines, for many years thoroughly standardized in the far west; and second, of the urban substation to substation moderate voltage transmission lines, which it became frequently necessary to tap for larger power customers during the war period. The result has been that companies have become familiar with the economic advantages of true high voltage distribution lines, stepping down directly to the customer's service voltage without the interposition of subsidiary voltages. For such lines automatic induction regulators and other distribution devices are rapidly becoming standardized and in the not distant future we may expect urban and suburban distribution at voltages above 10 kv. to be an ordinary procedure.

The rural line problem continues to be largely an economic one. The types of construction which should be used are well known; the difficulty lies in justifying proper construction for the scattered business involved.

Underground Distribution Practise on Edison D-C. Systems

Low-Tension Feeder Cable. With the relatively steady increase in density of Edison loads, it has been found desirable to increase the size of feeder conductors to as large a figure as may be installed safely, or as the existing ducts will admit.

In all but a few of the largest systems the cables contain no pressure wires. Pressures at the feeder junction boxes are frequently taken over special multi-conductor pressure cables, or in some cases calculated drops are used to estimate what voltage may be delivered at the feeder terminals.

The use of self-contained pressure wires in the feeder cables is quite generally opposed, for the reason that experience has shown that these wires are a very general source of failure; but where the use of this type of cable has persisted it has been found possible to eliminate the possibility of failure due to poor cable design, which was the fundamental cause of dissatisfaction.

A very decided point in favor of the use of feeder cables containing pressure wires has resulted from the adoption of circuit breakers to be installed in the junction box at the feeder termination. These circuit breakers are connected through one of the pressure wires so that they may be tripped either by closing the switch in the substation or as the result of the pressure wire being energized when a fault occurs in the cable itself.

This arrangement gives instant notice of development of serious grounds throughout the length of the cable, and since its general adoption it has practically eliminated serious feeder cable burn-outs.

Edison Mains. The divergence in opinion and practise as to type and sizes of cables to be used for mains seems to be greater than in any other matter. Some companies use rubber insulated cables exclusively, whereas paper insulation is the standard of by far the larger number of companies.

The sizes of mains cable conductors generally range from 200,000 cm. to 2,000,000 cm. In many cases

so-called "sub-feeders" of 1,000,000, 1,500,000 and 2,000,000 cm. are used to interconnect junction boxes without serving as supply for customers directly at all. In other cases the largest mains never exceed 500,000 cm., with the majority of the installation being of only 200,000 cm., and as these small mains are still giving adequate service on some of the largest systems, the question of whether the service given by the larger mains is commensurate with their cost, is very pertinent.

Junction Boxes. The practise as to when junction boxes are to be used is non-uniform to a large degree, and in this particular the tendency seems to be toward a still greater difference. Where Edison tube is used extensively it is agreed that junction boxes must be used frequently so as to provide suitable test points, but where cable in ducts is used the necessity for this is less apparent. Many companies have continued to use junction boxes with cable exactly as had been done with tube, while others have definitely abandoned the use of junction boxes except as feeder terminations,—and excepting always, existing tube. Practise and experience in this case have shown conclusively that there is no greater hazard evident without the junction box than with it for cable main systems.

Fusing Feeders and Mains. There is little or no change being made apparently in regard to whether mains and feeders are to be fused or not. Those companies which have always fused both mains and feeders, fear to change; those that have fused mains only, see no advantage in changing, but feel that they should not fuse the feeders in order to insure more continuous service, and those that have never fused either feeders or mains will not now install fuses, as it is their opinion that fuses would cause a definite lowering of their standard of service maintenance. Some of the engineers feel that it is better to have the fuses blow out than to burn the cable open, while the others feel that service should be maintained as long as possible regardless of overload conditions that may exist during an emergency. No definite agreement on this phase of operation seems to be possible because of the decided difference of opinion concerning the fundamentals involved.

TESTING OF UNDERGROUND TRANSMISSION AND DISTRIBUTION CABLE

As pointed out in the report of last year, this subject can be sub-divided as follows:

1. Testing at factory.
2. Independent laboratory testing by independent laboratories.
3. Acceptance inspection and tests.
4. Testing of installed cable.

1. Testing at Factory. Research work on the part of manufacturers is being carried on although there has been some temporary retrenchment in this direction by some of the manufacturers because of business conditions. On the other hand, certain manufacturers who had not done much research work heretofore are making relatively extensive preparations to do so. The general conditions in this respect are very satisfactory and much progress is promised for the near future,—a condition which could not have been said to be the case, so far as power cables are concerned, a few years ago. All of the progressive manufacturers are not only doing research work looking toward improvements in cable as a whole, but they are exercising more systematic control over the routine manufacturing processes and are giving more systematic attention to minor details, all of which is having its effect in improving cables in a very important respect, namely uniformity. However, no striking developments as a result of any of this research work have been announced during the year.

The practise in regard to the routine factory tests of finished cable has not changed during the year except that dielectric loss testing of occasional whole reels of cable at high temperature is now a regular factory test with several manufacturers.

2. Testing by Independent Laboratories. Research investigations by independent laboratories which have been completed or are now under way are referred to in connection with the report of the work of the Paper Insulated Cable Research Committee.

Independent laboratories are being more and more utilized for:

(a) Making the acceptance inspection and tests of cable being purchased under specifications.

(b) Making check tests of samples of new cable where the purchaser has not made any factory inspection or tests before acceptance and shipment.

(c) Investigating samples from cables which have given trouble in service. The standard tests made in such an investigation of paper insulated cable include composition and physical properties of the paper (tensile strength, folding strength and tearing strength), dielectric loss-temperature characteristic, composition of impregnating compound, ratio of compound and paper in insulation, thermal resistivity of insulation, effect of bending and dielectric strength.

3. Factory Acceptance Inspection and Tests. The specifications for paper insulated cable recently prepared by a joint subcommittee of this committee and the Underground Systems Committee of the N. E. L. A. are not only becoming more generally adopted, but, what is more important, more care is being taken by purchasers to see that the material supplied complies with the specifications. It has always been more or less customary for large purchasers to attach to their orders specifications which were more or less complete but more often than not, that was the only purpose which the specifications served. But there is undoubtedly a trend toward uniform specifications, a simplification which has obvious economic and other advantages.

There have bee nno innovations in the factory inspection and testing practise. The value of the bending

test has been demonstrated on several occasions. The practise of measuring the resistance of the conductors of each length of cable,—(a practise which has not been universal heretofore) has been found to be well worth while as a check of deficiency in area, excessively short lay and errors in measurement of length. Most of the manufacturers have provided facilities for making dielectric loss tests on whole reels of cable so that now an occasional whole section can be tested as a routine matter.

The routine testing facilities of the manufacturers have, in general, kept pace with the advancement of the art, particularly, for example, in the case of dielectric loss tests, but there is one exception and that is facilities for making puncture tests of samples of cable. Operating voltages have risen to a point where samples of cables designed for such voltages, that is of the order of 33,000 volts and over, cannot always be tested with entirely satisfactory results due to either insufficient voltage being available or, what is more generally the cause, defective methods of preparing the ends and attaching the test leads. With still higher operating voltages being contemplated, this matter becomes more important and it is therefore obvious that the manufacturers have an immediate problem of developing a means of making thoroughly satisfactory tests of this character.

4. Tests of Installed Cable. The use of direct potential rather than alternating potential for high-voltage tests of installed cable is being investigated by operating companies. The large size of the testing equipment which is required for alternating potential tests because of the large charging current, makes it highly desirable to find a satisfactory d-c. method.

For several years one of the larger manufacturing companies has been making direct-current cable testing outfits using a thermionic valve (kenotron) for rectifying purposes. This device is particularly valuable in connection with long high voltage transmission cables. For example, in order to test a 33-kv. transmission cable fourteen miles long at double voltage after installation, as required by the Institute Standards, a transformer of about 2500 kv-a. is required. If a d-c. outfit is used for the purpose, the capacity can be reduced to about 5 or 10 kw. if the outfit is used only for making the high voltage test. However, for reducing the fault after failure so that the trouble can be located, it is necessary to be able to burn the insulation with the high voltage testing set so that the resistance of the fault will be within the reach of the lower voltage testing facilities available, and this may make it necessary to increase the capacity of the d-c. testing outfit to about 50 kw. Even in this latter case, however, the cost is only about one-quarter of the cost of the a-c. testing set.

One of the larger companies has installed one of these direct-current testing sets for use in testing high-voltage lines. While the experience to date does not warrant any definite conclusions it appears reasonable to hope that, with the co-operation of the manufacturers, so as to adapt the device to operating conditions, and with more experience in the use of this testing outfit, it will be possible to entirely eliminate the difficulties that have been encountered and thus render this scheme of testing available for high voltage transmission cables.

In this connection it should be pointed out that all of our experience heretofore has been with the use of alternating direct current for testing purpose and that before the use of direct current for this purpose can be considered successful the proper ratio between d-c. volts and a-c. volts, to secure the same results, should be definitely known. Foreign investigations indicate that this ratio should be about 2.5, but the American manufacturers up to the present writing have not been willing to agree to a ratio higher than 1.5. If the ratio of 2.5 is correct, then a test made with the direct-current voltage limited by a ratio of 1.5 will be entirely without value, as it is not high enough above the normal operating voltage to give results that are at all comparable with those heretofore obtained with alternating current. Two of the cable manufacturing companies have undertaken to make tests of this character and results should be available very shortly. In view of the importance of this ratio, it is recommended that the Standards Committee investigate this subject and incorporate the proper ratio in the Standards of the Institute.

Foreign Practise in Transmission and Distribution Systems

The data on this subject have been submitted by foreign engineers of such prominence that it may be taken as representative of the best and most reliable opinions in their respective countries, namely, England, France, Italy and Norway.

The maximum voltage for transmission systems now in operation in any of the four countries is 110,000 volts. This system which is in Norway is 55 miles in length and has an ultimate capacity of 75,000 kw. In Italy the Pescara system operates at a maximum voltage of 88,000 volts and the maximum length of transmission in bulk is approximately 115 miles. The Energie Electrique du Littoral Mediterranean system is the most important high voltage system in France, and is composed of 560 miles of overhead lines operating at voltages varying from 55,000 to 30,000 volts, and 870 miles of overhead lines operating at voltages varying from 13,000 to 10,000. The total capacity of this system is 111,900 kw. The Societe Hydroelectrique de Lyon system operates at 70,000 volts but is a much smaller system, being composed of 105 miles of overhead lines and having a capacity of only 2984 kw. There is now under construction in France a transmission system to operate at 125,000 volts. The most important English overhead system is that of the North-East Coast Company, the connecting lines of which run from Newcastle up through Northumberland to the southern border of Scotland, and south from

Newcastle through Durham into Yorkshire. This system operates a considerable mileage of overhead transmission line with the great majority of it on wooden poles. The voltage of this system is 30,000 volts. A short transmission line operating at 33,000 volts has recently been put into operation for supplying the City of Chester.

The maximum voltage reported for underground cables in actual operation is 40,000 volts. This is in Italy where underground cable is operated at 40,000 volts on one system, at 30,000 volts on five systems, and at 25,000 volts on six systems. The distribution system for the City of Christiania is composed of 30 miles of underground cable operating at 35,000 volts. In England a 33,000-volt cable has been in operation some time in the Manchester district and a 66,000-volt cable under the River Tee is ready to be put in operation. In France, the Union d' Electricite, a consolidation of a number of small systems around Paris, is at the present time installing a 60,000-volt underground cable system with single-phase cable.

With regard to the comparative reliability of overhead and underground systems, from the point of view of continuity of supply, the opinion in all four countries is that underground cable gives the least trouble. The State Railways of Italy use extensively cables operating at 25,000 to 27,000 volts as primaries for electrification and interruptions due to cable trouble are quite exceptional.

As to the comparative cost of overhead versus underground transmission for approximately the same reliability and continuity of supply, no definite opinions are expressed. In England, up to the present time there has been no great difference between the cost of an overhead line and that of a cable. The reason for this is that the allowances for wind pressure, ice and factors of safety were formerly so stringent that the expense of an overhead line was vastly greater than in the United States. The Electricity Committee of England has, however, brought these regulations up to date and they will soon be issued in pamphlet form. Several lines, based on the new regulations, are at the moment being projected and the estimates show that such lines will be closely comparable in cost with similar lines in America.

In France it is possible to install an overhead transmission line for less cost than a cable. Due to this and also the voltage limiting features of cable, it is the practise of the French engineers to consider only overhead transmission where possible. For Norway and Italy no opinion was expressed as it is thought the question depends very largely on local conditions.

The reports of the most serious troubles encountered in transmission systems differed in each country. In France the chief trouble is that of voltage regulation due mainly to the lines having been overloaded during the war and not having sufficient copper. With this exception the French engineers have experienced no special trouble. In Italy the only element of the line which causes trouble is the insulator and these troubles are not severe. Trouble has been experienced from the breakage of insulators after a number of years of operation. The fracture shows that the break is due to the expansion of the cement, and that the quality of porcelain is not altered by age. Lines in operation from 15 to 25 years are still in good working condition. English engineers have experienced no serious trouble in connection with insulators, towers or poles as the lines in England operate with such a large margin of insulation. Practically no troubles are experienced due to the expansion of cement or to insulator aging. On the other hand, a great deal of trouble has been experienced with insulators by the Norwegian engineers, due to cracking caused by the expansion of cement.

The tendency in all four countries is towards the use of higher voltages. In France the main sources of hydraulic power are over 250 miles from the Paris district, the center of power consumption, and the transferring of this power in large amounts is a problem which must soon be considered. This will necessitate the use of voltages from 165,000 to 200,000 volts. The Norwegian government is now contemplating the use of 150,000 volts on the lines from a new plant now being constructed. The Norwegian engineers are also considering the transmitting of power to Denmark at 220,000 volts three-phase or 200,000 volts d-c. In Italy several overhead 110,000 volt lines are under construction and in England 110,000-volt lines are contemplated.

In England, France and Italy the three-phase system of transmission is the only one considered. Only one direct-current system has been installed in the last ten years. Some Norwegian engineers are of the opinion that while three-phase transmission will take care of any overhead situation likely to be encountered, they are not at all certain that constant current would not be better in many cases on very long lines. They believe that direct-current transmission up to 200,000 volts and 250 amperes is entirely practical and that the insulator question will be greatly simplified.

The tying together of existing hydroelectric or steam plants has been carried out to a large extent in Norway and Italy. Practically all of the large plants in Northern Italy are connected together and similar ties with Middle and Southern Italy are contemplated. In Norway a number of 50,000 to 60,000-volt hydroelectric plants have been connected in the last few years. In France and England a great many of these projects have been contemplated, but few have materialized.

In regard to the arrangement of transformer connections for a system, the opinion of engineers in all four countries is in favor of having the high side connected Y and the low tension side connected Δ.

It has been the experience of the foreign engineers that protection against lightning and power surges on lines up to 60,000 volts is very difficult. In Norway the experience has been that the operation is equally good without lightning arresters as with them. In

both Italy and Norway engineers favor the use of choke coils with resistance and also the use of ground wires. In England the majority of engineers favor the aluminum cell type of arrester. In France the operating companies object to the aluminum cell on account of its high cost and the necessary maintenance. The other types of lightning arresters in use in France do not give satisfaction on large systems.

As regards the use of outdoor substations the engineers of the different countries are divided in their opinions. The English and French engineers favor the use of the outdoor substation and the few in service in these countries have proved satisfactory. In Italy the opinion of the engineers is divided and in Norway no advantage is seen in an outdoor substation for voltages up to 60,000 volts.

The engineers of England, France and Italy have had very little experience with grounding coils, reactance coils or Dressel-Spuhle for limiting electric surges and no opinion was expressed. The Norwegian engineers have had some experience with the Peterson grounding coil and advocate its use on lines up to 66,000 volts.

Review of Papers Submitted During the Year

In the March, 1921, issue of the Journal, Messrs. H. W. Fisher and R. W. Atkinson presented an article on "The Effect of Heat on Paper Insulation."

After discussing in detail the mechanical properties of paper especially as influenced by drying, heating, and impregnating, tests for measuring the changes due to these causes are considered. It is shown that the measurement for tearing resistance is a satisfactory test and two machines for this purpose are described. The results of tests made to determine the effect of heat upon the properties of paper are discussed and measurements of rate of deterioration of paper at different temperatures are given. The relation of these data to allowable operating temperature is considered, and emphasis is placed on the importance of not exceeding intended temperatures through lack of knowledge of conditions.

In the same issue of the Journal is a paper by Mr. D. W. Roper on "Permissible Operating Temperatures of Impregnated Paper Insulation in Which the Dielectric Stress is Low."

This paper deals with the writer's experience with concentric cables which have been operated at high copper temperatures in Chicago. The author cites instances where the insulation of cables known to have been operated at a copper temperature of over 100 deg. cent. steadily throughout the day for a number of months, was found to be in good condition when the cables were removed for reinstallation elsewhere. In one or two cases he has found the copper temperature as calculated by Atkinson's method to be as high as 200 deg. cent. The author believes it desirable to establish two limits of copper temperature; the first to be a lower limit at which the insulation will not be injured even when the temperature is maintained for long periods of time; the second to be an upper limit above which it is known that the insulation will be injured if such temperature is maintained for any considerable time.

A paper on "Transformers for Interconnecting High-Voltage Transmission Lines" is presented by Messrs. J. T. Peters and M. E. Skinner in the Journal for June 1921.

This paper brings out the advantages to be realized by the use of the star-star connection in interconnecting high-voltage transmission lines. This connection however, requires the use of an auxiliary winding in delta to stabilize the neutral point or to decrease the inductance in the ground connection. Consequently the great majority of transformers designed for interconnecting transmission lines are three-winding transformers. Another type of transformer which would be included in this general class is one having an auxiliary winding for feeding a synchronous condenser used in controlling the voltage at the receiver end of the line. The important features peculiar to three-winding transformers when used for interconnecting transmission lines are discussed and the way in which the design and performance of the transformers are influenced by these peculiarities is pointed out.

In the June 1921 issue of the Journal there was an article by Mr. L. L. Elden entitled "Notes on Operation of Large Interconnected Systems."

After describing the interconnections made between the Boston Edison Company's system and the systems of the Eastern Massachusetts Electric Company and the New England Power Company, the author discusses the operation of these connections and the troubles encountered. Some trouble has been experienced on account of short circuits on the systems and to variation in frequencies, but as a whole the operation is considered satisfactory.

Messrs. W. I. Middleton and E. W. Davis presented a paper in the September, 1921, issue of the Journal on "Skin Effect in Large Stranded Conductors at Lower Frequencies."

This paper deals with tests made by the writers to obtain experimental data concerning the effective resistance of large-size stranded conductors to alternating currents of the low frequencies of 25 and 60 cycles. The tests are described and the results tabulated and discussed. The results are also compared with those obtained by using three common formulas for skin effect, in order to determine how far and with what modifications one of the formulas can be applied to stranded conductors. Two of the conclusions drawn are that the skin effect of rope-stranded cables can be calculated to a fair degree of accuracy by assuming the same current penetration as for solid or stranded conductors, and that the current penetration should be calculated from the pitch diameter of the outside layer of strands.

"Use of the Tangent Chart for Solving Transmission Line Problems" is the title of paper presented in the

November, 1921, issue of the JOURNAL by Mr. Raymond S. Brown.

In this paper there is presented a method, devised by the author and based on hyperbolic functions, for solving transmission line electrical problems by means of a special diagram, called a tangent chart. After discussing the general conditions met with in transmission line problems and pointing out the advantages of the tangent chart, the author explains in detail the underlying theory. Diagrams and descriptions are given and the manner of using the chart is explained.

A paper on "Questions of the Economic Value of Overhead Grounded Wires" by Mr. E. E. F. Creighton is included in the January, 1922, issue of the JOURNAL.

After a general discussion of the history of overhead grounded wires and the mechanical vs. electrical factors, the author presents a detailed discussion on the functions of overhead grounded wires, relation of overhead grounded wires to cloud lightning, detrimental effect of grounded wires on semi-insulated structures, relation of grounded wire to direct stroke, overhead grounded wires on wooden pole structures, steel structures and overhead grounded wires. The author analyzes the functions of overhead grounded wires under nine distinct headings. The conclusion reached is that the overhead wire is, in general, a detriment rather than an asset to a semi-insulated or high-resistance pole-line structure. On metal structures no technical function is found detrimental. The relation between the earth resistance and the decrease in protection to insulators is yet to be determined.

The February, 1922, issue of the JOURNAL presents an article on "The Effects of Moisture on the Thermal Conductivity of Soils" by Mr. G. B. Shanklin.

The article describes some thermal conductivity tests made on soils containing different percentages of moisture and compares the results with those of other investigators. These results show that moisture is the predominating factor in determining the thermal conductivity of soils. The relative thermal capacity of various types of perfectly dry soils, such as sand, clay, gravel, etc., covers a range from only one or two, while the addition of moisture increases the range to five times or more that of dry soils.

In the February, 1922, issue of the JOURNAL Mr. E. E. F. Creighton presented a paper "On Deviations From Standard Practise in Lightning Arresters."

This paper is an endeavor to answer questions of practise and the criticism of arresters brought out in an investigation conducted by the Protective Devices Committee. The writer presents a brief review of some of the factors relating to arresters not of the electric valve type and points out the inefficiencies and objectionable characteristics of arresters of low discharge rate. The other extreme, namely, the practise of using no lightning arresters, is then discussed from three viewpoints and the conclusion is drawn that in all three cases the argument in favor of using no lightning arrester is dangerously faulty. A new method of inspection of aluminum arresters is proposed and experiments are given to show that the power factor of cells is a sensitive indication of their condition. The investigation of two arresters in service thirteen years without overhauling is described and the possibility of overhauling arresters in the field is discussed.

A paper on "The Petersen Earth Coil" by Messrs. R. N. Conwell and R. D. Evans was included in the February, 1922, issue of the JOURNAL.

The theory of the earth coils is explained and a discussion is given on the operation of the earth coil under various electrical conditions encountered on transmission systems. Attention is called to the fact that the installation of the earth coil necessitates a change in lightning arrester settings, is unsatisfactory on a transmission network protected by a relay system, and compared to a grounded neutral system will increase the voltage stresses which would be imposed upon line insulators, cable insulation, and switching equipment. Tests were made on a 26,400-volt, three-phase, 60-cycle network of five lines totaling 59.8 miles to obtain information relative to the operation of the Peterson earth coil and to collect data indicating the suitability of such an installation for the suppression of arcing grounds. These tests are described and the results are discussed. The authors have considered five methods of grounding the neutral and give an order of preference for each, from the viewpoint of voltage stresses, current stresses, relay operation, continuity of service and cost. In conclusion the advantages and disadvantages are discussed.

Mr. Herbert Bristol Dwight presented a paper in the March, 1922, issue of the JOURNAL on "Skin Effect and Proximity Effect in Tubular Conductors."

The purpose of this paper is to present sets of curves to determine the effective a-c. resistance of tubular conductors as required to be predetermined by designers for radio installation, for large underground cables with non-magnetic cores, and for electric furnace circuits. The basis of the curves and formulas given in this paper is explained and discussed. Curves are given showing the skin effect for isolated tubes and for stranded conductors. A curve is also shown for proximity effect ratio to be used when the return conductor is near. Typical examples are solved and in conclusion the writer expresses the opinion that it seems scarcely worth while to provide a non-magnetic core with a 2,000,000 cir. mil 25-cycle cable in order to reduce the skin effect, but in other cases considered, the tubular form seems very advantageous.

In the June, 1921, issue of the JOURNAL Mr. F. W. Peek, Jr. presented a paper on "Voltage and Current Harmonics Caused by Corona."

This paper deals with investigation made to study the effects of corona in producing voltage and current harmonics in transmission systems. Tests were made on short three-phase lines of very fine wire so that the

corona loss would be excessive and exaggerate conditions. The different tests are described and the results discussed. Two of the conclusions drawn are that corona will cause voltage and current harmonics, of which the third is the most prominent, and that in properly designed practical transmission lines, the harmonic introduced by corona should be inappreciable.

In the same issue of the JOURNAL was a paper by Mr. Raymond Bailey on "Voltage and Power Factor Control of 66,000-volt Transmission Lines Connecting Two Generating Stations."

The problem which confronted the Philadelphia Electric Company, that of providing for the control of voltage and power factor of the two 66,000-volt transmission lines connecting its Schuylkill and Chester generating stations, is presented in this paper. An outline of the specific problem with its requirements, a discussion of the factors determining the selection of equipment, and a presentation and discussion of data on operating characteristics are included. The situation required that the control of voltage and power of the transmission lines permit of the transfer of energy of either direction, at suitable power factor, up to the rated kv-a. capacity of the lines, with the generating stations operating at approximately equal bus voltages. Other complications are also considered. The comparisons made to determine the most satisfactory type of regulating equipment and the reason for the selection of three-phase induction regulators are given and certain conclusions of more or less fundamental character are brought out.

Messrs. Edwin H. Fritz and George I. Gilchrest present an article on "Modern Production of Suspension Insulators" in the June, 1921, issue of the JOURNAL.

This paper records the progress made during the past few years in the production of electrical porcelain. The information covers the engineering and works-organization, the manufacture, and design and test. Each of these topics is discussed in detail and explained. In conclusion the writers state that rapid strides in the manufacture of electrical porcelain have been made in the past few years and perhaps the greatest advancement is in the methods of production in the factory.

In the June, 1921, issue of the JOURNAL there appears a paper by Messrs. E. E. F. Creighton and F. L. Hunt, on "A Solution of the Porcelain Insulator Problem."

After a discussion of the main causes of insulator failures, the writers describe the satisfactory results of a method developed by them for eliminating the cracking of insulators due to the Portland cement. This method consists of thoroughly impregnating the cement, after it has set and thoroughly dried, with a pitch compound. Eleven hundred insulators made in this manner have been in service nearly three years without a failure. In conclusion the authors present comments on the mechanical strength, electrical tests treatment, line testing, aging of porcelain, and open porosity of porcelain.

Mr. W. W. Lewis presented an article in the June, 1921, issue of the JOURNAL entitled "Some Transmission Line Losses."

This paper deals with tests for corona loss made on a 30-cycle, 140,000-volt system and gives a full description of lines on which the tests were made. The tests are described and the results in the form of tabulations and curves are shown. These results are discussed in detail. The conclusions drawn from these tests are presented and it is pointed out that the tests indicate the desirability of operating a transmission line below the corona voltage, thus avoiding corona loss and its accompanying effects.

A paper entitled "Long-Distance Transmission of Electric Energy" by Mr. L. E. Imlay is included in the June, 1921, issue of the JOURNAL.

This paper discusses the long-distance transmission of electric energy from the economic viewpoint, the physical viewpoint and the point of view of service. The economic conditions which justify long distance transmission are pointed out and considered.

In dealing with the plant required for long-distance transmission some of the considerations that effect the design are discussed. A graphic method of determining line performance is illustrated by an example and essential data on other lines are given. Right-of-way, spacing of towers, line insulators, high-tension switches and lightning arresters are discussed.

Service is considered from the viewpoints of what people demand, what perfect service will cost, and the service that may be expected from a large interconnected system consisting of steam plants at the mines, hydro plants, wherever available, and local steam plants.

In the August, 1921, issue of the JOURNAL there is a short article on "Self-Corrosion Not Stray Current Electrolysis, Shown at Selkirk, Manitoba."

This paper describes the investigation of a case of chemical corrosion of iron pipe at Selkirk, Manitoba. The corrosion of the pipe was found to be due to the chemical activity of the solution of so-called alkaline salts in the soil.

Mr. F. G. Baum presented an article on "Voltage Regulation and Insulation for Large Power, Long Distance Transmission System" in the August, 1921, issue of the JOURNAL.

In this paper a standard frequency of 60 cycles is advocated for the national system, and 220,000 volts is proposed as standard for extra large-power, long distance transmission. The voltage regulation of transmission lines is discussed and a simple diagram is given which shows that for a 60-cycle, 220,000-volt line, the line charging current supplies about two thirds of the capacity current required for about 0.8 load or 320 ampere load current, and that for larger loads the synchronous condensers supply leading, and for smaller loads, lagging current. A system of regulation is pro-

posed which will result in practically constant voltage at all points of the line at all loads. The advantages of such a system are given and discussed.

The problems of line insulation are discussed and especial attention is called to the necessity for low air and leakage resistance stresses and results of a large number of tests are given. A new diagram resulting from the analysis of experimental data is given. From this diagram the characteristics of long strings of insulator strings may be calculated, knowing the constants of the unit relatively. Illustrations are presented showing that wet and dry arc-over may be controlled but it is believed best to strive for the elimination of arcs. In conclusion the writer states that while present insulators with some form of shielding or grading will no doubt give more satisfactory results for a 220,000-volt system, such as he advocates, than is now obtained on lower voltage lines, it is desirable that further work be done with a view to developing the best way of handling line insulation.

In the February 1921 issue of the JOURNAL, Mr. Philip Torchio presented a paper on "Permissible Operating Temperatures of Impregnated Paper Insulation in which Dielectric Stress is Low."

After a review of the effect of temperature on insulating materials, abstracting from the 1913 Steinmetz and Lamme Report, and the 1905 British Engineering Standards Committee tests, the author questions the present temperature limit adopted for impregnated paper when used for low-tension cables. Results obtained from surveys of low-tension cables in large distributing systems, and also the results of special tests on cables including sheath cracking, high temperature tests, effect of bending on cables heated at high temperatures and distillation of cable compounds are shown and discussed. The vital importance of ambient temperatures in subway ducts as affected by the thermal conductivity of concrete, amount of moisture in the soil, different arrangements of ducts, and load factors at which the cables are operated, is pointed out. The conclusions derived by the author are that the permissible operating temperatures are to be a function of the load factors at which the cables operate, and he recommends 105 deg. cent., 95 deg. cent., and 90 deg. cent., for load factors of 33 per cent, 50 per cent, and over 66 per cent respectively.

In the same issue of the JOURNAL Mr. L. L. Elden has also contributed a paper on "Permissible Operating Temperatures of Impregnated Paper Insulation in which the Dielectric Stress is Low."

The conditions considered in adopting 85 deg. cent. as the limiting conductor temperature for impregnated paper-insulated, low-tension cables are discussed and conditions which hazard the safety of the cable when operated at the higher temperature limits are pointed out. The results obtained by a large operating company, one whose cables the limiting temperature of 85 deg. cent. has not been exceeded, are described and discussed. The practicability of operating cables on a load factor basis, or by specifying an allowable overload rating in terms of temperature is questioned. The conclusion drawn is that a conservative standard, such as the present Standard rule, is the more desirable policy.

A paper entitled "The Maximum Safe Operating Temperature of Low-Voltage Paper-Insulated Cables was also presented in the same issue of the JOURNAL by Mr. W. A. Del Mar.

The mechanical strength of low-voltage cables is discussed and a tearing test for paper is described. The results of experiments made to determine the effect of continuous heating are given and indicate that the mechanical strength of paper insulated cables is destroyed by continuous exposure to a temperature of 100 deg. cent. for three or four weeks. The author believes the operation of cables at higher temperatures than that allowed by the present Standards is in the nature of a gamble and questions whether the Standards should take cognizance of it.

Mr. Wallace S. Clark contributed a paper entitled "Notes on the Effect of Heat on Impregnated Paper from Cable Insulation."

This paper covers tests made to determine at what temperature marked deterioration in the paper of impregnated paper cable took place. The tests are described and the results given and discussed. The conclusion drawn is that the temperature limit fixed for the operation of a low-tension cable, to avoid undue deterioration, must take into consideration the length of time during which temperature is maintained.

E. B. MEYER, *Chairman.*

TRACTION AND TRANSPORTATION COMMITTEE REPORT

To the Board of Directors:

In conformity with the President's request for a discussion of some phases of the conditions prevailing in the field covered by this Committee, we beg leave to submit the following:

The year has been practically devoid of large or interesting developments in the electric transportation systems in the United States. The use of the one man car, trackless trolley and the motor bus has become more general in the light traction field but in heavy equipment construction activity has been limited almost wholly to foreign countries.

The introduction of important new or novel ideas in traction equipment also has been largely lacking and those engaged in engineering in this field appear to have been occupied mainly in efforts to standardize and perfect equipment of existing types and to adapt them to special local conditions.

In the face of such a situation, we have found a dearth of technical material for subjects of papers and discussions that did not promise to degenerate into a rehash of old and threadbare questions. Exhaustive treatments of electrification of steam railroads such as

that presented in the recent Super Power Report have covered very completely most of the technical aspects of this problem. The question then naturally arises whether the limitation of the Institute's papers and discussions to more or less technical electrical detail subjects is either wise or a full performance of our duty as a trained body of men with special information at our command which might be beneficial to the public if presented in a form readily grasped. Is there not a further obligation upon us?

Is there not an equal duty laid upon us to give to others not technically equipped a clearer view and better understanding of great public questions which to be wisely solved must be based on a sound engineering foundation? Is it right to confine our papers and discussions to the engineering detail technique of great subjects for the sole benefit of our own and our professional brethren? By such a procedure do we not stand aloof from the great national and world problems creating the impression that we do not comprehend their wider phases or are timid about venturing beyond our own limited self-prescribed professional boundaries?

Take for instance the steam railroad situation as it is before the country today and the bearing of electrification thereon. We have had ream upon ream of papers and hours without end of discussion of direct vs. alternating traction and coal economy of, steam vs. electric engines.

How often have we gone below the surface and discussed the function of railroads as a necessity in the life of our country (the United States) and the fact pointed out by such far-seeing men as President Willard that in the immediate future it is not a question of rates but a question of capacity which we face when business shall again become normal?

There is no longer need for technical discussions of whether electric traction will add capacity to a given railroad track system; that is admitted, demonstrated, and settled. Practically every steam railway in the country has an electrification problem of some sort under consideration and on the larger systems there are many such.

To carry them out and to make possible any general advance toward a wider use of electric traction on our great national arteries, public opinion must first be awakened to the basic economic facts and a general nation wide realization must be created of the necessities of these systems. A clear conception of the fundamental function of these railway lines to the nation as well as the effect upon general business of their failure to keep in step with the growth of the country is not easily acquired and yet it must come before we can secure full financial support for the program which must come before long. The Chairman of the Joint Committee of Congress recently stated as follows:

"We believe that the transportation facilities of the country must be placed upon a solid foundation. It will not do to make up deficits by appropriations of public funds. The railroad companies must be operated with the expectation that the gross revenues will be sufficient to cover operating expenses and leave a reasonable return upon the investment. It is of paramount importance to the public welfare that the transportation companies be made going concerns; that they be placed upon a substantial foundation in every respect, and that the operating expenses be reduced by careful and efficient management."

Is not this news to many people and is the situation not one warranting our best analysis?

The engineer has a trained mind familiar with the physical facts of this subject, he has acquired the habit of straight honest thinking step by step from premises to conclusion, why should he not broaden out his field and embrace the opportunity to inform and build up public opinion upon sound facts and impartial criticism.

There are many engineers who are members of this Institute who seldom or never appear or take part in discussions because their field has broadened and they no longer deal with details. Why should we not bring in these men and popularize, if you please, for the benefit of the public this subject so that by our keen logic of presentation of the economic facts we may attract the attention and interest of the mind of the man on the street.

Here is a really big subject of vital importance to the life and prosperity of the nation. We have the training and the knowledge, why should we not step outside the narrow confines of our technical field and show that engineering is more than handling kilowatts and kilovolts, that it is and must ultimately be the controlling factor in the economics of many natural problems if they are to be solved permanently.

H. W. BRINKERHOFF, *Chairman*

TELEGRAPHY AND TELEPHONY COMMITTEE

To the Board of Directors:

During the past two years the Institute has to an increasing extent served as a clearing house for information dealing with technical advances in telegraph, telephone and radio engineering, one direct result of which is the rapidly growing number of communication engineers applying for membership in the Institute.

Electric communication engineering in all its branches made marked progress during the war years and the improvements made to meet the needs of war have as rapidly as economy permitted been applied to the needs of peace time and of commerce.

One of the features of the committee's plans which has been followed closely is that of providing for the presentation of technical papers at meetings of the Institute giving detailed information of the noteworthy advances made in the various departments of the art. It may safely be stated that the present progress of communication in all its branches is recorded in the various papers published in the Institute JOURNAL during the past two or three years.

PROTECTIVE DEVICES

It has been suggested that the Protective Devices Committee of the Institute might to advantage include

in its investigations a study of the problems of communication line and apparatus protection against lightning disturbances and accidental contact between power wires and communication wires. The subject has been given engineering consideration by individual companies but a wide diversity of devices is used on lines throughout the country and it would seem that there is opportunity for standardization of devices to meet like conditions in various localities, both in railroad and commercial line operation, telegraph and telephone.

Inductive Interference Prevention

The movement mentioned in last years report of increasing cooperation in studying the needed procedure in the coordination of signal and power circuits has gone forward with growing impetus during the present year. This effort is general among all of the utility interests concerned and reflects a recognition on all sides of the mutual nature of the problem and of the duty of all to so harmonize their facilities as to afford the public the various services that it needs, with convenience and economy.

Several committees have been actively engaged in studying various phases of the inductive interference problem, some being joint committees formed upon the invitation of state regulatory bodies, others being established by groups of public service companies. The purpose, in general, has been to develop a more comprehensive understanding of the subject and to make available systematic working principles and standards for guidance in field practise.

In this direction, perhaps the most prominent work of national scope has been done through the cooperative efforts of the American Telephone & Telegraph Company representing the Bell Telephone System, and the National Electric Light Association. A joint committee of these two interests is conducting studies for the purpose of preparing comprehensive principles and practises of coordination for the guidance of the associated operating companies in planning the location, construction and operation of their facilities. Two progress reports thus far issued embody rather complete principles of inductive coordination and encourage the expectation of further constructive results toward solving the inductive interference situation.

On all sides there is a growing realization of the importance of maintaining a broad view to the future and of consulting cooperatively in advance on the development of plans for contemplated plant extensions.

The committee has not learned of the advent during the year of any outstanding new devices applicable to the prevention of inductive interference.

Automatic Telephony

The further installation of automatic telephone exchanges has continued during the past year. At Omaha, Nebraska, a panel automatic plant was placed in service in December, 1921. During the year automatic exchanges have been built in accordance with predetermined policies as to design. There is, however, nothing particularly new to report in the way of engineering change.

Printing Telegraphs

The Western Union Telegraph Company has continued to increase the number of its circuits operated by multiplex printer methods. In many places all of the circuits operated into an office are "printer"—no manual Morse circuits being worked at these points. The extension of printing telegraph systems has necessitated opening additional repeater stations, but this is an economy in view of the increased volume of words in a given time which may be handled over a wire properly spaced with repeaters.

During the year the Postal Telegraph-Cable Company once more has placed a printing telegraph system in service on certain New York-Chicago circuits. The system is the Morkrum Multiplex. The Postal Company has been operating manual Morse exclusively since early in 1919, at which time the printer duplex system then in use was discontinued.

Radio Telegraphy

Trans-oceanic commercial radio telegraphy has continued to improve in reliability, with the natural result that the volume of traffic has steadily increased. Radio duplex channels now are continuously operated between New York and stations in England, France, Norway, Germany, with stations soon to be opened in Sweden, Holland, Italy and Poland. The station of the Radio Corporation of America, at San Francisco, works continuously with stations in Hawaii and Japan.

A noticeable tendency is to employ vacuum tube oscillators for transmission, both for telegraphy and telephony.

On the Pacific Coast continuous radio telegraph service is performed by a commercial company between the cities San Francisco, Los Angeles, San Diego, Tacoma, Portland and Seattle. A large volume of business is handled in competition with the wire companies.

Radio Telephony

One of the most spectacular developments during the year has been the application of radio telephony. This art has advanced rapidly, along technical and scientific lines for several years, and today many startling demonstrations, of special circuits, instruments of high sensitivity, special amplification and accurate modulation are in use. This valuable scientific work has of course been continued, but the committee wishes to report, this year on the engineering development of the art.

Although several scientific developments and inventions could be recorded the great work has been the extensive application of radio telephony, increase in efficiency, power and quality of transmission, and the increase in efficiency and simplification of receiving

equipments to meet the great demand of the general public for telephone reception in the home.

The regular public broadcasting of news, church services and entertainment from the Pittsburgh district created nation wide interest in radio broadcasting and within the year the manufacturers and distributors of radio apparatus have started additional regional broadcasting service from large radiophone stations, giving news, music, speeches, church services, grand opera, athletic events, market reports, etc.

The fascination and value of radio telephone broadcasting service in the city, home and on the isolated farm has created such a demand for telephone receiving equipment that an active industry has grown up within the year.

The design and production of high efficiency instruments suitable for the novice, with simple operation, and suitable in appearance for the living room, has been an engineering development worthy of note, and it is felt that the great activity in this art justifies the present extensive engineering development to meet the large future application of radio telephony.

Railroad Telegraphy and Telephony

Plans for additional railroad intelligence transmission reflect the general interest in radiophone developments. Operating departments have expressed a need for a simple, reliable and comparatively inexpensive radiophone equipment. It is anticipated that such sets will have a field in train operation for communication between caboose and engine. Today railroad trains a mile long are quite common and there is a positive need for communication between conductor and engineer on such trains.

Also there are possible applications for portable radiophone sets for use in bridging gaps temporarily when washouts or floods destroy pole lines carrying wires.

At large seaports the railroad companies maintain extensive fleets of tugs and it is found that radio telephony affords an opportunity to maintain continuous communication between tug captains and tug dispatchers.

The Telegraph and Telephone Section, American Railway Association during the year completed reports dealing with "Telegraph and Telephone Transmission," "Wire Crossings," and "Education and Training of Telegraph and Telephone Employees."

A technical development of the year was the introduction of a vacuum tube rectifier used to transform alternating current into direct current at 80 to 400 volts.

Aerial Cables

Further extension of the aerial cable plant of the American Telephone and Telegraph Company includes a section between Harrisburg and Pittsburgh, Pennsylvania, a distance of about 200 miles. This cable provides approximately 300 telephones and 175 telegraph circuits.

Submarine Telephone Cables

On April 11, 1921, commercial telephone service was inaugurated between the United States and Cuba, over three submarine cables laid across the Florida Straits between Key West, Florida and Havana, Cuba. These submarine cables are the longest and most deeply submerged which are in use for telephone communication. The cables are 104.9 nautical miles (195 km.) long. These cables are loaded and vacuum tube repeaters are employed at the terminals for connecting land lines to the cabled circuits. In addition to the telephone facilities provided, conductors in the cable are used also for direct current telegraphy and for carrier current telegraphy—over the latter four-channel multiplex printers may be operated.

Pneumatic Tubes in Telegraph Service

In large cities it becomes necessary to establish branch offices in addition to the main telegraph office, so that the public may have convenient access to the telegraph. In the business districts the volume of traffic at some branches, if handled by wire, would necessitate the use of a large number of circuits to the main office with operators at both ends of each circuit, in order to move the traffic promptly under normal load conditions. To handle peak loads or abnormal rushes would require additional wires, equipment and operators, that would be idle a greater part of the time.

This has led to extensive use of underground pneumatic tubes between the main office and the more important branch offices. Tubes are generally laid in pairs in order to handle traffic in both directions simultaneously. While the initial installation is expensive, the annual charges are found to be less than the cost of handling large numbers of messages by wire.

The load limit of a tube is seldom reached, even during abnormal peaks, since the power required to move the carriers containing messages is a small part of the total power required to move the carriers and the air column in the tube. Approximately constant speed of service can be maintained under varying traffic conditions. In addition, chances for errors in receiving and in re-transmitting the message are eliminated.

Tubing of 2¼ inches inside diameter has been standardized as most suitable for telegraph service. The terminal equipment and carriers are not too bulky, yet the carriers are large enough to contain a considerable number of messages. Outbound tubes are operated under pressure and inbound under partial vacuum, the power supply usually being at the main office end.

The outer ends of a pair of tubes are joined together to permit the circulation of the same air repeatedly. This tends to reduce condensation in the tubes, and, in case of stoppage, allows pressure to build up behind the carrier at the same time increasing the degree of rarefaction ahead of it.

Power is supplied by reciprocating air compressors for large systems, and by rotary pressure blowers for small systems. Compressors are driven by electric motors through short belt drives with idlers. Rotary blowers are usually mounted on sub-bases with their driving motors and connected through special worm gearing. Compressor systems are operated at 5 to 10 lb. gage pressure and 10 to 18 inches of mercury vacuum. Blowers range up to 3 lb. pressure and 6 inches vacuum. Separate blowers are used for each tube pair with "start and stop" control of the motor to reduce power consumption.

STANDARDIZATION

The Report of the Standards Committee, last published, contains for the first time a representative list of terms and their definitions employed in communication engineering. Most of these definitions were prepared through cooperation of members of the Telegraphy and Telephony Committee serving on a sub-committee.

The terms now incorporated in the published report constitute a good start along this line of useful work, and the present year's sub-committee will undoubtedly add many more definitions so that in time the communication section of the Report will contain most of the terms which are of a permanent nature.

FUTURE ACTIVITIES

A year or so ago a project was submitted to the Board having in view the compilation and publication of a Bibliography of communication literature, the work mainly to be done by members of the committee. Actual work on this undertaking very likely will be delayed pending the return of more favorable printing costs.

It is noteworthy that practically all of the technical papers procured for presentation at meetings have come from members in the New York district, notwithstanding that all sections of this country and Canada are represented on the committee. It is hoped that chairmen of the various Sections will in future encourage communication engineers in their territory to prepare papers for Section presentation and for printing in the JOURNAL. Naturally, those members who regularly attend meetings of the committee are prevailed upon to contribute or procure papers of interest. However, members remotely removed from New York should recognize the fact that papers sent in from the field are particularly welcome and should be forthcoming. It is of serious importance that members of the Institute in all sections of the country have the opportunity to present papers at meetings and that the best of these should be published in the JOURNAL. To this end it is desirable that telegraph, telephone and radio engineers take more active interest in Section meetings.

DONALD MCNICOL, *Chairman*

INSTRUMENTS AND MEASUREMENTS COMMITTEE

To the Board of Directors:

The following report for the year summarizes briefly the activity of the committee, a reference to articles dealing with new or essential instruments and measurements, and a brief description of new apparatus for electrical measurements that may have been designed and developed during the past twelve months.

During the year there was very marked activity abroad in the matter of standardizing rules for instruments. Several instrument specifications have been issued as follows:

England. The latest Standard Specifications of the Engineering Standards Committee are: for Indicating Instruments, No. 89, 1919, for Instrument Transformers No. 81, 1919.

France. A Proposal for Standardization of Electrical Measuring Instruments, Instrument Transformers, and Shunts was prepared by the Technical Committee of the "Chambre Syndicale des Constructeurs de Gros Materiel Electrique" and was adopted by the Chambre on Jan. 20, 1921. These rules appeared in the *Revue Generale de l'Electricite* of May 28, 1921.

Germany. Rules for Electrical Measuring Apparatus proposed by the Verband Deutscher Elektrotechnicker were published in the *E. T. Z.* of Mar. 31, 1921. Those for Instrument Transformers on Mar. 3, 1921, with changes and additions on July 28, 1921. It is proposed that these become effective July 1, 1922.

The French and German specifications were translated by Mr. H. B. Brooks of the Bureau of Standards and copies were circularized among the members of this committee and other individuals throughout the country who might be interested in the subject.

A comparative analysis of the foreign specifications shows some lack of agreement among the different countries. Apparently the rules are not to be considered final; many admittedly tentative parts are included, awaiting revision in the light of further research or practical experience. In general the rules take up questions of construction, accuracy and nameplate markings. Grades are established and requirements prescribed which apparatus must satisfy in order to be entitled to use the grade symbols. These requirements involve considerations of case protection, scale and pointer construction, damping qualities, sensitivity to disturbing influences, insulation, safety, self-heating, standard-ranges, transformer ratios, potential drops in shunts, limits of error, identification of terminals, connections, etc.

Incidentally this standardization has involved questions of terminology, definitions, the setting of standard quantities such as temperature and frequency and the conditions under which tests were to be carried out.

In view of the activity abroad along the lines of standardization for instruments, there was considerable

discussion in meeting and correspondence by this committee as to the possibility of preparing similar American rules and the ways and means for preparing and accepting them. It was finally decided that a subcommittee be appointed to canvass the sentiment, particularly of the manufacturers of instruments in this country, as to the necessity or desirability of such standards. Mr. H. B. Brooks volunteered to conduct such a canvass inasmuch as he intended to visit many of the instrument makers in this country. He was, therefore, appointed a subcommittee of one to make such a canvass and report back to this committee. This trip is still in progress and no report is available at this writing.

The committee devoted considerable time in meeting and correspondence to the consideration of standardizing certain terms of measurements and instruments relative to which there was a divergence of usage. The findings of the committee were discussed with the subcommittee of the Standards Committee on Meters, Instruments and Instrument Transformers. It was felt that the particular terms in question represented only part of a large number that might properly be considered. The matter is, therefore, held open for further consideration and action.

The committee feels that report can briefly be made of the following instruments or devices which have appeared during the past year, some of which are novel in principle and others that may be considered modifications of an old principle, applied in a different manner or placed in a more practicable form of instrument. A new design of current transformer called a "two-stage" transformer, consisting essentially of the usual primary and secondary winding and an additional secondary compensating winding to correct for the ratio and phase angle distortions encountered in the ordinary type of two winding transformer, was advanced. This transformer is being designed and developed with a view to improving the accuracy of current transformers for use with instruments and watt-hour meters. A paper by H. B. Brooks and F. C. Holtz is scheduled for presentation, which describes in detail the design and performance characteristics of this transformer.

In response to the demand for a simple inexpensive equipment for testing current transformers, numerous arrangements for making such tests have been developed. Although several of these methods are comparatively old, none has come into general use because of certain limitations, such as time required, insufficient accuracy and lack of robustness. Some of these methods utilize deflection instruments, and others employ integrating instruments for measuring the quantities involved. On the other hand, all of the precision laboratory methods now in use for measuring the constants of current transformers are based on null methods.

Dr. F. B. Silsbee of the U. S. Bureau of Standards embodied the null measurement principle in a simple method for the comparison of two-current transformers of the same nominal ratio. The method is described by him in Scientific Paper No. 309 of the Bureau of Standards. A current transformer testing set embodying the principle of Dr. Silsbee's is now available. The ratio and phase-angle of the transformers being tested are determined by comparison with a standard transformer, the calibration of which has been determined previously by some absolute laboratory method.

What the instrument actually measures is the differences in ratio and phase-angle between the transformer being tested and the standard transformer. It is important to note that the instrument measures differences because difference measurements can be made with much greater accuracy than absolute measurements.

One of the makers of recording instruments reports the development of a new movement in a round chart electrical recording instrument, consisting essentially of a coil acting as a solenoid with the core located in a horizontal position in the center of the coil and supported on knife edges so that its motion backward and forward in the coil varies as a current flowing through the coil varies. Claim is made from tests on these instruments that a greater degree of accuracy is to be obtained over the entire scale than was formerly obtained with the similar design consisting of the movement of two coils attracted to one another. This new design is developed in recording voltmeters and ammeters.

Various devices have been used for some years to indicate phase rotation on polyphase circuits. Arrangements of a more or less complicated nature have been made up and used locally by various operating companies to serve this purpose, but during the past year a manufacturer has developed and placed on the market a phase-sequence indicator. This is a device in small compact portable form, consisting essentially of an arrangement of coils operating on a single lamp as an indicator. A set of directions accompanies the device, so that by two trials in connecting the binding post to a polyphase circuit, the phase rotation can be determined.

Current transformers for laboratory and portable use of the through type, permitting the threading of one or more primary turns, have been available for sometime. During the past year, however, one of the instrument makers has developed a current transformer of this type with additional self-contained primary connections which can be varied through a certain number of combinations giving an extremely wide primary range of current from 10 to 800 amperes. This transformer has, primarily been designed and constructed to give results of a better degree of accuracy than can be obtained from other preceding types of portable current transformers of this type.

The continuing necessity for an electrostatic type of voltmeter is referred to in an article by E. H. Rayner

in the *Journal of the Institution of Electrical Engineers* (British) of January 1921. Description is given of a precision form of Kelvin electrostatic voltmeter. Several mechanical and structural changes have been made in the new type of instrument with a view to eliminating known limitations and to increase the range and precision of the instrument.

One of the manufacturers reports the development of a portable frequency indicator, self-contained in a carrying case comparable with the remainder of their line of portable instruments. The armature circuit has two branches, one unaffected by changes of frequency, the other approximately resonant at normal frequency. The scale covers 90 angular degrees and gives an effective range of 55 to 65 cycles.

In the same line of portable instruments referred to above is a self-contained capacitance meter. This consists essentially of a standard condenser mounted in a case and the condenser or capacitance to be measured is compared with the standard by an armature construction equivalent to that of the power factor meter.

The very considerable activity in the field of radio transmission and reception has stimulated the design of instruments, particularly adapted to the quantities encountered in this field. Without endeavoring to list here all of the small low priced instruments for current and voltage measurements in connection with wireless equipments, developed by various manufacturers which have been placed on the market recently, reference is made to one or two devices only which seem new in principle or new in construction.

A standard radio wave meter has been designed and constructed by the radio section of the Bureau of Standards and this instrument, when calibrated, will be capable of measuring wave lengths from 65 to 85,000 meters, or in terms of frequency from 3500 to 4,600,000 cycles per second. A new type of standard inductance of the astatic principle has been developed and placed on the market.

In the field of electrical instruments for boiler or chemical measurements are the following developments. A new conductivity cell has been developed for direct insertion into a boiler drum in order that the concentration of salts in a boiler may be easily determined. The cell is constructed in such a manner that it may be safely used on pressures up to 300 lb. per sq. in. The electrodes are made of heavy nickel and the insulating structure is practically unbreakable.

The concentration indicator used with the cells may be calibrated in total dissolved solids or chlorine content. Calibration is made for the average operating pressure so that the effects of temperature variations are minimized. The advantages of this new cell are due to the elimination of sampling methods and of the necessity for extra piping to the boilers.

A thermocouple for direct insertion into a boiler under pressure has been developed. It may be installed at almost any point in the drums or headers and will safely withstand pressures up to 300 lb. per sq. in. Preliminary tests indicate that it is reliable and accurate. It is expected that this new thermocouple will be found useful for measuring variation in temperature throughout a boiler under varying loads.

A new recording meter for measuring acidity and alkalinity of boiler feed water has been recently developed. The method of measurement is based upon the determination of the hydrogen ion concentration of the feed water. The recorder operates on the potentiometer principle and records the voltage existing between two electrodes immersed in the feed.

The most important feature of the apparatus is the ability to measure actual acidity as distinguished from the total acidity determined by the usual titration methods. Actual acidity depends upon the hydrogen ion concentration and is one of the important factors involved in boiler corrosion. Another great advantage lies in the ease with which the recorder can be utilized to automatically operate signal lights or alarms to indicate undesirable conditions of the feed. Experiments are under way to determine the value of such apparatus used in conjunction with automatic valves to control the amount of alkali added to feed water, and thus maintain the alkalinity of feed within certain limits.

Considering methods of measurements rather than specific devices which may have been under consideration during the past year, reference should be made to the continued activity in analyzing and discussing methods of calibrating instrument transformers. A significant appreciation of the inherent errors in current and potential transformers is growing throughout that part of the electrical industry using instrument transformers for accurate measurements. This is confirmed by the continued development of apparatus for checking current transformers, one being referred to elsewhere in this report. Some of the central stations have equipped their testing and standardizing laboratories with instrument transformer checking equipments, these being, in general along the lines recommended and used by the Bureau of Standards. The equipment is essentially a potentiometer method, based on standard resistances and provides an extremely accurate and rapid means for calibrating instrument transformers over their entire range. It is a laboratory equipment and is not applicable for use in the field.

During the past year there appeared an article by Messrs. J. R. Craighead and C. T. Weller in the *General Electric Review* of July 1921, analyzing the advantages and limitations of the watt-hour meter method of testing current transformers for ratio and phase angle.

At the suggestion of President McClellan, inquiry has been made by your committee of various individuals in the field of activity covered by the scope of this committee for suggestions of future line of research and

investigation. Two lines of activity have been indicated.

There is apparently a demand among the central stations for an accurate and ready means of determining the character and extent of faults in cables and after the fault has been determined by measurement, there is need of some form of apparatus, preferably portable in character which will localize the fault so as to permit the cutting out and repair of the faulty section of cable. It is possible that some of the apparatus for all of the foregoing necessities falls outside of the scope of this committee. However, inasmuch as part of the problem involves measurements to determine the fault, it is advanced here as a matter of record.

In this connection reference should be made to the method of locating faults in underground cables described by Mr. Luigi Selmo in *L'Elettrotecnica* December 5, 1921. It is stated that this new scheme, tested recently, has been found very satisfactory in locating faults on the lines of the Societa Napolitana per Imprese Elettriche. The method has the great advantage of simplicity requiring only the use of two commercial type a-c. voltmeters (for instance, the hot wire type) which do not require any special instructions to set up and are easily read.

The other subject which was advanced for continued investigation and research is the question of the measurement of high potentials, particularly in view of the recent rapid increase in potentials in commercial apparatus in connection with the high voltage transmission lines. The committee does not, of course, overlook or ignore the considerable amount of very excellent work which has already been done in this direction, but with the steady extension of the previous limits of commercial voltages there arises a definite need for continued and extended activity to provide practicable, simple and accurate means for measuring these potentials.

F. V. MAGALHAES, *Chairman*

LIGHTING AND ILLUMINATION COMMITTEE

To the Board of Directors:

The Committee herewith submits its report in two sections—first, activities of the Committee, and second, progress in the art.

ACTIVITIES OF THE COMMITTEE

The Committee was appointed about the middle of October. Early in November, a "correspondence meeting" was held, by which the views of the Committee were obtained on subjects which appeared important to the Chairman. This was followed by a meeting at the Association's headquarters. At this time, the plans for the year were finally agreed upon and arrangements made for carrying them out.

ILLUMINATION ITEMS

The principal innovation of this year's Committee is the inauguration in the JOURNAL, of a section under the heading "Illumination Items." It is the purpose of this section to set before the membership, brief articles of interest on topics falling within the field of this Committee. It is the hope of the Committee to supply, through this channel, comprehensive, up-to-date information, in such form as to make it of greatest value to practising electrical engineers. Among other things, it is the intention to review, briefly, valuable material from other sources, which, in its original form, is too specialized or voluminous for the convenience of engineers who do not specialize on lighting.

Mr. W. M. Skiff has undertaken the compilation of material for the Committee. This section was initiated with the issue of February 1922, and already quite a number of favorable comments have been received. In the three issues published to date, the volume of text is as follows—February, page 149, six columns; March, page 223, five columns; April, page 278, five and one-quarter columns. Material in excess of the requirements of the May issue is in the Editor's possession.

In connection with this activity, the Committee has undertaken to supply the Editor, at his request, with "fillers" on lighting to be used at his discretion.

GENERAL MEETINGS

Dr. B. E. Shackelford was designated to take charge, for the Committee, of any arrangements for papers to be presented before General Meetings of the Association. A paper on "Glare" was presented at the Niagara Falls convention.

SECTION AND BRANCH MEETINGS

The Committee stands ready to cooperate, so far as practicable, with sections and branches in arranging for papers on lighting. An announcement has been made in the JOURNAL, but on account of lateness in the season, it is not anticipated that much will be done during the current year.

LIGHTING PROGRESS

Lighting along with other activities was slowed down during the year 1921, due to business depression. While the lamp consumption was within 80 per cent of that of the previous year, the demand for construction materials fell off considerably more. Under the circumstances, the energies of manufacturers were naturally toward the disposal of existing stocks, rather than toward the development of new devices. The magnitude of the use of electric lighting is best indicated by the sales of incandescent lamps. In 1921, one hundred and sixty-six million large, and ninety-five million miniature lamps, were sold in the United States.

While practise in the lighting of commercial and industrial interiors is tending strongly toward general lighting from overhead locations, there are certain conditions where local or temporary lamps are required.

To meet these conditions, there has been developed a new type of mill type tungsten filament lamp, which is somewhat more substantial than any of its predecessors. Utilizing similar principles of construction, some new or improved sign lamps have also been developed. Considerable improvement has been made in the construction of the incandescent lamps for motion picture projection, and it is reported that over one thousand theatres are now so equipped.

For several years there has been under way, a development for providing a more convenient means of hanging fixtures, so that by means of a plugging device, they could be put up and taken down by novices. Since standardization is a prime requisite for such a device to insure interchangeability, an especial effort has been made to bring various inventors together. It is understood that such interchangeability devices are about to be made available by the various manufacturers of wiring devices.

This development led to the contradictory expression "removable fixtures," and the Illuminating Engineering Society has proposed the term "luminaire" as a substitute for "fixture," "lighting unit," etc.

There has been a number of developments in luminaire or fixture design. There is a marked tendency to use enclosed semi-indirect equipment, to facilitate cleaning. Also there is an increasing use of more or less dust-proof enclosing globes. The shape of such globes is tending to the flat or squat forms, in order to increase the vertical components of light and reduce the horizontal.

A number of new color-matching equipments have been designed, adapted to particular applications. There are indications of an increasing use of diffusing glassware in industrial lighting. The equipment requiring round bulb lamps is still in favor for home lighting, although some new developments, taking diffusing glassware, appear very interesting.

Not the least important development in regard to lamp equipment, is the movement toward the standardization of mechanical parts and dimensions of fixtures and glassware.

That there has been considerable activity in the installation of street lighting, is evidenced by the report that a leading manufacturer sold about 15 per cent more equipment in 1921 than in 1920. An investigation reported during the year, gives an indication of the importance of good illumination as a preventative of traffic accidents.

The general tendency has been toward better street lighting with more or less ornamental units, of which the single globe upright has been predominant. Better means have been devised for maintaining attractive appearance without sacrificing the effectiveness of light distribution. Among the important means to this end has been the use of rippled or prism glassware (with or without refractors) so arranged as to diffuse the light without largely modifying its direction.

Highway lighting is assuming a new importance, since it has been shown to be effective in promoting safety on heavily travelled thoroughfares. Moreover, the expense of such installations and maintenance is moderate, compared with the other features of construction suitable for dense and heavy traffic. Special reflectors are being developed for this service, which utilize much of the light ordinarily delivered outside of the roadway.

Outdoor sign lighting stands out on account of the rapidly increasing quantities of light employed. A year ago, relatively few outline signs were using larger than 10-watt lamps. Now, 25 and 50-watt lamps are common, while 75 and 100-watt lamps are used to a considerable extent in the large metropolitan signs.

Electric lighting of signals in streets, railway crossings and on the railway systems themselves, has made quite an advance.

In interior lighting, no application has fallen farther short of the canons of good practise than the school house, despite the fact that the welfare of the future generation was involved. Educators and others have, during the year, pointed out the need of better lighting, and reports from all sections of the country show a very keen interest in school lighting, in connection with both new and old buildings. The State of Wisconsin is the pioneer in adopting a school lighting code, although the New York Board of Education had already been requiring compliance with the Illuminating Engineering Society's code, in all schools receiving State aid.

The Illuminating Engineering Society's Industrial Lighting Code, referred to in previous reports, has been made an American Engineering Standard. This has resulted in renewed activity in several states which have not adopted such regulations.

Automobile headlighting regulations, based upon the Illuminating Engineering Society's code, are now in force in fourteen states, which represent about 50 per cent of the automobile registration of the country. About 40 per cent of the Canadian automobilists fall under similar codes in the several provinces. As a result of experience in Massachusetts, the requirements of the Illuminating Engineering Society's code has been strengthened.

In the field of research and investigation, much new data have been brought out. Some of the subjects include color temperature, ocular functions, gloss on paper, reflection characteristics of paints, and other surface finishes, refraction and interlaboratory photometric comparisons. New investigations of lighting practise in various classes of interiors have been reported.

The year has been one of activity in matters of lighting education. Lecture courses have been held in several cities and portable lighting demonstrations have been exhibited in a large number of places. An excellent example of a permanent lighting demonstra-

tion at the Massachusetts Institute of Technology has exerted a perceptible influence on the practise in that part of the country.

G. H. Stickney, *Chairman*

POWER STATIONS COMMITTEE

To the Board of Directors:

The Power Stations Committee was appointed somewhat late in the administrative year, which naturally handicapped its activities. However, the report of last year's committee was so comprehensive and complete that it is probably unnecessary and perhaps undesirable to try to attempt a similar kind of report so soon thereafter.

In past years there has been some overlapping of subjects by committees of the various national societies. In order to eliminate duplication of effort as far as is thought advisable, a group of chairmen of committees dealing with power station subjects in the various national societies was called together at the invitation of President McClellan for the purpose of coordinating their work. At this meeting an informal committee was formed of those present with the Institute Power Stations Committee's chairman as the chairman of this Committee on Coordination.

At the conference it was generally agreed that while the N. E. L. A., A. E. R. A. and A. E. I. C. committees dealt particularly with new developments and their application in electric power and railway fields, with special emphasis on desirable developments as determined by experience, the Institute committee should deal more particularly with the technical and scientific side of the problems involved in the design and use of equipment. When such problems arise in the work of the committees of the N. E. L. A. and similar bodies, the chairmen of those committees will refer such problems to the Institute committee for attention. The agreement of all of the chairmen at the conference to this plan should insure a proper coordination of the work and allocation of the various phases to the proper society. It is the intention in the annual reports of the Power Stations Committee to call attention to some of the more interesting developments described more fully in the committee reports of these other societies. However, such reports are usually not issued until May or June and it will therefore be difficult to embody these references in a report presented to the Institute at its summer meeting. This suggests the desirability of having some of the Institute committee reports presented at a later meeting in the year.

In addition to the above, the committee has aided the chairman of the Meetings and Papers Committee in the selection of papers on power station subjects for presentation before Institute conventions.

R. F. Schuchardt, *Chairman*

MINES COMMITTEE

To the Board of Directors:

During the past year the Mines Committee has arranged for two combined meetings of local sections of the A. I. E. E. and the A. I. M. & M. E. One of these meetings was held in Pittsburgh on April 18th, at which time a paper was presented by Mr. J. C. Damon of the West Penn Power Company under the title of "The Use of Central Station Power in Coal Mines." A number of Bureau of Mines officials were present and the papers brought forth a lively discussion among coal operators and central station men present.

A second meeting was held in May in Chicago where two papers were presented; one by Mr. Clayton of the Illinois Central Power Company and the other by Mr. Adams, Electrical Engineer of Allen & Garcia, Consulting Engineers. Both papers were on the subject of "Central Station Power in Coal Mines;" one based on the viewpoint of the Central Station Company and the other from the viewpoint of the customer. During the coming year it is suggested that the Mines Committee encourage similar combined meetings in other localities.

Owing to the large stocks of metal and the quiet condition of most all of the industries during the past year, both metal and coal mines have been operating at low outputs. A number of the metal mines are, however, taking active steps to get started again and with the gradual improvement in industrial conditions, both metal and coal mines will enjoy an increase in demand that will be very gratifying. A large number of the coal mines are closed down at this time, due to a nation-wide strike. The large stocks of coal on hand together with the general slack condition of the industries, makes the effect of the strike little felt and unless the strike is soon settled the non-union fields will enjoy a very steady business.

Both metal and coal mines are contemplating extensive changes in application in electric power and in some cases active steps are being taken to place the mines in the best possible condition in respect to the use of power.

The use of central station power for mines is growing in popularity each year and it is now the exception for a mining company to install an isolated power plant if central station power is available. During the war the central station power systems were greatly overloaded resulting in poor service in many cases. Since the war the load has decreased and the central station systems have spent a great deal of time and money in strengthening their lines and improving their service so that very few complaints are now heard regarding poor service from central station power.

Improvements in the use of electric power in mines during the past year have been more or less curtailed and consist largely of improvements in loading machines, the further application of automatic substation equip-

ment and automatic control systems for mines, fans and pumps.

There has been little activity during the past year in regard to car dumpers, coal and ore bridges, shovels and drag lines, but there seems to be an indication of some activity during the coming year.

The by-product coke oven industry has been very quiet during the past year, but there seems to be indications that there will be considerable activity during the coming year. This will give the builders of by-product coke oven plants a chance to take advantage of some of the new schemes that have been recently developed and tried out.

GRAHAM BRIGHT, *Chairman*

MARINE COMMITTEE

To the Board of Directors:

The activities of your Committee have been somewhat affected due to the sudden and serious illness of the Chairman, Mr. Arthur Parker. However, we are pleased to report his gradual return to health.

Your Committee being associated with an industry, (shipbuilding), which received a great impetus during the war, finds itself in a somewhat similar position to that industry. The large fleets of merchant vessels tied up in all parts of the country and the question of disarmament has had a retarding effect on the program laid out by the Chairman at the beginning of the year.

Seven meetings have been held. The first, September 23rd, at which time the Committee was organized, Subcommittees appointed and the following work left from the previous year was undertaken:

1. Work of the Historical Committee.
2. Fixtures, fittings and etc. to meet requirements of the New Marine Rules.
3. Terminal facilities at piers.
4. Joint Meeting with the Society of Naval Architects and Marine Engineers for November 17th.
5. Adoption of Marine Rules by the American Engineering Standards Committee.

The following Subcommittees were appointed:

(a) To further the cause of having the Marine Rules adopted by the American Engineering Standards Committee.
(b) To write specifications for standard appliances.
(c) To detail power apparatus for auxiliary machinery.
(d) Propulsion Committee.
(e) Historical Committee.
(f). Radio Committee.
(g) Joint Meeting with Naval Architects and Marine Engineers.
(h) Wires and Cables.
(i) To have Steamboat Inspection Service include some requirement of electrical knowledge by licensed engineers and a separate electrical license for motorships.
(j) Editing Committee.

The year's work has been rewarded with many successes.

Through the efforts of Subcommittee (a), American Engineering Standards, the Institute is the sponsor body for "Electrical Installations on Shipboard," "Marine Rules." Thus, concluding the labors of our Subcommittee. President McClellan appointed our Subcommittee as an organization committee for the Institute to form the American Engineering Standards Committee and the work has progressed very satisfactorily and it is believed the Committee will be organized this Institute year.

Standard Appliance, Subcommittee (b), has completed specifications for feeder, junction and branch boxes:

Conduit and conduit fittings.
Fuses.
Receptacles, plugs, switches, non-watertight.
Receptacles, plugs, switches, watertight.
Bulkhead and conduit terminal tubes.
Steamtight fixtures and fittings.
Electric air heaters.

It is the intention to have these specifications incorporated in the reprint of the specifications and some arrangement made for the testing and approval of the appliances.

Power Apparatus Subcommittee (c), in addition to collecting data from the increased number of motor driven auxiliaries on shipboard and the advent of the motorship, where all auxiliaries are motor driven, was assigned the duty of making much data available, bringing the Marine Rules up to date so that when the American Engineering Standards Committee was formed, these suggested revisions would be available for their consideration, and this work has been concluded.

The Propulsion Subcommittee (d) has concluded the work assigned it, that of preparing "Recommendations for Protection of Electrical Apparatus for Use on Shipboard" and referred to in last year's report and it is the desire to have these Recommendations issued to all those vitally concerned. It is the opinion of your Committee that rules for propulsion machinery should not be prepared until a later date.

The Historical Subcommittee (e) has prepared considerable data bearing on electrical installation on shipboard from very early dates to the present and it is the intention during the coming year to prepare several articles giving the date, title, brief of the article and publication, also, supplement these articles with papers on electric propulsion.

The Radio Subcommittee (f) found that due to the rapid changes, it was thought advisable to revise that section of the Marine Rules. The Institute of Radio Engineers very gladly appointed a committee to assist our Subcommittee with this revision, which has been completed and we take this opportunity of thanking them. This revision will be available for the consideration of the American Engineering Standards Committee.

The Subcommittee (g) Joint Meeting with the Society of Naval Architects and Marine Engineers in New York, November 17th, desire special mention owing to the success attending this meeting. Two papers were read.

"Electric Auxiliaries on Merchant Ships" by E. D. Dickinson, Marine Department, General Electric Company and "Electric Propulsion" by W. E. Thau, Commercial Engineer, Westinghouse Electric & Manufacturing Company.

Both subjects were well presented. The discussions were numerous, long and heated and brought out many interesting facts, the most notable perhaps was in the discussion of Mr. Thau's paper that to date the electric drive had not shown as good economy as reduction gear drive, which was much to the surprise of a majority of those present.

Subcommittee (h), Wires and Cables, has been active in discussion of proposed changes, and, no doubt, the coming year will bring forth some desirable changes in the present specifications, as well as, uniformity in specifications for wires and cables for shipboard work.

Subcommittee (i), Steamboat Inspection Service, is of recent origin. The ever increasing use of electricity on shipboard, on steam driven vessels for economy, and on motorships from necessity suggests the necessity of the licensed engineer being familiar with the subject of electricity, which today is not a requirement for a license. The additional hazard can only be attended with diaster unless the personnel to whom the care of electrical apparatus is entrusted are required to have sufficient knowledge for its proper operation and maintenance.

Editing Subcommittee (j) has about concluded the work prepared by the Subcommittees (b), (c), (a), (f).

I desire to take this opportunity to thank each individual member and the Chairman of the Subcommittees in particular for their good attendance, enthusiasm and untiring effort, and congratulate them for the amount of good work done, particularly, in view of the absence of the Chairman and the lack of interest in the shipbuilding industry during the past year.

The coming year will bring many arduous duties, particularly, to the Subcommittee on Steamboat Inspection Service and it will only be by persistent and studious application that results will be obtained.

Acting for the Chairman, I will repeat the concluding paragraph of his 1920-1921 report:

"It is this thought in particular that I would leave with the Marine Committee for the ensuing year, that good work can only be accomplished through good will, consistant application and real cooperation."

G. A. Pierce, Jr., *Chairman pro tem*

IRON AND STEEL INDUSTRY COMMITTEE

To the Board of Directors:

Reversing Mill Drive Equipment

At present, economic conditions are such that an expansion of steel mills to produce a greater tonnage of steel is not important, and reversing mill electrification consists mainly in revamping present plants. This is either done by installing an electric reversing mill equipment in place of a steam engine, or it may be that the mill itself is obsolete, and the mill with its drive is replaced with electric drive and a new mill. This is usually done in order to replace worn out machinery, or to obtain advantage of lower cost of production. In the last two years, considerable attention has been given to the cost of producing steel and the reversing mill drive has received as much attention as any other type of mill. Considerable cost data are being published from time to time on electrically driven mills, so that it is a simple matter for those who are considering the installation of an electric reversing equipment to determine their cost with a very great degree of accuracy. This is something that has not been available heretofore, due to the difficulty in actually determining the amount of steam an engine takes. Several reversing engine installations have recently been made on the basis of obtaining some very substantial improvements in economy, but no results have been published from their installations, so that it is only natural to infer that the results which they had anticipated have not materialized.

In 1907, the first installation of an electric reversing mill was made in this country. Since 1913, the growth of the electrically driven reversing mill has been rapid, until today there are approximately forty installations in operation rolling all kinds of products. Although there are many features of this equipment which are still retained, the improvements in the design of reversing mill equipments have taken place so rapidly that our present day equipments have an entirely different appearance from those first installed. With each new installation, manufacturers have endeavored to incorporate features which permit the apparatus to perform its duty with greater ease, and thereby reduce the attendance and maintenance. Today, the majority of the electric reversing mill drives, regardless of manufacture, require very little attention, and the delays upon the mill are almost negligible. Attention over the week-end is seldom more than an inspection, which requires the service of one man for only a few hours. This is in quite a contrast to that required in reversing mill engines, including those which have been installed in the last few years. The art of applying electric drive on reversing mills has now reached a point where the capacity and characteristics of each machine involved can be determined very

definitely, and assurance given that the cost of attendance and maintenance is almost a negligible item in the total cost of producing steel.

A most important fact was the replacement of a twin tandem reversing engine which drove the first finishing stand, a rail mill, by reversing motor equipment. This equipment was the *first main roll electric reversing drive sold in this country to replace an engine.* It was sold in 1917, and delivered in 1918, but conditions at the user's plant were such as to make it inexpedient to install this equipment until this year.

The motor unit has the *highest continuous* horse power capacity (8000 h. p. 50 deg. cent.) of any electric reversing drive in the world. It was designed to roll the first four of the last five passes on a 105-lb. rail section at the rate of 240 gross tons per hour. The last pass is made in an adjacent mill driven by a separate engine. Although the equipment has not been fully loaded as yet, the mill has rolled at the rate of 198 gross tons per hour of 105-lb. rail, which exceeds all previous tonnage records on this mill. A particularly interesting feature is that this rate of rolling was made with the last finishing stand disconnected from its engine, and connected to the first finishing stand so that the motor was driving both stands and rolling five instead of four passes.

Owing to the depression in the steel industry no new tonnage records were made last year.

There has been some controversy as to whether the motor should be shunt or compound-wound. Both types of motors are giving entire satisfaction, from both a tonnage and maintenance point of view. The motors are built very strong mechanically, on account of the great shock to which they are subjected, and are provided with forced ventilation, as the natural ventilation of such machines would be extremely poor.

This equipment has been developed to such an extent that today it is practically standard, and installations can be made, and mills started in operation at their maximum capacity without any question as to the electrical equipment. In spite of the claims that have been made by some engine manufacturers, the economy of such equipments is so much superior to the engine driven mills that during the last six or eight years almost all reversing mills have been motor driven, and in the rehabilitation of older plants where engineering questions are given proper considerations the electric drive is the only type seriously considered. The ability of the electrically driven mill to turn out tonnage is beyond question, and in certain mills where the time element is of vital importance in providing tonnage, the figures obtained on machines driven by engines have been very materially improved upon.

Yard Electrification

Several of the largest steel plants of this country have under consideration, the electrification of their railroad yards, and considerable study has been given this subject with a view toward settling some fundamentals such as the selection between straight locomotives, storage battery locomotives, or a combination locomotive, using just sufficient battery to operate when a contact system cannot be continuous throughout the yard. The merits of each type of locomotive depend to some extent on the particular plant under consideration, but from a purely economical standpoint, the straight electric locomotive has a considerable advantage over the others. It is true in the case of straight electric locomotives that contact systems such as the overhead trolley line or the third rail conductor, have certain objections in a more or less congested yard with complicated track layout, but there are certain advantages which may or may not outweigh these objections. For instance, full time operation is possible since there is no tying up the locomotives to charge or change batteries, consequently for a given amount of work, fewer units are required; there is no periodic replacing of batteries; and rough usage of the locomotive such as it is very likely to get in steel plant yard service will not result in failure of battery, jars, etc. On the other hand, a locomotive which carries its own source of power has a primary advantage over any locomotive which must collect its power as it moves along. The storage battery has reached a high state of development in the mining industry, and there seems to be no good reason why the mine type of locomotive cannot be enlarged to fill the needs of the steel plant. Part of higher cost of operation over the straight electric machines can be compensated for by charging the batteries during off-peak load periods. The principal disadvantages of a storage battery locomotive, are the high first cost and renewal cost of the batteries, and to a lesser degree, the loss of energy which occurs in the battery.

It seems to be the opinion that third rail construction is preferable to an overhead contact system, due to the interference of any overhead wires or structures with the use of locomotive cranes, which are quite a necessary adjunct to the steel plant. Of the two designs, under-running and top contact for third rail construction, the former seems to be preferable because it is somewhat easier to protect with guards and occupies less space.

The standard direct current voltage for practically all large plants is 250 volts, and it would seem advisable to operate the yard locomotives on this circuit provided generating or converting apparatus can be so located that transmission losses are not excessive. In the event that heavy loads must be handled to a considerable distance from any substation, it has been pointed out that double voltage (500) could be used, and either the motor equipment on the locomotive connected for series operation, or 500-volt motors used which would operate at reduced speed in the 250-volt zone.

For railway work it will be necessary to ground one side of the plant distributing system, and some opera-

ting engineers will undoubtedly object to this, but the fact remains that systems are operating successfully with one side grounded. Return feeders on the grounded side will be required in most cases to prevent electrolysis.

Owing to the dull business period during the past year or more, finances have not been available for undertaking electrification work on a very large scale, but it is the present policy to start electrifying small portions of the yard and gradually adding to these portions until eventually electric operation will have been thoroughly tried out and the whole system will be changed over.

Main Roll Motors

In spite of the general depression from which our industrial interests are slowly but surely beginning to emerge, and in spite of the fact that the steel industry throughout the country has reached a point of low production wholly without precedent, a review of the large motors and auxiliary equipment purchased and installed during the twelve months period ending June, 1922, for driving rolling mills makes a very creditable showing. All motors purchased for main roll drives with the exception of those for reversing blooming mills are included in this analysis, whether for use in production of ferrous or non-ferrous metals. The application for rolling non-ferrous materials did not exceed 7.4 per cent of the total, and is but approximately 1.75 per cent for brass and copper.

Three of the large manufacturers of this type of equipment report a sale of sixty-four units with an aggregate normal rating of 97,590 horse power. It is a regrettable fact that the general adoption of a uniform method of rating proceeds so slowly. The Association of Iron & Steel Electrical Engineers has adopted the maximum continuous rating with 50 deg. cent rise in an ambient temperature of 40 deg. cent with a maximum momentary torque guarantee, but with no guarantee of sustained overload capacity.

Sixteen of the above motors aggregating 27,620 horse power were purchased on this basis.

Fifteen more aggregating 28,900 horse power were purchased on the so-called Steel Mill Rating under a guarantee to carry rated load continuously with 35 deg. cent. rise in an ambient temperature of 40 deg. cent. 125 per cent load continuously with 50 deg. cent. and 150 per cent load for one hour with 60 deg. cent. rise.

The remainder, thirty-three, aggregating 41,070 h. p. were purchased on basis of continuous operation at rated load with 40 deg. cent. rise in an ambient temperature of 25 deg. cent. and 125 per cent load for two hours with 55 deg. cent. rise.

This multiplicity of ratings is confusing and every effort should be made toward the universal use of a uniform standard method of rating as, for example, the maximum continuous 50 deg. cent. basis officially adopted by the A. I. S. E. E.

The types of mills electrified during the period under consideration include:

8 motors for Rod Mills	12,070	horse power
3 motors for Bar Mills	4,900	" "
14 motors for Merchant Mills	12,400	" "
4 motors for Cold Mills	1,950	" "
3 motors for Continuous *Sheet Bar and Billet Mills*	14,700	" "
15 motors for Hot Strip Mills	27,720	" "
1 motor for Structural Mill	4,000	" "
1 motor for Plate Mill	4,000	" "
2 motors for Hoop Mills	4,000	" "
2 motors for Sheet Mills	4,000	" "
3 motors for Tin Plate Mills	3,000	" "
1 motor for Tube Mill	1,600	" "
7 motors for Copper and Brass Mills	3,250	" "
Total 64 motors ... Total	97,590	horse power

It is interesting to note that five of these motors aggregating 15,600 horse power have been installed to replace steam engines.

The tendency toward higher speed with resultant lower first costs, improved power factor and efficiency continues. The successful operation of a 5000 h. p. 450-rev. per min. motor appears to have justified the design and construction of a 5750 h. p. 500-rev. per min. motor included in the above list for driving a Morgan Continuous Sheet Bar and Billet Mill. This is the largest capacity mill motor thus far built for this high speed.

The desirability of adjustable speed drives is still in evidence from the fact that 21 of the units listed, aggregating 35,370 horse power, have provision for adjustable speed control.

Thirteen of these units aggregating 26,970 horse power are of the well-known double range modification of the Scheribius system using an independent high-speed regulating set. This auxiliary set consists of a polyphase commutating machine and a squirrel-cage induction motor which receives the output of the main motor secondary at slip frequency and returns it to the supply system at line frequency. It also impresses on the secondary of the main motor a counter e. m. f. and frequency corresponding to the desired speed of the main motor.

Seven adjustable speed units, aggregating 7400 horse power for two mills, are ordinary direct current machines with shunt field control supplied from synchronous motor-generator sets. This reversion to an earlier type of adjustable speed drive in these two mills was determined largely by the greater simplicity of the direct current motor with shunt field control as compared with the a-c. adjustable speed sets, in spite of the lower over-all efficiency of the former.

Two adjustable speed units aggregating 1000 horse power are of particular interest as they embody some very recent developments. The main driving unit in this case consists of a mill type induction motor with a direct-connected synchronous machine on a common base.

The auxiliary machine consists of a frequency con-

verter driven by a synchronous motor. In the operation of the equipment, no torque is developed by the frequency converter and the driving motor supplies the power for windage and friction of the auxiliary set. In the operation and during regulation, the secondary of the main induction motor is connected to the commutator of the frequency converter and the slip-rings of the frequency converter are connected to the synchronous machine connected to the mill. This machine has the property when driven at synchronous speed, of taking the frequency impressed on the commutator and adding to or subtracting from the line frequency which in this case is the secondary frequency of the induction motor. The voltage delivered at the commutator end of the frequency converter is the same voltage as that impressed on the slip-ring end and as supplied from the synchronous motor. The synchronous machine on the main set and the synchronous driving motor for the frequency converter are excited with direct current.

After starting the main motor in the regular way as an induction motor, the secondary circuit is transferred to the frequency converter. This is done with no field on the synchronous machine and with the frequency converter running at synchronous speed. If it is desired to use a speed other than the normal, the rheostat, in the synchronous machine field is manipulated, putting a field on this machine. This causes the synchronous machine to generate a certain voltage which is transmitted through the frequency converter and impressed on the secondary of the main induction motor. This voltage, according to whether it opposes or helps the generated secondary voltage, causes the set to slow down or speed up. Any speed within the speed range can be obtained by simply adjusting the above mentioned field rheostat giving the desired practical range of speed above and below normal or induction motor speed.

Central Station Power

The use of central station power in the iron and steel industry, stands today as follows: Most of the major steel plants have their own power generating equipment, but quite a number of the large works with coke ovens and blast furnaces as a part of the plant, are using a central station connection and buying a small portion of the electrical energy required by the plant. This condition was brought about in some instances due to the fact that during the war, the power requirements in the mills increased faster than it was possible to secure and install additional generating capacity to take care of same, and it was found expedient to buy sufficient power to take care of these requirements. In other instances a lack of finances, or a higher rate of return on an investment in plant equipment other than power generating apparatus was the reason for central station power coming into the plant, but in all cases where there is a central station connection, it has been found to be a very great asset when a breakdown or trouble occurs in the local plant power houses, and as a matter of fact, it is an additional insurance against a total shut-down of the plant.

In some localities the question of frequency has kept central station power out of the plant. The central station generates 60-cycle power, but many steel plants use 25-cycle power for the reason that the motor equipment for large low-speed mill drives is better adapted for operation on this frequency, and until recently converting apparatus, for securing d-c. power which is essential for operating the mill auxiliaries was not as satisfactory on 60-cycle as on 25-cycle operation. In such localities, the use of central station power would require frequency converters or the changing of the mill equipment to accommodate the higher frequency.

Recent studies and reports on super-power systems have pointed out the advantages to be gained from a conservation and economical standpoint by interconnection, and the large steel plants with central station connections are a step ahead of the others in the super-power plans; however, there is one point to which the central stations which burn fuel to generate power, must sooner or later agree, and that is that they cannot always sell power over this connection, but in the interests of conservation and better mutual relations they should in return purchase some power from the steel plant, when this power can be generated from a by-product which would otherwise go to waste, such as is the case over week-ends when the coke ovens and blast furnaces must maintain uninterrupted operation, while a greater part of the remainder of the plant and the mills are shut down.

Now as regards the smaller steel plants where by-product energy is not available for the generation of power, it is almost invariably the case when these plants are located in some large central station power zone that they purchase the major portion of their power requirements. It is this type of plant that has demonstrated the fact that the steel mills can be operated just as well on 60 cycles as on 25 cycles, and that the central station power is found to be very reliable.

The steel mill engineer has two objections to central station power; its cost, and the hazard of a long line connecting his plant with the source of power supply. Under the first objection, he says that the restrictions or price penalties, under the present complicated rate schedules, when applied to his load, the nature of which is highly fluctuating with moderately low power factor, puts central station power out of discussion. On the other hand the central station power solicitor claims (and that very justly in most cases) that the steel man does not accurately figure his power plant costs, forgetting to take into account the fixed charges against the investment in his plant. However, in the final accurate analysis, it will be usually found that central station power cannot compete in prices with steel plant power, when the latter is all generated from the plant

by-products. Under the second objection; the length, type of construction, and territory over which the line is built, carry most consideration in determining the hazard. In plants where duplicate feeders over separate routes and into separate substations can be obtained, the hazard is reduced to a very low point, but in most cases this is not obtainable and it is advisable to have some reserve generating capacity sufficient to handle the vital plant load, such as pumps and hot metal handling apparatus in the event of a line disturbance or service interruption.

The Electric Furnace

Since its inception about forty years ago, the progress of development of the electric furnace has been one of unusual activity, especially the decade 1909 to 1919.

From the date of the first commercial electric steel furnace in this country, April 5th, 1906, with a capacity of four tons, the growth in number and capacity has been continually upward, so that in Januray 1st, 1922, there were 388 electric furnaces in the United States, and 50 in Canada. In maximum capacity this was reached in 1921, when two forty-ton electrics were placed in operation at the U. S. Naval Ordnance Plant at S. Charleston, W. Va.

These furnaces are basis lined and have a transformer capacity of 3300 kv-a. One furnace operates with 24-in. diam. amorphous carbon electrodes, the other with 14-in. diam. graphite electrodes, this giving current densities of 46.8 and 137.5 amperes per sq. inch respectively with the transformers at their maximum output of 21,000 amperes per phase. The relative electrode consumption on intermittent operation is approximately 20 lb. of carbon and 10 lb. of graphite per ton of steel.

During December of 1921, an order was placed by the Ford Motor Company for a 60-ton electric furnace for their River Rouge plant. This furnace will have six 24-in. diam. carbon electrodes and transformer capacity of 9000 kv-a. The year 1921, while not productive of much growth numerically, will be notable principally for the development of large capacities.

After the first development of the induction furnace, which came ahead of the arc furnace, it seemed to be overshadowed by the latter, as prior to 1914 the largest unit of the induction type in the United States was two tons capacity. The inherent low power factor of the furnace and the difficulty of maintaining a satisfactory refractory lining were greatly responsible for this lack of development. In 1914 two induction furnaces of 20-tons capacity were installed, but have not been entirely successful. Special applications of a 2-ton induction furnace have been made in the last two years, and a lining developed which, at last report, has withstood 555 heats. This is exceptional performance. It would be a great mistake to surmise that the retarded progress during the past year foretells any slowing down in electric furnace development. Indeed, it rather lays emphasis on how far and how fast the art has advanced.

Electric Cranes

The electric cranes used about the up-to-date steel plant represents as much development and as many changes compared with those in plants of twenty years ago as have been made in almost any steel plant equipment. When one considers the cranes of many years ago driven by a square shaft, running the entire length of the building; or a little later, equipped with a single motor and the various motions manipulated through clutches, with the modern steel mill four-girder ladel crane, equipped with the latest electric motors and apparatus, double-bridge drive, sturdy cast steel or structural steel construction, bronze bushed quickly replaceable bearings in place of the old style with babbitt poured in place, and equipped with the various safety devices, it is hard to realize they belong to the same family.

Dynamic braking and the use of additional electric brakes has supplanted, to a very large degree, the troublesome mechanical load brake. Accessibility and interchangeability of parts, the elimination of overhung gears, substitution of either bars or angles for the old style copper span wires, the use of automatic control for motors of, say, 35 h.p. and above, and the development of a control whereby additional speed may be obtained in lowering, and also, a magnified effort towards standardization are among the developments made in recent years.

During the last five years (the last one and a half due to the extreme depression, and the three and one-half years prior to that, to the war and after effects), there has probably been less actual development in connection with electric cranes than there were during the five years prior to that time. The last year has seen very few notable installations made. One of the largest and best known crane builders reporting, "There has been little of importance brought out within the last year or so, but we are working on several propositions that probably, eventually, will be of considerable interest."

The Association of Iron and Steel Electrical Engineers is working on a crane standard which will undoubtedly be recognized as a standard specification throughout the country, for heavy duty cranes.

Control Equipment

A most important development in magnetic control equipment has been perfected and put on the market during 1921. The design of contractors now makes it possible to obtain a steel mill controller with contacts and arc chutes having such life that it needs no longer be the regular week-end duty of the repair man to renew these parts on the severe service applications. Some plants have experienced the life of such parts to be as much as fifteen to twenty times that of former design. The newer design of contactor has several radical departures from the older type, in that all parts as far as

possible are made of punchings, being light in weight and very uniform, instead of castings which are heavier and require considerable machining. The result is a quicker operating switch of greater reliability. These contactors have been combined into standardized lines of magnetic controllers, utilizing the voltage drop relay scheme of current limit acceleration. Some of the advantages resulting from the use of the voltage drop relay system of control may be enumerated as follows:

The voltage drop accelerating system provides a combination of current limit and time element which allows the current limit setting to be high enough to provide torque for the heaviest loads and yet when the load is light and requires less starting torque, the time element will reduce the current and torque peaks to lower values. This prevents unnecessary punishment of motor and machinery during the light load periods.

The torque and current peaks during acceleration are, therefore, more nearly a function of the load than with any other system of acceleration. This feature is particularly desirable for applications requiring variable starting torque, such as steel mill auxiliaries. The time element is obtained by purely electric and magnetic means. No dash pots or mechanical devices are used.

Power House Equipment

In reviewing data submitted by various committeemen, the Chairman feels that this subject is one to be taken care of by the Power stations Committee, in that the developments in the power Stations located in the iron and steel industry, are identical with those of power stations in general, except that in a steel plant operating blast furnaces, the gas engine is used to great extent in place of the steam turbine on account of its higher thermal efficiency and greater flexibility in choice of unit size.

Electric Heating

Considering general industrial conditions, the use of industrial heating in the iron and steel industry has made a very satisfactory advance in the last year. The number of installations made shows that the industry is beginning to realize that, while electricity is essentially a high cost fuel, the actual cost of obtaining a desired result may be less when this high cost fuel is employed than when some cheaper heating agent, as gas or coal, is used.

Consideration has been given in one or two cases to the possibilities of electrically heated soaking pits. Several large steel plants have given consideration to the metallic resistor type of furnace for low-temperature heat treatment. In general, however, the possibilities of the metallic resistor type of furnace for work up to a temperature of 2000 deg. F. have not been followed up by the iron and steel industries to the same extent as has been increasingly noticeable in industries manufacturing steel products. This furnace is being used in the annealing of automobile castings and of locomotive parts, such as crank shafts, etc.

Arc Welding

While, in general, there have been no radical changes in arc welding processes employed in steel mills within the past year, there are indications that welding will be advantageously used in an increasing number of applications in this great industry. Undoubtedly, with but little attention and study, there could be found many new applications in which arc welding could be successfully and economically employed, especially since continued research has revealed new and more desirable methods of metal deposition, as well as new metals and alloys for use in repairing different materials.

It is well known that the repair of worn wobblers, one of the oldest applications of electric welding in steel mills, was formerly accomplished by the carbon arc process used primarily because metal could be rapidly deposited. This process is gradually being replaced by the metallic arc, with which 1/4, 3/8 x 1/2 inch diameter electrodes are used, with current values varying from 300 to 800 amperes. The use of large electrodes and heavy current values is similar to the carbon arc process in that rapid deposition of metal is accomplished, but the use of the metallic arc has the advantage over the carbon process in that a less skillful operator is required to produce reliable welds.

A departure from the more or less standardized practise of using ordinary iron electrodes for building up of worn wobblers and spindles, is that of the use of high carbon steel, recently undertaken with success by different steel companies. There have been instances where old files have actually been used as the steel for the repair of worn wobblers, and when the supply of files was exhausted, electrodes were obtained having practically the same chemical composition. In all cases, the metallic arc was used in the process of repairing.

Aside from the more or less standard welding applications such as the repair of driving spindles, pinions, chipped and worn rolls, etc., the electric arc can be used extensively in the repair of all kinds of machinery in service in a steel mill. Until actually tried, the saving effected by repairing worn or broken machinery by the electric arc, cannot be fully appreciated.

E. S. Jeffries, *Chairman*

Some Development in Insulating Materials and Processes in Great Britain with Special Reference to Thermal Consideration

BY A. P. M. FLEMING
Member, A. I. E. E.
Metropolitan-Vickers Electrical Co., Manchester, England

This paper is intended to show the lines along which the manufacturers of electrical apparatus in Great Britain are dealing with their insulation problems.

Particulars are given of the facilities that have been established for insulation research, and the more important developments in insulating materials and processes employed in the various classes of electrical apparatus are discussed with special reference to thermal characteristics and consideration.

The opinions of British electrical engineers upon certain aspects of temperature rating of machinery as affected by insulation are considered.

Survey of Research Facilities

In 1903 an investigation of the thermal properties of various insulating materials was made on behalf of the British Engineering Standards Committee (now the B. E. S. A.) by the National Physical Laboratory in conjunction with a few of the leading electrical manufacturers. Aside from this, prior to 1914, electrical manufacturers in Great Britain pursued independently investigations in insulating problems, and except for occasional papers presented before technical institutions and contributions to the technical press, rarely made an interchange of experience of mutual interest and importance.

In 1914 the Institution of Electrical Engineers established through its research committee a number of panels for the investigation of certain groups of insulating materials. Similarly the British Electrical and Allied Manufacturers Association appointed a research committee, which has directed considerable attention to a number of insulating problems that were marked as needing immediate inquiry in a census taken among the members of the Association.

The establishment by the Government of a Consultative Committee led in 1916 to the formation of the Department of Scientific and Industrial Research. This department has organized and assisted in the financial support of research associations in various industries in cooperation with manufacturing firms.

Later the Institution joined forces with the Manufacturers Association and established the Electrical Research Committee which obtained grants from the Department of Scientific and Industrial Research and in due course became incorporated in the British Electrical and Allied Industries Research Association (Electrical Research Association).

During this period great difficulty was experienced, due to war conditions, in obtaining adequate supplies of insulating materials, and the Electrical Research Association focussed its attention largely on this problem.

The work of the Association is carried out under the direction of a council operating through sectional and subcommittees. The attention paid to insulating problems can best be judged from the fact that seven out of eleven sectional committees and twenty-three out of a total of thirty-four subcommittees deal with groups of investigations relating to insulation. These groups comprise:—

Fibrous Insulating Materials, including:
- Fabrics untreated and treated.
- Papers untreated and treated.
- Fibres, boards and tubes.
- Varnishes and cements.
- Enamelled wire.
- Rules for conducting electric strength tests.

Composite Insulating Materials, including:
- General research.
- Tooling of composite insulating materials.

Porcelain, including:
- Electrical and mechanical tests.

Mica, including:
- Mica and micanite for commutators.
- Mica for condensers.
- Mechanical properties of mica, etc.
- Micanite.

Insulating Oils, including:
- Chemical, physical and electrical tests and specifications.

Synthetic Resins, including:
- Supplies of constituent raw materials for manufacture of synthetic resins.
- Synthetic varnish-paper boards, tubes, etc.
- Moulded insulation employing synthetic resin.

Dielectrics (in general), including:
- Dielectric losses.
- Thermal resistivity.
- Effect of heat on insulation.

Materials

Most researches, whether carried out cooperatively through the Electrical Research Association or by individual makers and users of insulation, have been directed principally to extending knowledge of the behavior of insulation under varying physical conditions, improving quality, developing more scientific insulating

Presented at the Niagara Falls A.I.E.E. Convention, June, 1922.

processes, defining the requirements of insulation users, and standardizing the methods of testing materials for the benefit of maker and user alike. A most important development has been the increasing tendency in recent years for makers and users of insulation to cooperate either individually or through the medium of the Electrical Research Association. For the most part insulating materials had in the past been supplied by firms having little knowledge of electrical uses or requirements. Conversely, the user, except a few large firms controlling their own sources of supply, knew very little of the problems that confronted the manufacturer of insulation, especially in such materials as fabrics, varnishes and fibrous sheets. For the purpose of this paper the principal developments that have taken place in processes and materials in Great Britain are grouped according to whether they are employed in connection with:

a. Industrial machines.
b. Turbo alternators and other large machines.
c. Transformers.

Industrial Machines

For machines other than traction, crane and mill motors, Class A materials are employed, *i. e.* organic insulation of cotton, silk and paper, either impregnated or untreated. In addition, however, mica wrappings or linings of similar material are employed to a very considerable extent on the slot portions of windings.

Apart from an improved knowledge of their characteristics and their supply in greater uniformity, no very great advance in quality has been made or can be looked for in Class A materials. Certain improvements that are worthy of some note, however, are briefly as follows:

Pressboard

This name is now given to that fibrous insulating material otherwise known as fullerboard, presspahn, etc. which before the war was made only to a very limited extent in England, the supplies being obtained from America or the Continent.

While materials similar to those originally imported are now manufactured in England to meet the requirements of certain markets, newer types of pressboard have been developed along two distinct lines, having the following characteristics:

1. A soft, porous sheet material made from selected and carefully proportioned mixture of fibres and subjected to a manufacturing process which renders the product as absorbent as possible.

This material is principally used for transformers, but is also applicable to machine insulation. Its great absorbent property is secured at the expense of a comparatively low density and correspondingly decreased electric strength.

2. A dense non-absorbent sheet material, during the manufacture of which the fibers are subjected to a process which reduces them to a semi-colloidal state resulting in a product which is very hard and dense, possessing exceptionally high electric strength and capable of withstanding prolonged immersion in hot oil without loss of mechanical properties.

For most uses up to the present, this material has not been required to withstand temperatures over 100 deg. cent., and for convenience in manufacture it has been prepared from a mixture of fibers containing a large percentage of jute. Owing to its ligno-cellulose character however, jute has the characteristic property of becoming somewhat brittle at temperatures higher than about 100 deg. cent., and therefore, if required to meet more severe temperature conditions than this it will probably be necessary at some manufacturing inconvenience to employ a cotton base to secure improved aging properties.

The following table indicates the principal characteristics of these two types of materials together with those of pressboard of ordinary quality, the test for comparative purposes having been made on 1/32-in. thickness of sheet:

Quality	Density	Break-down voltage per mil in air after one minute's application	Per cent of water absorption after 24 hours	Tensile str. in tons/sq. in. With Grain	Tensile str. in tons/sq. in. Across Grain	Minimum radius bent without fraction after 24 hours in hot oil at 100 deg. cent.
Soft absorbent...	1.10	250	110	3.80	3.50	Folds flat.
Dense non-absorbent......	1.43	518	44	5.2	3.80	⅜ in.
Ordinary grade...	1.25	300	110	4.00	3.00	⅝ in.

Varnish Cloth

Considerable progress has been made in the manufacture of varnished cloth and in investigating the behavior of this material under working conditions, particularly the well-known phenomenon of the very excessive reduction of the electric strength with increase in temperature which is more marked in varnished cloth than in other Class A materials.

In manufacture, particular attention has been paid to the specially important point of dressing. A controversy still exists on this point, but many large manufacturers claim that a dressing is essential to prevent varnish coming into close contact with the cotton fibers, as it is considered that such contact deteriorates the cloth in that:

1. The impregnated cloth swells and appreciably lowers the electric strength per unit thickness.

2. The varnish within the capillaries of the fiber does not completely oxidize, at any rate for a very long period, and thus also lowers the electric strength of the material.

3. The above-mentioned slow oxidation of the varnish in close contact with the fiber sets free organic acids which attack the fiber and produce serious weakening or so-called "tendering."

Another important consideration is the suitability of the varnishes used. As to this there are two principal considerations, viz., the resin content and the contents of driers.

If the resin content is too high, the cloth lacks flexibility; if too low, the varnish film lacks sufficient strength to withstand tension without serious diminution of electric strength.

As regards the contents of driers this is a matter of supreme importance. For a varnish film to possess a high dielectric strength the varnish must be oxidized as completely as possible. Too low a content of driers causes poor dielectric strength. There is, however, an upper limit of drier content, and if this is overstepped in the slightest degree bad "tendering" of the fabric results. This "tendering" frequently does not reveal itself until several months after manufacture, and it can take place in a batched and wax protected roll in the absence of air. It is thought that in the presence of excess driers, unstable oxides are formed in the varnish film, and that these gradually decompose with the liberation of free oxygen which causes the "tendering." In all cases where "tendering" results the dielectric strength of the varnished cloth is found to be exceptionally good. No knowledge has yet been found as to the effect of such unstable oxides on the varnish film under actual working conditions, but it is quite possible that in a temperature of 100 deg. cent. their decomposition would be accelerated, and that the film might be further oxidized, either with the formation of an acid sticky mass, or possibly of a friable power. In any case there would be considerable mechanical weakening of the cloth which, coupled with the effects of vibration, might bring about a breakdown.

Synthetic Varnish Paier Boards and Tubes

Materials of this description have of late been the subject of considerable controversy, and the general tendency is to curtail their use until their properties, particularly as regards absorption of moisture and low surface resistance, are more thoroughly understood. A great deal of investigation in this direction is in progress and the limitations of the materials are better understood.

The uneasiness felt in the use of these materials in Great Britain has been intensified by the fact that during the war many different makes were supplied by manufacturers insufficiently equipped in experience and plant to produce commodities requiring such a high degree of technical skill.

Moisture Proof Treatment of Windings

Much consideration has been given to the most satisfactory method of treating windings and two general processes are in favor, viz: vacuum impregnation and dipping, or surface treatment.

For vacuum impregnation on stationary windings bituminous compounds are generally employed, and for rotating windings a varnish which oxidizes only to a limited extent and contains a large percentage of volatile solvent which consequently hardens reasonably well even although it penetrates into interstices not freely exposed to the air. Under such conditions the difficulties of completely oxidizing linseed oil base varnishes are fully appreciated.

In none of the materials employed in these processes has there been any marked improvement in recent years.

While it is generally felt that Class A materials have nearly reached their physical limits of durability under the temperatures and conditions met with in practise, there is still much knowledge to be obtained which will correlate the results obtained in the laboratory with those of practical experience in service.

Turbo-Alternators and Other Large Machines

The tendency has been to employ as far as existing processes render practicable materials of Class B. Some manufacturers do this to a limited extent in the case of stator windings where the materials employed usually consist of combinations of mica with paper or cambric. The volume of mica ordinarily contained in a commercial grade of these materials may be as low as 25 per cent, and as will be seen later this proportion does not compare favorably with that of the insulation practicable on turbo-rotors.

Some other manufacturers insulate the stator windings throughout with mica applied in the form of mica paper tape. With this combination the proportion of mica is much lighter, the thin paper serving only as a support during the application of the mica. Mica silk is also used to a considerable extent and enables the application of a higher percentage of mica to be made.

In the processes of insulation, especially those applied to the slot portions of the windings, every effort is made to compress the insulation to as dense a condition as possible and to eliminate as far as is practicable volatile matter which, apart from a tendency to cause insulation to swell when heated, is liable to condense in the coolest parts of the windings with very deleterious effects to the insulation and risk due to its inflammability.

No effective fire-proof treatment of stator insulation has yet been found, although many investigations are proceeding to this end.

Turbo-rotor windings can be insulated almost entirely with hard-pressed micanite containing not less than 90 per cent by volume of mica. The small quantity of grade A insulation that has to be employed during the assembling of these windings can be disregarded. Further, in supporting the end of the windings an almost non-flammable insulation, such as that prepared from asbestos and synthetic resin, can be used, thus rendering the whole of the insulation of the rotor extremely heat-resisting.

Probably the most marked improvements in the insulation of this group of electrical machinery is the

closer technical control and supervision that is now exercised of insulation processes in the shops and the more rigid selection of the insulation materials employed.

Transformers

Materials of Class A are to a very large extent used. In oil-cooled transformers the solid insulation usually consists of pressboard or varnish-paper board (micarta). In the core type construction the latter material has hitherto been largely used. There is, however, a tendency now to employ pressboard of the very dense quality already described. This material is found to be very strong both electrically and mechanically at the highest temperatures met with in practise. On the other hand shellac varnish-paper in either tube or board form, as ordinarily supplied, softens at temperatures between 75 deg. and 90 deg. cent., and its electric strength at these temperatures is very low. Dense pressboard does not soften and possesses extremely good electrical characteristics. Tests on a cylinder of this material after exposing to a temperature of 80 deg. cent. for twenty hours and, then to oil at a temperature of 90 deg. cent. for two hours, yielded the following breakdown figures:

Instantaneous breakdown............550 volts per mil.
Breakdown after 1 minute............445 volts per mil.
Breakdown after 5 minutes.........400 volts per mil.

These results give a time voltage curve at this temperature of a very favorable character.

A very considerable amount of research has been carried out in connection with improvement in the quality of oil used with transformers. The disastrous effects of sludging noted some twelve or fourteen years ago by large transformer users, led to the discovery of the non-sludging character (when properly refined) of the bituminous base white Russian oils. There was a marked tendency among British users before the war to employ this expensive oil, and when the sources of supply were cut off attention was paid to the refinement of paraffin base oils from other sources which up to that time had not shown such excellent properties. A long series of investigations led to the establishment of methods of testing which are now generally accepted in Great Britain and which are about to be embodied in a specification by the British Engineering Standards Association.

The correlation between laboratory tests on highly refined non-sludging oils and their behavior in practise is not as yet very complete. It is possible that their use affords an unnecessary margin of safety in the case in certain types of transformers, and that somewhat cheaper oils would be satisfactory in transformers where there is a minimum amount of bare copper exposed to the catalytic action, and where there is a minimum amount of oil surface exposed to the air.

A considerable amount of research is being carried out in connection with the temperature characteristics of cable insulation both at the National Physical Laboratory and at the works of various cable companies. The complete results of these investigations are not yet available.

Some Rating Considerations

Laboratory Tests and Service Experience

While it is indisputable that the rating of electrical machinery must be based upon the temperature which insulation will withstand, it is becoming appreciated that life tests of insulating materials made under laboratory conditions are of little value as compared with practical experience with the operation of machines under known service conditions and for long periods, and that it is only upon the results of such experience that conclusions as to the durability of insulation can satisfactorily be drawn.

Laboratory tests are of the utmost value in enabling comparisons to be made of the relative properties of different materials and also in the development of new materials and processes. In the past, however, there has been a tendency to attach too great importance to laboratory investigations directed to the determination of the temperatures at which mechanical deterioration occurs and on which temperature ratings should be based. Such investigations have not always taken into account the fact that the surfaces of insulated windings exposed to oxidation are relatively very small as compared with the exposed surfaces of test specimens; and that the rate of deterioration of insulation in the case of windings in service, where there may be a considerable temperature difference between the surface and the cooling air, is likely to differ greatly from that occurring in a laboratory aging oven where no such temperature difference exists. Then again in almost all types of windings the insulation is so completely supported mechanically that any hardening, stiffening or embrittling of its layers may proceed without any attendant risk of failure to a point far beyond that which would appear alarmingly unsafe if such support did not exist.

The increasing tendency for power plant engineers to maintain careful records of temperature performances of their large generator and transformer units will eventually afford data of the utmost value and serve to confirm or amend present ideas as to correct temperature ratings.

Temperature Considerations

It has for long been recognized, especially in connection with large machine windings, that internal temperatures existed considerably higher than the values which have been adopted as standard limits for many years in connection with the older methods of measurement. The temperature limits now proposed for Class B materials under the new methods of measurement, while apparently higher than the figures formerly recognized, do not actually imply higher internal temperatures than have existed in the past, or than the results of experience indicate as safe.

In those cases where conditions permit the use of materials which withstand high temperatures, all the features of design should be viewed in proper perspective and full advantage taken of high temperature limits if by so doing better all round performance results.

In connection with the tendency on the part of British manufacturers to employ in transformers highly refined non-sludging oils, coupled with the use of dense fibrous materials which will withstand high temperatures without deformation or serious loss of insulating value, it is felt by some that the employment of oil conservators safely permits higher temperature limits both in oil and windings than are permissible without the use of these devices.

Ratings Based Upon Temperature Rise

In the case of industrial machines there is a strongly growing opinion among British engineers that in the rating of electrical machinery the decision of the I. E. C. to establish a basis for comparing tenders by different countries according to total temperature was a mistaken policy, and that temperature rise affords a much more satisfactory means of securing this object.

As already noted in connection with Class B materials the combinations of insulation used particularly on turbo-alternators and other large machines differ considerably in the proportions of organic and inorganic materials that they contain, and consequently also in their heat-resisting properties. It is felt that the present classification is unsatisfactory and should be revised, some differentiation being made in the limits set according to the quality and the position in which any particular type of material is used. For instance the insulation that is possible for rotor windings throughout may be relatively of superior heat-resisting quality to that which is sometimes used on the slot portions of stator windings, which again is, in general, superior in this respect to the insulation on stator end windings.

Influence of Temperature on Insulating Materials Used in Electrical Machinery

BY ERNESTO VANNOTTI
Member of Italian Electrotechnical Association, Milan

Laboratory tests, as well as the condition of machines which have been running a number of years, show that the temperatures that can be withstood without damage to the insulating materials are considerably higher than those prescribed by international rules.

The present values have probably been chosen so as to guard against too high temperatures caused by defective construction of certain parts of the machines.

If exploring coils are placed suitably and with care at the points where overheating is most likely to occur, the value of the permissible temperature, as recorded by the coils, should be 10 to 20 per cent higher than the rules permit, in order fully to utilize the materials of construction. Windings for over 5000 volts should not contain any air pockets.

THE influence of temperature on insulating materials is a question of great importance which is to be discussed by the American commission for the standardization of electrical machinery, to which electrical engineers of various countries have been invited. It is much to be desired that a thorough investigation of the subject might lead to the acceptance of the same standards by different countries, so far as these standards concern the permissible temperature rise compatible with the present state of development in the maunfacture of insulating materials.

The president of the commission of Italian electrical engineers asked me to prepare a paper on this subject. However, I must call attention to the fact that the subject is very extensive and involved, and that causes of heating of the insulated portions of the machines, as well as of the insulating materials themselves, may be exceedingly numerous and complicated. I am therefore unable to enter into a detailed discussion, or to compare thoroughly the properties of the different materials used, but will only attempt to give a general survey and summarize the conclusions, which, it seems to me, can be drawn from practise.

Laboratory tests, and the process of manufacture of different insulating materials and insulated windings have shown that the insulated conductors used for electric machines are capable of withstanding, without damage, temperatures which are appreciably higher than the maximum values laid down by the International Electrotechnical Commission.

This observation is borne out by the fact that insulated current-carrying parts of many machines—the temperature rise of which corresponds to standards approximately in accordance with those now prescribed by the International Standardization Rules—are still in excellent condition after 20 years' service, even in cases when notable overloads occur. In other words, the running of these machines for a long time, which corresponds to a continuous service lasting at least 10 to 20 weeks, with temperatures 20 to 30 per cent greater than the maximum values now allowed by international standards, has scarcely affected the structure and dielectric strength of the insulating material.

Practise has shown, moreover, that machines whose temperature rise, measured by the increase of resistance of the windings, remains within the limits allowed by International Standards, are sometimes liable to failures after a comparatively short time on account of excessive temperature rises which cause failures to occur in parts of the winding. As an example, I may mention the case of a three-phase, 6000-kv-a. turbo-alternator, at 1500 rev. per min., 6250 volts, 580 amperes, 50 cycles. The stator is well ventilated and has bar winding of massive copper as shown in Fig. 1. This winding should have an average temperature rise of 60 deg. cent. according to the method of measuring the increase of the resistance. Nevertheless, the insulation was damaged after a certain time on account of the abnormal temperature rise of the bar placed nearest the air gap. The small iron wedges which partly close the slots of the stator are evidently much too small to prevent or dampen to any great extent the variations of the magnetic field in the copper bars. For this reason, large eddy currents occur which entail excessive local heating and consequent damage to the insulation. The copper bar near the air gap was replaced by a stranded conductor composed of a great number of fine wires. Although the copper cross section was 20 per cent less than the section of the solid copper bar, no further damage occurred to the insulating material under the same operating conditions.

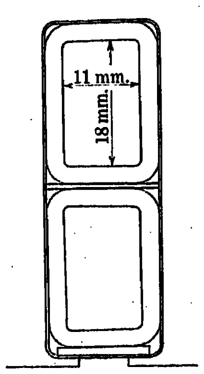

FIG 1.

With high-voltage windings for 5000 volts and over (and occasionally for 3000 volts), it is well known that, if air is present between the individual coils on account of breakages in the insulation, damage is likely to occur as though the temperature rise had been excessive, notwithstanding the fact that the latter is well within the prescribed limits. In this case, the harm to the insulating material is caused by the formation of ozone which is produced by static discharges in the air gaps between the coils.

Displacements of commutator segments have been known to arise, even when the commutator appears to be correctly designed, which entail sparking at the brushes. This occurrence is due to insufficient attention having been paid to the expansion caused by heating.

Presented at the Niagara Falls A. I. E. E. Convention, June, 1922.

It appears, therefore, that abnormal temperature rises, or occurrences met with in practise which are due to constructional shortcomings prejudice the preservation of the insulation in service. Furthermore, it is not always possible to discover these faults or their origin during acceptance tests.

The precise determination of these conditions forms part of the programme of the committee appointed to determine the permissible temperature rises. In my opinion, the existing values have been chosen unnecessarily low so as to insure against concealed faults in construction.

I think that it is pertinent to give an example, which, although not directly related to the subject under discussion, is of certain importance as it serves to confirm my statement that the tendency is to prescribe stringent acceptance tests in order to guard against any unforseen circumstances.

At a meeting of the Italian Electrotechnical Commission the following motion originating with a foreign association was discussed: "Insulation tests for turbo-alternators, contrary to those for ordinary machines, should comprise a pressure test for pressures corresponding to three times the working voltage, since this particular class of machines is most likely to be damaged by insulation failures." I cannot understand the reason for this special treatment of turbo-alternators, and consider that the recorded damage to the insulation is due rather to constructional shortcomings than to insufficient insulation, or to an insulation test that was not severe enough.

In reality, I believe that insulation failures of portions of conductors embedded in the stator iron are caused by excessive local overheating of these conductors, similar in fact, to the case of the 6000-kv-a. turbo-alternator already mentioned. With conductors of ordinary dimensions, that is to say, those having sections sufficient to preclude eddy currents, special precautions have to be taken to prevent local overheating which may be sufficient to cause the best micanite insulation to deteriorate rapidly.

Defects of windings situated outside the stator iron, especially where the conductors leave the iron core, are most probably due to mechanical imperfections, which are easily produced by short circuits or false parallel connections when the end windings outside of the stator core are not properly secured and braced.

I will, therefore, go a step further and assert that the running conditions will be less satisfactory in the case of a machine which has been damaged through one of the reasons just enumerated, and has been rebuilt so as to be able to withstand a test voltage of three times the operating voltage, without altering the principles of its construction. The reason for this is to be found in the excessive thickness of the insulating layers of the parts embedded in the stator which have been renewed with the consequently increased difficulty of ensuring efficient cooling—a problem which has always needed great care with turbo-alternators. If the distance between end connections is augmented in order to allow a test pressure equal to three times the operating pressure to be withstood without reinforcing their supports, the mechanical stresses, damage to the insulation, etc. will be increased on account of the greater distances and higher electromagnetic stresses in the end connections.

I consider, therefore, that the allowable temperature rises prescribed by international standards are too low for machines which are designed and built correctly. These standards, moreover, do not permit the active material of electric machines to be fully utilized, and consequently increase the cost of manufacture.

Moreover, it is logical that excessive local overheating should be objected to and that its cause should be found out during the acceptance tests in order to obtain a guarantee from its after effects. The occurrence of abnormal local overheating can be revealed by inserting exploring coils in places which are most likely to overheat. It goes without saying that these thermo-indicators must be manufactured and put in place with care so as to preclude errors of measurement.

Finally, I should like to make the following suggestions:

1. If the temperature rise is measured by suitably placed and reliable thermo-indicators so that no doubt exists as to the correct measurements of the temperatures at the hottest parts of the machine, new figures should be prepared for the international standards giving the highest permissible temperatures in such cases, the values of which should be 10 to 20 per cent higher than those now allowed.

2. All windings for voltages greater than 5000 volts must be provided with impregnating material in order to prevent air spaces between the individual conductors and the different layers of insulating material.

3. Commutators should be allowed to run at a maximum temperature of 115 deg. cent. provided that no deformation or sparking occurs at this temperature.

The Relation of Overload to the Inner Temperature of Machines

BY GUIDO SEMENZA
Associate, A. I. E. E.
Consulting Engineer, Milan, Italy

OVERLOAD is generally regarded by users of electrical machinery as a convenience. Very few consider the meaning of a rating containing overload allowances (double rating) from the point of view of the comparability of different makes of machines and of the effects that overload allowances may have on the duration of the insulation of the machine. The object of this paper is to show, in an elementary way, the process of heating going on in electrical machines and to consider what is the fundamental difference between single rating (no overload allowed) and double rating (overloads allowed) and to supply a clear and sound basis for an eventual discussion. I shall here only refer to continuous rating and the word machine will indicate generators, motors, converters and transformers cooled by natural ventilation.

If we want to design a model of an electrical machine in order to follow its thermic behavior, we can imagine it as drawn in Fig. 1. M is a mass of iron thermically insulated by a coating K, and leaving open in contact with the air, the surface a b, the diffusing surface. A is a conductor. I the insulation. We shall neglect the representation of the heat produced in the iron, as this does not change the results of this study. In the conductor A a certain quantity C of heat is produced per unit of time and is transmitted across the insulation

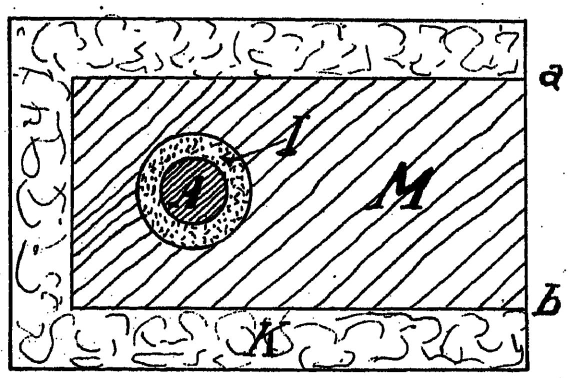

FIG. 1

and the iron mass M to the diffusing surface from which it passes by convection and radiation to the cooling air. If we suppose the temperature t_0 of the cooling air to be constant after a certain lapse of time we shall reach a condition of equilibrium in which all the heat produced in A in a second is transmitted to the air in the same time and therefore all the points of the machine will have reached a steady temperature. In such a condtion if we measure these temperatures we shall be able to plot them in a diagram, more or less, of the appearance of the one shown in Fig. 2. The temperature t_1 of the conductor or heat generator falls across the insulation to t_2, the fall being ruled by a law similar to Ohm's law; the fall of temperature in fact is directly proportional to the flow of heat and to the inverse of the thermal conductivity of the mean. A second fall of temperature occurs in the mass M to t_3 the diffusing surface temperature, and a third on $t_3 - t_0$ the fall occurring between the surface and the mass of the cooling air. The effect of heat generated in the iron

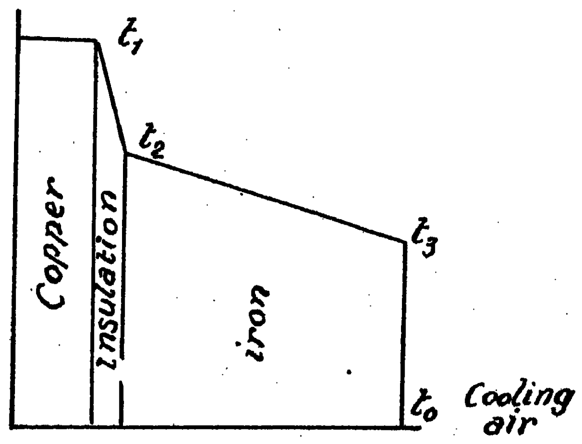

FIG. 2

mass will be to increase the inclination of the line $t_2\,t_3$. As we have means of measuring t_1 and t_0 and the current in A, we can, in these steady conditions, know exactly what is going on in the machine. If we assume t_0 to be the maximum cooling air temperature, we can at any time in the life of the machine be sure that the temperature of the copper, hence of the insulation in contact with it, will never rise above the value t_1, provided that the current in A does not increase over the rated intensity.

We can easily realize also that with the same production of heat (that is, losses in the machine) even with very large difference in the thickness of insulation and of the mass of iron we can keep the temperature t_1 of the conductor below a certain allowed maximum, by adapting the area a b of the diffusing surface to the conditions of the special case. A thick insulation (high-tension machine) will give a greater fall $t_1 - t_2$ in the insulation than a thin one (low-tension machine) therefore in order to have t_1 constant, the value of t_3, that is the surface temperature of the machine, will have to be lower in the case of thick insulation, which can only be attained by increasing the diffusing surface. The same may be said for any condition which will increase the internal thermic drop of the machine.

Presented at the Niagara Falls Convention, June, 1922.

Therefore machines of different tension, speed, construction and make can be so designed, that in the steady normal conditions, or in other words, at their rated power, the temperature of the conductors, hence of the insulation, shall never exceed the prescribed value.

Going back to our model let us suppose that a certain steady thermal condition is reached and let us increase by a certain per cent the current in the conductor, so that the production of heat per unit of time would be increased from C_1 to C_2. At the first instant after the increase the thermal flow is still determined by the pre-existing conditions, so that the quantity C_1 of heat is transmitted through the insulation under a difference of temperature $t_1 - t_2$. As in these conditions not more than C_1 can leave the conductor, the extra heat $C_2 - C_1$ is stored up in the conductor raising its temperature from t_1 to t_1'. This allows an increase of flow of heat across the insulation. But if we suppose the

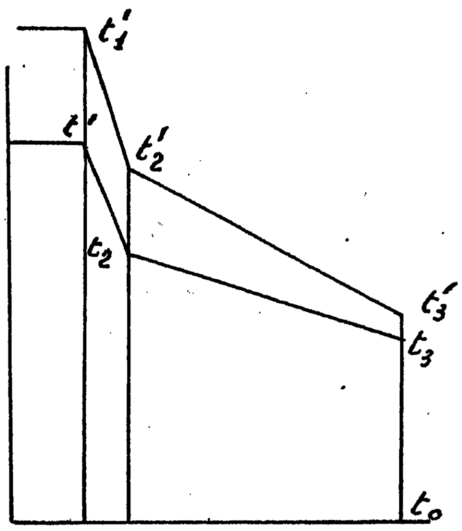

Fig. 3

insulation is formed by a superposition of very thin layers, each of them, receiving more heat, stores up a part of it in order to increase its temperature before it can increase its transmission to the following layer, and so on. Considering the whole path through which heat is transmitted (insulation and iron) we can say that in the variable period following an increase in the quantity produced, each element in a first period stores up heat then transmits it to the following one, and this process goes on till a new steady condition is reached in which in every unit of time an equal quantity of heat is produced and diffused in the air. For this condition we shall be able to plot a new diagram. Now what it is of interest to know is the new value of t_1 and the time the system takes to reach it. The knowledge of both these elements is necessary. When overloads are stated for a limited period of time it is important not only to know what is the maximum temperature reached, but also if during such period the new steady temperature is reached.

Many causes may influence the behavior of the machine in this variable period.

First, the thickness and nature of the insulation, or in other words the thermal conductivity of the whole layer of insulation, as upon this will depend the fall of temperature and the length of the variable period.

Then comes the construction of coils. As to transmission of heat, a single bar conductor is something very different from a coil of very thin wire with heavy insulation. Thoroughly impregnated coils are in this respect different from coils merely coated with shellac or varnishes.

The magnitude of the iron mass and its laminated construction with respect to the direction of the flow of heat, have a good deal of importance, and here especially we meet with differences in the storing effect and in the fall of temperature necessary to drive the heat across the mass itself.

Where the heat produced comes to the diffusing surface the temperature of the surface has an influence on the quantity of heat diffused by convection and by radiation; the diffusing coefficient is not constant, but increases with temperature and with the difference of temperature between the surface and the air. This phenomenon, which is from a certain point of view beneficial, is different in different machines.

In conclusion machines of different tension, speed and construction, which at their steady normal conditions of work reach the same rise of temperature in the copper, when overloaded say for one hour with the same percentage of overload, necessarily reach different temperatures in the copper as all the elements by which they differ (insulation thickness, revolutions, power, storing capacity, dispersing surface) have different effects on the rise of temperature. Moreover in some machines the end of the overload period will find the new steady conditions established, in others, especially in heavy machines, this state will not have been reached.

So we may summarize by saying that machines quite comparable at their normal rating for continuous service are not comparable the same percentage of overload imposed for the same period of time.

All forms of rating with overloads (double ratings) in use or proposed up to the present are intended to apply to a large variety of machines, and contain only rough divisions in two or a few classes according to power. If the German rules are excluded (in which it was not question of thermal overload) no mention is made of temperature. The buyer must be satisfied with the seller's declaration that overloads will not spoil the machine.

The aim of an international rating rationally considered is to provide a manner of defining what a machine really is. The buyer must be able to compare offers of machines of different makes and countries by their ratings.

With the single rating he can do it quite well; he

knows that a machine rated at 10 kw. will give him 10 kw. in a continuous manner without submitting the insulation to dangerous temperatures. If he wants to overload his machine it is at his own risk. All this is clear, plain and simple.

When a double rating is given in the ordinary forms without stating the final temperature what does the buyer know about his machine? He knows that at the rated power for continuous run, the insulation of the machines will not have to bear a temperature higher than a certain specified value, but how can he compare offers if, as we have seen, the different machines under overload all have different behaviors as to the rise of temperature? How can the buyer be sure of the duration of his machine knowing that high temperatures are dangerous if applied for a certain time, and not knowing anything of the value of such temperatures and of the length of time they are applied?

One conclusion is that the rating of machines for continuous service, without any allowance for overloads (single rating) is a definite and clear specification and constitutes a fair basis for commercial transactions.

A rating given for continuous service but allowing overloads (double rating) could only be compared to the single rating provided it can be demonstrated that the same overload applied to machines of all sizes, tensions, speeds and construction bring practically to the same ultimate temperature and to the same fatigue of the insulation.

That such a demonstration can be given in the actual conditions of the industry is a matter of discussion.

Should the answer be negative then the only solution, when double rating is wanted is to call for the specification of the temperature reached after the allowed period of rated overload.

Report of the Board of Directors

FOR THE FISCAL YEAR ENDING APRIL 30, 1922

The Board of Directors of the American Institute of Electrical Engineers presents herewith to the membership its Thirty-eighth Annual Report, for the fiscal year ending April 30, 1922. A general balance sheet showing the condition of the Institute's finances on April 30, 1922, together with other detailed financial statements, is included herein. The following is a brief summary of the principal activities of the Institute during the year; more detailed information has been published from month to month in the Institute JOURNAL.

Directors' Meetings.—Because of the wide geographical representation upon the present Board of Directors a bi-monthly meeting policy was adopted beginning with October, 1921; meetings of the Executive Committee were held during the alternate months.

The Board of Directors held seven meetings during the year; six of these were held in New York and one at Salt Lake City, Utah. Three Executive Committee meetings were held in New York.

Information regarding the more important activities of the Institute which have been under consideration of the Board of Directors, the committees and the various officers, is published each month in the section of the JOURNAL devoted to "Institute Activities."

Meetings.—The Board of Directors at the meeting of May 20, 1921, upon recommendation of the Committee on Coordination of Institute Activities adopted a new policy by which all the regular monthly meetings throughout the country were placed upon the same basis, that is all made Section meetings. A resolution was adopted in August to the effect that in addition to the Annual business meeting there shall be four general meetings of the Institute each year including the Midwinter, Annual and Pacific Coast Conventions.

Annual Meeting.—The Annual Business Meeting was held at Institute headquarters, New York, on May 20, 1921. The Annual Report of the Board of Directors for the fiscal year ending April 30, 1921 was presented. The Tellers Committee presented its report upon the election of officers for the year beginning August 1, 1921. The business meeting was followed by a technical lecture.

Annual and Pacific Coast Convention.—The combined Thirty-Seventh Annual and Tenth Pacific Coast Convention was held at Salt Lake City, Utah on June 21 to June 24, 1921. Four technical sessions were held, all of them during the mornings, at which fifteen technical papers were presented in addition to the Presidential address, the Technical Committee Reports and an address by the Local Honorary Secretary for Italy. The annual conferences of the Sections Committee were held with an attendance greater than at any previous meeting, forty Sections were represented. The discussions were reported in the August 1921 JOURNAL.

New York Meeting.—The 372nd Institute meeting was held in New York on November 17, 1921. Two sessions were held. The afternoon session was held jointly with the Society of Naval Architects and Marine Engineers and two papers were presented on electric auxiliaries and electric propulsion of ships. The evening session was occupied by a lecture on "World Communication."

Mid-Winter Convention.—The tenth Mid-Winter Convention was held in New York on February 15-17, 1922. Five technical sessions were held at which twenty papers were presented. Thursday evening was devoted to the presentation of the Edison Medal to C. C. Chesney, followed by a lecture on "Colloids." Friday afternoon was assigned to inspection trips and the meeting closed on Friday night with the Annual Dinner-Dance.

Spring Convention—The first Spring Convention of the Institute was held in Chicago, Ill., April 19-21, 1922. Three technical sessions were held at which ten papers were presented. In addition two sessions were devoted to symposiums on subjects of general engineering interest and an afternoon and two evenings were occupied by an inspection trip, theatre party and dinner-dance.

Abstracts of the reports of the chairmen of many of the Institute committees and delegations are included herein under various headings.

Meetings and Papers Committee.—The Committee has obtained during the past year an ample number of papers, both for the two conventions already held and for the scheduled meetings at Niagara, Vancouver and a proposed meeting next November.

The Committee has been reorganized on a new basis to obtain general cooperation of its membership, irrespective of geographical location. Members have been supplied with dockets of papers received, giving author, title, size and contents of each paper, and this has aided materially in reaching conclusions and laying plans.

The Committee has clearly stated to prospective authors the bases for choice of papers, and this has enabled authors to meet in advance the imposed conditions, and has considerably lightened the work of review which falls upon the technical committees. The Committee has also endeavored to solve the ques-

tion of the balance of technical and general interest matter published in the JOURNAL by having written for each specialist's paper a "story" of the paper which briefly tells of the conditions of the art, the reasons for writing the paper, the new material added by experimental and analytical work, the general conclusions reached—all in language that is found acceptable to executives, and therefore readable to the membership at large.

Condensed into a few words—in the evolution of the affairs of the Meetings and Papers Committee, the endeavors are definitely to further organize, systematize, coordinate and codify.

Committee on Coordination of Institute Activities.—The function of this committee is to consider, investigate and report recommendations to the Board on such matters, involving the interests of more than one of the other committees or not relating to the field of any other committee, as may be referred to it by the Board.

The most important action taken during this year was to recommend a new policy for the publications of the Institute. This recommendation was made in conjunction with the Meetings and Papers Committee and the Publication Committee and was subsequently approved by the Board.

Among other matters discussed by the committee were the organization of the Standards Committee and the determination of a definite policy as to the number and location of Honorary Secretaries.

Publication Committee.—This committee has general supervision of all the technical publications of the Institute and has been active this year in modifying the methods of publication of the JOURNAL and the TRANSACTIONS to meet the general financial stringency. The most important problem before the committee this year was to determine a method whereby the expense involved in printing the TRANSACTIONS in the form heretofore issued could be eliminated. Several meetings of the committee have been held during the year resulting in procedure for publishing the JOURNAL and TRANSACTIONS which has been explained in previous notices to the membership and which is in effect for the 1922 publications.

Sections and Branches.—The growth in Section activity which has been noted in the Directors' Reports of the last few years continued during the past year both as to new Sections organized and number and attendance at meetings as evidenced by the figures given in the following table. The regional Vice Presidents have in many cases visited the Section headquarters in their territories and this has resulted, as it was hoped when the plan of dividing the representation of the Board into geographical districts was instituted, in a closer relation and greater interest of the membership as a whole in Institute affairs.

During the past year Sections have been organized at Columbus, Ohio, Oklahoma and Santiago de Chile. An extension of territory was granted to the Vancouver Section.

The development of Institute Branches has during the past year lived up to the post-war promise of greatly increased scope. This development is recorded not so much in the increased attendance at meetings but by the greater number of schools of all classes from which the student enrollment is now drawn. The work of passing upon these Student applications from schools never before listed has required considerable time on the part of a special subcommittee of the Board of Examiners. New Branches have been authorized at Swarthmore College and Rutgers College.

	For Fiscal Year Ending						
	May 1 1916	May 1 1917	May 1 1918	May 1 1919	May 1 1920	May 1 1921	May 1 1922
SECTIONS							
Number of Sections	32	32	34	34	36	42	45
Number of Section meetings held	251	265	245	217	262	303	373
Total Attendance	28,553	31,209	31,614	25,837	30,741	37,823	51,378
BRANCHES							
Number of Branches	54	59	59	61	62	65	67
Number of Branch meetings held	360	368	268	156	360	443	439
Attendance	15,166	16,107	10,683	6,441	16,827	21,029	25,358

Scholarships.—The governing bodies of Columbia University have placed at the disposal of the Institute a scholarship in Electrical Engineering beginning with the academic year 1922-23 and continuing until further notice. The scholarship pays $350 toward the annual tuition, and reappointment for completion of course is conditioned upon maintenance of good standing. An Institute committee will consider the candidates and make a recommendation to the Board of Directors regarding the award.

Standards Committee.—The Standards Committee has held five regular meetings during the year for the transaction of its business.

The Committee has adopted, subject to confirmation at the May meeting, modifications and additions to various parts of the Rules, including a new chapter on rules for storage batteries adopted provisionally last year. The Committee has also initiated work on rules for electric welding apparatus, which work is now well under way.

The Committee has prepared an unusually complete report on screw lamp-caps and lamp-holders, presenting a complete historical picture beginning with the original designs and extending through the development to the American standard screw-shell base over a period of years.

A report has been completed comparing the rating of motors using Class A insulation in accordance with the

various rules which have been suggested in the United States and in England. This comparison shows some important differences, but in view of the fact that the rules for open-type motors employing Class A insulation are still in the hands of the Sectional Committee on Rating, the Standards Committee has refrained from taking any definite action during the present year.

The Committee has arranged for the appointment of an Institute representative on the Sectional Committee on Safety Code for Aircraft and nominated members for the Sectional Committee on Electrical Installations on Shipboard.

A large number of communications covering all branches of its work has been received and acted upon.

Considerable attention has been given to the best method of organizing the standardizing work of the Institute, with particular reference to the Standards Committee, the Technical Committees, the various Sectional Committees appointed under the rules of the American Engineering Standards Committee, and the United States National Committee of the International Electrotechnical Commission. The Committee expects to submit to the Board for approval at its May meeting, a comprehensive plan which will tie these various committees more closely together.

American Engineering Standards Committee.—The following statistical summary of the work of the American Engineering Standards Committee is taken from the report of the committee for 1921.

Member-bodies	20
Organizations represented	28
Representatives on main committee	52
Approved standards	17
Standards up for approval	17
Projects having official status	79
Projects for which sponsorship has been accepted	51
Organizations acting as sponsors	43
Cooperating bodies	160
Individuals on sectional committees	548

The committee is receiving government cooperation through the active participation of numerous branches of the Federal Government in the work of the committee. The committee has a large number of specific projects on hand which are being handled by sectional committees in the regular way. International cooperation is assured through the committees being in touch with the national standardizing bodies of Austria, Belgium, Canada, Czecho-Slovakia, France, Germany, Great Britain, Holland, Italy, Japan, Norway, Sweden and Switzerland. Three new member bodies were added during the year. Additional financial help over that derived from dues from the member bodies was received from companies interested in standardization and through special contributions to the extent of $7425.

The Department of Commerce at Washington has arranged to promulgate standards to be known as Standards of Simplified Practise. At the request of the Secretary of Commerce, the A. E. S. C. has designated Mr. A. A. Stevenson, the retiring chairman of the committee, as a special representative to work with the Department in the cooperation between the Department's Division of Simplified Practise and the standardization work of the A. E. S. C. and a representative of the Department has been designated to act on the A. E. S. C. This arrangement is considered one of the important steps taken by the A. E. S. C. during the last year, providing, as it does, definite cooperation and coordination of the work of the Department of Commerce with that of the committee.

Mr. Albert W. Whitney was elected chairman of the committee for the year 1922.

U. S. National Committee of the I. E. C.—This Committee has held only one general meeting (October 14th, 1921), but the Executive Council of the Committee has held several meetings from time to time. By letter-ballot of the membership of the Committee an amendment in the Statutes of the Committee, the purpose of which was to provide for *ex-officio* representation, in the Committee, of the War Department, the Navy Department, the Bureau of Foreign and Domestic Commerce, "and any other Department of the United States Government interested in the objects of the I. E. C." was adopted. The Departments accepted the invitation, and the representatives designated were: for the War Department, Major General G. O. Squier, Chief Signal Officer of the U. S. Army, and, for the Navy Department, Commander C. S. McDowell, U. S. N. The Bureau of Foreign and Domestic Commerce will also be invited to accept ex-officio membership in the Committee.

The work on proposals to the Commission, suspended last year in order to wait for the report of the A. E. S. C. Sectional Committee on Rating of Electrical Machinery (of which the A. I. E. E. is the sponsor-body), has had to remain in abeyance, because the work of the Sectional Committee has not yet been completed.

The Committee was represented by two delegates at an unofficial conference of delegates of various national committees of the Commission in Paris last November, to consider the difficulties of various kinds which have arisen in regard to the adoption of I. E. C. Recommendations and Rules, in certain countries, since the Brussels meeting of the Advisory Committee on Rating in 1919, and which have forced the Commission to postpone its meetings several times.

The Committee cooperated with the Organization Committee of the International Conference on Electrical Super-Power Systems, which was held in Paris in the week of November 21-26. Several important papers were presented by prominent American electrical engineers. The Committee was represented, informally, at the conference, by Dr. A. E. Kennelly,

Mr. F. D. Newbury, and Dr. C. O. Mailloux, who was made Honorary President of the Conference.

National Committee of the International Commission on Illumination.—The work of the U. S. National Committee of the International Commission on Illumination, during the past year, largely centered about the meeting of the International Commission, which was held in Paris, July 4-8, 1921. The U. S. National Committee secured and transmitted for use at that meeting, reports on the following subjects: Lighting Legislation; Automobile Head Lighting; Nomenclature and Standards of Photometry and Illumination; Relative Visibility Function and the Mechanical Equivalent of Light; Heterochromatic Photometry; Use of Light Filters in Heterochromatic Photometry.

The Commission concerned itself chiefly with fundamental definitions, and adopted definitions of "luminous flux," "illumination", and "luminous intensity", which are in accordance with those currently used in this country, and appearing among the A. I. E. E. standards. Furthermore, the Commission recognized the fundamental candle-power unit, which is maintained by the National Laboratories of Great Britain, France and the United States, as the "International Candle." The Commission also appointed subcommittees on "Heterochromatic Photometry," on "Definitions and Symbols," on "Lighting in Factories and Schools," and on "Automobile Head Lights."

It is proposed that the next meeting of the Commission shall be held, (assuming that conditions are favorable), in this country, in 1924. Dr. E. P. Hyde of the U. S. National Committee was elected President of the International Commission.

At the meeting of the U. S. National Committee, held in November, 1921, C. H. Sharp was elected Chairman of the U. S. National Committee, and Howard Lyon was elected its Secretary.

Code of Principles of Professional Conduct.—Two cases of alleged breaches of our code by members of the Institute have been presented to the committee during the past year. In one of these cases, involving the presentation of false information, the committee found the charge warranted and recommended that the member's resignation, presented in the interim, be accepted by the Board. In the other case, involving the unauthorized use of the name of the Institute for advertising purposes in a printed document, the committee recommended severe censure and the withdrawal of the document in question.

Both of these recommendations were accepted and acted upon by the Board.

At its meeting on February 16, the committee recommended the policy of publishing the findings of the committee in the Institute JOURNAL, each case to be presented as an example of the interpretation of the code, and without names. After referring this matter to the legal counsel of the Institute, the recommendation was approved by the Board, and a brief statement of the cases above mentioned was prepared and published.

During the past two years, a committee of the American Society of Mechanical Engineers, cooperating with representatives of the other societies, has been preparing a joint code of ethics. After careful consideration of this code, your committee has recommended that the Institute adhere to its present code, rather than adopt the proposed joint code. It is the opinion of the committee that the existing code of the Institute is more complete and explicit than the proposed joint code, and more unquestionable in its interpretation. This recommendation was also approved by the Board of Directors.

Committee on Safety Codes.—The Committee has cooperated with the Electrical Committee of the National Fire Protection Assoc. by having representatives on its subcommittee on Industrial Applications, and by the suggestion of certain ways in which the work of that Association can be more closely related to that of the A. I. E. E. The Institute is also represented by a member of this Committee in the Electrical Safety Conference Section Committee on Safety Code for Electric Power Control.

American Committee on Electrolysis.—The Institute's representatives on the American Committee on Electrolysis have attended all meetings of the Committee held during the year 1921, the last one of which occurred on May 3, 1921. The great interest taken in the work was evidenced by the fact that all of the organizations constituting the committee were represented, there being present 24 out of the 27 representatives.

At this meeting the reports of the various subcommittees were thoroughly discussed and unanimously adopted. These reports were then referred to an editing committee and, together with an introduction by the Chairman, published about October 21, 1921, as the Second Report of the Committee. They are being distributed through the A. I. E. E. in the same manner that the First Report was handled.

While the main committee has been inactive since the May 3, 1921 meeting, the work of the Research subcommittee is going actively forward.

Board of Examiners.—The Board of Examiners during the year held eleven meetings, averaging about three hours each. It considered and referred to the Board of Directors a total of 3420 applications for admission or transfer to the higher grades. This is a decrease of about 21% from the record figures of last year and is undoubtedly accounted for by the industrial depression from which the country suffered during the year.

During the early part of the year a code of practise

was drawn up by the Board giving the consensus of opinion on the various types of doubtful cases which arise. This code was adopted by the Examiners as a guide for future decisions.

APPLICATIONS FOR ADMISSION

Recommended for grade of Associate......	1662	
Not recommended........................	4	1666
Recommended for grade of Member.......	111	
Not recommended for admission to this grade..............................	46	157
Recommended for grade of Fellow..........	1	
Not recommended for admission to this grade..............................	5	6
Recommended for enrolment as Students...	1390	
Not recommended for enrolment...........	1	1391

APPLICATIONS FOR TRANSFER

Recommended for grade of Member........	131	
Not recommended for transfer to this grade	38	169
Recommended for grade of Fellow.........	21	
Not recommended for transfer to this grade	10	31
Total number of applications considered....		3420
Applications reconsidered.................		4
Total....................................		3424

Membership.—The results of the Membership Committee's efforts this year should be considered excellent in view of the period of industrial depression through what the country has been passing. The larger Sections of the Institute located in manufacturing centers felt the effect of business curtailment most sharply, twelve of the smaller Sections on the other hand exceeded last year's figures.

The total applications received were 1748 as compared with 2442 last year and 1596 the year before. The accompanying table shows the changes in membership in detail.

	Honorary Member	Fellow	Member	Associate	Total
Membership, April 30, 1921..	6	541	1,903	10,765	13,215
Additions:					
Transferred.............		23	146		
New Member Qualified....	1	1	114	1,646	
Reinstated..............		2	9	39	
Deductions:					
Died....................	1	5	11	45	
Resigned................		3	20	187	
Transferred.............			14	155	
Dropped.................		1	30	461	
Membership, April 30, 1922..	6	558	2,097	11,602	14,263

Net increase in Membership during the year.......................... 1048

Deaths.—The following deaths have occurred during the year.

Honorary Member: E. A. Budde.

Fellows: Wilson L. Campbell, Warren H. Fiske, R. T. E. Lozier, L. S. Randolph, Edward B. Rosa.

Members: Francis B. Crocker, Charles R. Cross, Leo Daft, W. F. Doherty, Roland S. Feud, Alexander M. Gray, George G. Grower, Peter C. Hewitt, Llewelyn Owen, Richard Pfund, James A. Walton.

Associates: Joel E. Anderson, Walter E. Aymonds, Milton P. Baker, William E. Baker, James H. Becker, Rayner M. Bedell, Joseph E. Biggs, Winthrop G. Bushnell, Dean B. Cobb, Harry L. Darrah, S. I. Felder, Wm. Lee Fitzpatrick, Clark W. Francy, Alonzo Gartley, Frank T. Gash, C. M. Gear, Carl F. Grimm, Henry Harvie, Percy C. Henry, Earl S. James, A. Pinto Joseph, Shuso Kawado, Edwin W. Kelly, Frederick A. Keyes, Joseph F. Krause, Walter A. Leason, W. W. Lighthipe, Myron Manwaring, Robert McKay, Ferdinand C. Miller, Edward S. Morrell, Fred C. Muench, Charles A. Rohr, Earl E. Sayre, Leon H. Scherck, Albert C. Schweizer, Harry M. Steven, Albert Taylor, Willis H. Trenner, Alfred R. Van Horn, Arthur S. Wheeler, B. D. Wilber, J. F. Wilson, Noble A. Wolfe, Roy C. Zoll.

Total deaths, 62.

Employment Service.—The employment service which has been maintained for many years at Institute headquarters and which during the latter part of 1918 was coordinated with the similar service of the other Founder Societies, was transferred to the auspices of the newly organized American Engineering Council on January 1, 1921 upon the recommendation of the secretaries, and the Joint Finance Committee, of the four Founder Societies.

In addition to a direct service, the Bureau prepares an engineering service bulletin which is published each month in the Institute JOURNAL and it has served to place many members in positions of responsibility, both in this country and abroad. The bulletin is subdivided into two parts: one containing announcements of vacancies; and the other containing lists of men available, with condensed records of their experience. All announcements are published without charge either to the employers or to the members of the Institute seeking positions.

With a view to increasing the scope and value of the Bureau a volunteer committee, composed of engineers registered with the bureau, was organized early in the summer of 1921 and has been at work almost continuously since that date systematically canvasing employers of engineers in and around New York, largely through the medium of personal calls, calling attention of these employers to the facilities offered by the bureau. This work has been productive of very satisfactory results and is also being undertaken in other cities.

Federated American Engineering Societies.—During the past year meetings of the Executive Board of American Engineering Council have been held as follows: April 16, 1921, Philadelphia; September 30, 1921, Washington; January 4 and 6, 1922, Washington; March 10, 1922, Chicago. In addition to this the first annual meeting of American Engineering Council was held January 5-6 at Washington.

The headquarters of the organization were early in 1921 transferred from New York to Washington and it is believed that one result of the first year's activities, as shown there, is a distinct field of usefulness for the organization; that distinct progress in securing the support and earning the confidence of the engineers of the country has been made, and the prestige of the profession—both in Government and in industrial circles—has been enhanced. It would seem that the Institute pursued a wise course in participating in the creation of this organization and of giving it whole hearted support.

Detailed accounts of the activities of American Engineering Council and of its Committees have been published throughout the year in the JOURNAL and will not be recapitulated here.

At the annual review of membership, the Institute became entitled to two additional members on American Engineering Council and to an additional member on the Executive Board. President McClellan, Past-Presidents Scott, Stillwell and Townley retain their seats on the Executive Board, the additional members being Messrs. Finney and Morehouse. In the Committee appointments, Professor Charles F. Scott has become Chairman of the Committee on Constitution and By-Laws, Mr. L. B. Stillwell, remains on the Committee on Public Affairs and Mr. Calvert Townley on the Committee on Finance.

United Engineering Society.—This Society performs for the national societies of Civil, Mining, Mechanical and Electrical Engineers, certain specific acts which are governed by contracts; the primary function of the United Society being to hold in trust and to administer for these societies the Engineering Societies Building, in which the headquarters of the National societies are located.

Extracts from the annual financial report of the United Engineering Society were published in the March 1922 JOURNAL.

Engineering Societies Library.—The library of the Institute is combined with the libraries of the national societies of Civil, Mining and Mechanical Engineers, administered as the "Engineering Societies Library" under the direction of the Library Board of the United Engineering Society; this board is composed of representatives of each of the four societies referred to above.

In order to place the facilities of the library at the disposal of persons residing at a distance from New York, a Library Service Bureau has been established, and a staff of expert searchers and translators is employed to cover almost any engineering topic, in the following manner: abstracting, translating, bibliographing, statistical searches and reports, searches for patent purposes, copying, preparing reference cards, etc.

An abstract of the annual report of the Engineering Societies Library covering the calendar year 1921 was published in the March 1922 JOURNAL.

Engineering Foundation.—Engineering Foundation is a trust fund established in 1914 by Ambrose Swasey, of Cleveland, Ohio, by gifts to United Engineering Society as a nucleus of a large endowment "for the furtherance of research in science and in engineering, or for the advancement in any other manner of the profession of engineering and the good of mankind." It is administered by the Engineering Foundation Board upon which the Institute and other national engineering societies are represented. The Board is a Department of United Engineering Society.

An abstract of the annual report of the Engineering Foundation for the seventh year, was published in the March 1922 JOURNAL.

Representatives.—The Institute has continued its representation upon various national committees and other local and national bodies with which it has been affiliated in past years, and has appointed representatives upon a number of new Sectional Committees of American Engineering Standards Committee. A complete list of representatives is published frequently in the JOURNAL.

Edison Medal.—The Edison Medal for 1921 which was awarded to Cummings C. Chesney "For Early Developments in Alternating-Current Transmission" was presented to Mr. Chesney with appropriate ceremonies at an evening session of the Midwinter Convention, February 16, 1922.

John Fritz Medal.—The John Fritz Medal Board of Award, which is composed of representatives of the national societies of Civil, Mining, Mechanical and Electrical Engineers, awarded the 1922 medal to Charles Eugene Schneider "for achievement in metallurgy of iron and steel; for development of ordnance, especially the 75 mm. gun, and for notable patriotic contribution to the winning of the war."

Visit of American Engineers to England and France.—A delegation of American engineers representing the four societies of Civil, Mining, Mechanical and Electrical Engineers visited England and France during the summer of 1921. The purpose of this visit was the presentation of the John Fritz Medal to Sir Robert Hadfield in London and Charles Eugene Schneider in Paris. The Institute was represented by

Dr. F. B. Jewett, Dr. A. E. Kennelly and Major General George O. Squier. The reception of the American delegation in both London and Paris was the occasion in both instances for the gathering of an unprecedented number of distinguished engineers and the keynote of most of the speeches was the international character of engineering, and the importance of developing intimate relations between the members of the professions of the different countries, leading to a better understanding between the nations.

Honorary Membership.—Marshal Foch was made an honorary member of the four national societies of Civil, Mining and Metallurgical, Mechanical and Electrical Engineers with impressive ceremonies on the afternoon of December 13, 1921 at the Engineering Societies Building, New York.

Finance Committee.—During the year the committee has held monthly meetings, has passed upon the expenditures of the Institute for various purposes, and otherwise performed the duties prescribed for it in the Constitution and By-laws.

Haskins and Sells, certified public accountants, have audited the books, and their report follows:

American Institute of Electrical Engineers,
33 West 39th Street,
New York.

Dear Sirs:

Pursuant to engagement, we have audited your books and accounts for the year ended April 30, 1922, and submit herewith our certificate and the following described exhibits:

Exhibit "A"—General Balance Sheet, April 30, 1922.

Exhibit "B"—Summary of Income and Profit & Loss for the Year ended April 30, 1922.

Yours truly,

HASKINS & SELLS

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

CERTIFICATE OF AUDIT

We have audited the books and accounts of the American Institute of Electrical Engineers for the year ended April 30, 1922, and

WE HEREBY CERTIFY that the accompanying General Balance Sheet properly exhibits the financial condition of the Institute at April 30, 1922, that the Summary of Income and Profit & Loss for the year ended that date is correct, and that the books of the Institute are in agreement therewith.

HASKINS & SELLS

NEW YORK,
May 15, 1922.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

EXHIBIT A. GENERAL BALANCE SHEET, APRIL 30, 1922

ASSETS

REAL ESTATE:			
One-Fourth Interest in United Engineering Society's Land, Building and Building Equipment, 25 to 33 West 39th Street, (Depreciation carried on Books of United Engineering Society).			$489,785.17
EQUIPMENT:			
Library—Volumes and Fixtures		$40,374.43	
Works of Art, Paintings, etc.		3,001.35

E. E. F. Creighton, John B. Klumpp, Elmer A. Sperry,
H. P. Davis, M. G. Lloyd, Schuyler Skaats Wheeler,
W. A. Del Mar, John B. Whitehead.

TECHNICAL COMMITTEES

EDUCATIONAL

C. E. Magnusson, Chairman,
W. C. Bauer, Charles S. Howe, R. F. Schuchardt,
Edward Bennett, John C. Parker, W. L. Upson,
C. R. Dooley, G. H. Pfeif, Wm. R. Work.
H. W. Price.

ELECTRICAL MACHINERY

B. A. Behrend, Chairman,
A. S. McAllister, Secretary,
B. L. Barns, V. A. Fynn, A. S. McAllister,
R. E. Brown, David Hall, F. D. Newbury,
James Burke, H. U. Hart, Philip Torchio,
G. Faccioli, V. Karapetoff, Herman L. Wallau,
W. J. Foster, Paul Lincoln, R. B. Williamson.

ELECTROCHEMISTRY AND ELECTROMETALLURGY

Lawrence Addicks, Chairman,
F. G. Clark, Carl Hering, W. H. Powell,
I. R. Edmands, L. E. Imlay, J. A. Seede,
James J. Farley, F. A. Lidbury, J. L. Yardley.

ELECTROPHYSICS

F. W. Peek, Jr., Chairman,
H. D. Arnold, J. C. Clark, E. P. Hyde,
E. F. Burton, C. P. Eldred, Chester W. Rice,
L. W. Chubb, Charles Fortescue, H. B. Smith.
Roy S. Glasgow,

INDUSTRIAL AND DOMESTIC POWER

W. C. Yates, Chairman,
P. H. Adams, Charles D. Fawcett, A. C. Lanier,
H. W. Cope, C. T. Guildford, M. J. McHenry,
W. E. Date, Henry D. James, A. G. Pierce,
E. D. Doyle, Fraser Jeffrey, H. P. Reed,
C. W. Drake, W. C. Kalb, Leo Schirtzinger,
H. W. Eastwood, C. W. Kincaid, Carl F. Scott.

INSTRUMENTS AND MEASUREMENTS

F. V. Magalhaes, Chairman,
C. W. Baker, F. P. Cox, G. A. Sawin,
P. A. Borden, E. D. Doyle, H. B. Smith,
Wm. M. Bradshaw, A. L. Ellis, Irving B. Smith,
H. B. Brooks, H. S. Vasser.

IRON AND STEEL INDUSTRY

E. S. Jefferies, Chairman,
F. B. Crosby, R. B. Gerhardt, G. E. Stoltz,
Gordon Fox, K. A. Pauly, Wilfred Sykes,
Eugene Friedlaender, D. M. Petty, F. H. Woodhull.
Wm. T. Snyder,

LIGHTING AND ILLUMINATION

G. H. Stickney, Chairman,
G. N. Chamberlin, W. T. Dempsey, Charles F. Scott,
A. B. Cooper, R. C. Powell, B. E. Shackelford,
J. R. Cravath, W. D'A. Ryan, W. M. Skiff.

MARINE

Arthur Parker, Chairman,
L. C. Brooks, Secretary,
J. B. Bassett, Wm. Hetherington, Jr. I. H. Osborne,
R. A. Beekman, H. L. Hibbard, G. A. Pierce, Jr.
Eskil Berg, J. S. Isdale, S. M. Robinson,
Maxwell W. Day, William F. James, H. M. Southgate,
David D. Faris, C. A. Jones, W. E. Thau,
E. G. Gallagher, C. S. McDowell, E. P. Townsend,
H. Franklin Harvey, Jr. W. E. Meschenmoser, A. E. Waller,
F. W. Wood.

MINES

Graham Bright, Chairman,
Willard C. Adams, L. C. Ilsley, W. F. Schwedes,
R. T. Andrae, G. M. Kennedy, F. L. Stone,
M. C. Benedict, R. L. Kingsland, W. A. Thomas,
H. W. Eales, A. B. Kiser, C. D. Woodward.

POWER STATIONS

R. F. Schuchardt, Chairman,
H. A. Barre, H. W. Eales, I. E. Moultrop,
J. T. Barron, F. C. Hanker, F. D. Newbury,
A. E. Bauhan, P. Junkersfeld, A. B. Stitzer,
E. T. Brandon, W. H. Lawrence, H. R. Summerhayes,
D. H. Braymer, H. P. Liversidge, R. B. Williamson.

PROTECTIVE DEVICES

H. R. Woodrow, Chairman,
G. H. Bragg, E. M. Hewlett, A. G. Pierce,
P. H. Chase, F. L. Hunt, N. L. Pollard,
W. H. Cole, J. B. MacNeill, F. E. Ricketts,
L. N. Crichton, John C. Martin, D. W. Roper,
F. C. Hanker, A. A. Meyer, E. R. Stauffacher,
S. E. M. Henderson, W. H. Millan, E. C. Stone,
E. A. Hester, John B. Taylor.

TELEGRAPHY AND TELEPHONY

Donald McNicol, Chairman,
O. B. Blackwell, C. E. Davies, W. O. Pennell,
C. W. Burkett, F. E. d'Humy, Stanley Rhoads,
G. A. Cellar, D. H. Gage, Edgar Russell,
R. E. Chetwood, H. Hulatt, A. E. Silver,
L. W. Chubb, F. H. Kroger, A. B. Smith,
E. H. Colpitts, L. F. Morehouse, F. A. Wolff.

TRACTION AND TRANSPORTATION

H. M. Brinckerhoff, Chairman,
A. H. Babcock, E. B. Katte, N. W. Storer,
Reinier Beeuwkes, John Murphy, R. W. Stovel,
R. H. Dalgleish, Hugh Pattison, H. M. Warren,
W. G. Gordon, W. B. Potter, F. E. Wynne,
Selby Haar, Ralph H. Rice, C. W. Young.
Guy A. Richardson,

TRANSMISSION AND DISTRIBUTION

Edward B. Meyer, Chairman,
R. W. Atkinson, John H. Finney, C. N. Rakestraw,
F. G. Baum, L. M. Klauber, C. C. Robinson,
Wallace S. Clark, J. A. Koontz, Jr., D. W. Roper,
W. H. Cole, W. S. Lee, C. H. Shaw,
W. A. Del Mar, G. J. Newton, A. E. Silver,
H. C. DonCarlos, A. M. Perry, W. K. Vanderpoel,
F. M. Farmer, C. T. Wilkinson.

A. I. E. E. Representatives

ON AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE, COUNCIL

F. B. Jewett, John B. Taylor.

ON AMERICAN BUREAU OF WELDING

W. L. Merrill.

ON AMERICAN COMMITTEE ON ELECTROLYSIS

Bion J. Arnold, N. A. Carle, F. N. Waterman.

ON AMERICAN ENGINEERING COUNCIL OF THE FEDERATED AMERICAN ENGINEERING SOCIETIES

Comfort A. Adams, W. A. Layman, Charles S. Ruffner,
A. W. Berresford, *William McClellan, *Charles F. Scott,
*John H. Finney, *L. F. Morehouse, *L. B. Stillwell,
F. L. Hutchinson, L. T. Robinson, Calvert Townley.
*Members of Executive Board.

ON AMERICAN ENGINEERING STANDARDS COMMITTEE

H. M. Hobart, Harold Pender, C. E. Skinner.
L. T. Robinson (Alternate)

ON BOARD OF TRUSTEES, UNITED ENGINEERING SOCIETY

H. H. Barnes, Jr., Bancroft Gherardi, H. A. Lardner.

ON ENGINEERING FOUNDATION BOARD

Frank B. Jewett, E. W. Rice, Jr.

ON FRANCO-AMERICAN ENGINEERING COMMITTEE

A. M. Hunt, L. B. Stillwell.

ON JOHN FRITZ MEDAL BOARD OF AWARD

Comfort A. Adams, A. W. Berresford, Calvert Townley, Wm. McClellan,

ON LIBRARY BOARD OF UNITED ENGINEERING SOCIETY

Edward D. Adams, F. L. Hutchinson, Alfred W. Kiddle, E. B. Craft, W. I. Slichter.

ON NATIONAL FIRE PROTECTION ASSOCIATION, ELECTRICAL COMMITTEE

The chairman of the Institute's Committee on Safety Codes.

ON NATIONAL RESEARCH COUNCIL, ENGINEERING DIVISION

C. A. Adams, Frank B. Jewett, W. R. Whitney.

ON U. S. NATIONAL COMMITTEE OF THE INTERNATIONAL ILLUMINATION COMMISSION

A. E. Kennelly, C. O. Mailloux, Clayton H. Sharp.

WASHINGTON AWARD, COMMISSION OF

John Price Jackson, Charles F. Scott.

U. S. NATIONAL COMMITTEE OF THE INTERNATIONAL ELECTROTECHNICAL COMMISSION

C. O. Mailloux, President,
D. C. Jackson, Vice-President,
[1]James Burke, Vice-President,
C. H. Sharp, Secretary,

C. A. Adams,	H. W. Fisher,	L. T. Robinson,
P. G. Agnew,	H. M. Hobart,	Charles Robbins,
B. A. Behrend,	A. E. Kennelly,	D. B. Rushmore,
J. J. Carty,	B. G. Lamme,	C. F. Scott,
L. W. Chubb,	A. S. McAllister,	C. E. Skinner,
[1]C. L. Collens, 2d,	[4]Com. C. S. McDowell	[3]Gen. George O. Squier
W. A. Del Mar,	W. S. Moody,	S. W. Stratton,
[1]A. L. Doremus,	A. H. Moore,	Elihu Thomson,
Gano Dunn,	R. W. E. Moore,	[2]C. L. Warwick,
W. C. Fish,	L. F. Morehouse,	R. B. Williamson.

[1]Representative of Electric Power Club.
[2]Representative of American Society for Testing Materials.
[3]Representative of War Department.
[4]Representative of Navy Department.

LIST OF SECTIONS

Name	Chairman	Secretary
Akron	H. C. Stephens	R. B. Fisher
Atlanta	J. E. Mellett	H. N. Pye
Baltimore	Douglas Burnett	Vern E. Alden
Boston	Lewis W. Abbott	F. S. Dellenbaugh
Chicago	M. M. Fowler	E. H. Bangs
Cincinnati	J. D. Lyon	Leo Schirtzinger
Cleveland	I. H. Van Horn	G. B. Schneeberger
Columbus	F. C. Caldwell	F. C. Nesbitt
Connecticut	C. F. Scott	A. E. Knowlton
Denver	B. C. J. Wheatlake	R. B. Bonney
Detroit-Ann Arbor	A. S. Albright	E. L. Bailey
Erie	C. H. Schum	P. B. Mansfield
Fort Wayne	R. H. Chadwick	A. B. Campbell
Indianapolis-Lafayette	D. C. Pyke	J. W. Hannon
Ithaca	J. G. Pertsch, Jr.	G. F. Bason
Kansas City	C. J. Larsen	Glenn O. Brown
Lehigh Valley	Charles Hodge	H. G. Harvey
Los Angeles	Herbert H. Cox	J. N. Kelman
Lynn	F. J. Rudd	D. F. Smalley
Madison	C. B. Hayden	H. M. Crothers
Milwaukee	F. J. Mayer	P. B. Harwood
Minnesota	W. T. Ryan	F. A. Otto
New York	Farley Osgood	H. A. Pratt
Oklahoma	F. W. Insull	A. D. Stoddard
Panama	R. D. Prescott	M. P. Benninger
Philadelphia	P. H. Chase	R. B. Mateer
Pittsburgh	H. W. Smith	E. C. Stone
Pittsfield	I. H. Sclater	A. C. Stevens
Portland, Ore	W. C. Heston	D. W. Proebstel
Providence	Nicholas Stahl	F. N. Tompkins
Rochester	Sidney Alling	A. M. Stetler
St. Louis	C. C. Robinson	J. M. Chandler
San Francisco	W.P.L'Hommedieu	G. Jones
Schenectady	S. H. Blake	C. W. Fick
Seattle	J. P. Growdon	E. S. Code
Southern Virginia	———	———
Spokane	L. J. Pospisil	H. L. Melvin
Syracuse	E. T. Moore	Elmer E. Strong
Toledo	G. Southern	Max Neuber
Toronto	W. P. Dobson	P. A. Borden
Urbana	E. H. Waldo	H. A. Brown
Utah	P. P. Ashworth	C. R. Higson
Vancouver	John R. Read	F. W. McNeill
Washington, D. C.	A. R. Cheyney	W. A. E. Doying
Worcester	G. M. Hardy	Dean J. Locke

LIST OF BRANCHES

Name and Location	Chairman	Secretary
Alabama Poly. Inst., Auburn, Ala.	V. C. McIlvaine	J. M. Dickinson
Alabama, Univ. of, University, Ala.	D. H. Davis	W. W. Bauder
Arizona, Univ. of, Tucson, Ariz	J. Mellen	H. W. Holt
Arkansas, Univ. of, Fayetteville, Ark.	J. W. Booker	B. R. Askew
Armour Inst. of Tech., Chicago, Ill.	R. P. Burns	L. E. Grube
Brooklyn Poly. Inst., Brooklyn, N. Y.	H. Ladner	O. Engstrom
Bucknell Univ., Lewisburg, Pa.	F. T. Tingley	J. A. Ammerman
California Inst. of Tech., Pasadena, Cal.	O. R. Bulkley	L. J. Wells
California, Univ. of, Berkeley, Cal.	F. A. Polkinghorn	S. R. Ruby
Carnegie Inst. of Tech., Pittsburgh, Pa.	E. A. Brand	H. W. Bryan
Case School of Applied Science, Cleveland, O.	M. A. Hyde, Jr.	O. Henderson
Cincinnati, Univ. of, Cincinnati, O.	J. R. Petree	C. B. Hoffmann
Clarkson Coll. of Tech., Potsdam, N.Y.	R. L. Conboy	F. H. Fults
Clemson Agri. College, Clemson College, S. C.	J. R. Reardon	W. M. Clatworthy
Colorado State Agri. Coll., Ft. Collins, Colo.	P. Garrett	F. Ayres
Colorado, Univ. of, Boulder, Colo.	T. D. Sylvester	F. B. Doolittle

LIST OF BRANCHES (*Continued*)

Name and Location	Chairman	Secretary
Cooper Union, New York	W. A. Colledge	A. L. Duna
Drexel Institute, Philadelphia, Pa.	D. Buchanan	R. E. Sidwell
Georgia School of Tech., Atlanta, Ga.	C. D. LeBey	E. V. Wallace
Iowa State College, Ames, Ia.	C. H. Hoper	G. L. Seaton
Iowa, Univ. of, Iowa City, Ia.	E. Paintin	P. F. Bowman
Kansas State College, Manhattan, Kans.	L. O. Sinderson	K. C. Frank
Kansas, Univ. of, Lawrence, Kans.	E. S. Miner	C. A. Harris
Kentucky, Univ. of, Lexington, Ky.	T. M. Riley	R. H. Craig
Lafayette College, Easton, Pa.	G. A. Moore	P. J. Brown
Lehigh Univ., South Bethlehem, Pa.	E. F. DeTurk	W. F. Tait
Lewis Institute, Chicago, Ill.	E. Millison	E. R. Lindberg
Maine, Univ. of, Orono, Me.	F. Blake	C. R. Lappin
Marquette University, Milwaukee, Wis.		
Massachusetts Inst. of Tech., Cambridge, Mass.	L. R. Culver	L. W. Codding
Michigan Agri. Coll., East Lansing, Mich.	E. A. Pryce	J. G. Lauffer
Michigan, Univ. of, Ann Arbor, Mich.	F. D. Johnston	A. J. Martin
Milwaukee, Engg. School of, Milwaukee, Wis.	B. A. Bovee	L. F. Berg
Minnesota, Univ. of, Minneapolis, Minn.	H. A. Dahl	E. S. Bjonerud
Missouri, Univ. of, Columbia, Mo.	A. C. Lanier	F. W. Hubbard
Montana State Coll., Bozeman, Mont.	W. W. Husemeyer	R. D. Sloan
Nebraska, Univ. of, Lincoln, Neb.	O. J. Ferguson	O. E. Edison
North Carolina State College, West Raleigh, N. C.	E. E. Inscoe	O. L. Bradshaw
North Carolina, Univ. of, Chapel Hill, N. C.	R. M. Casper	R. G. Koontz
North Dakota, Univ. of, University, N. D.	E. L. Hough	S. W. Winje
Notre Dame, Univ. of, Notre Dame, Ind	J. R. Fitzgerald	W. L. Shilts
Ohio Northern Univ., Ada, O.	L. A. Kille	I. W. Knapp
Ohio State Univ., Columbus, O.	W. M. Kellogg	O. McGinnis
Oklahoma A. & M. Coll., Stillwater, Okla.	C. S. Folk	I. T. Knight
Oklahoma, Univ. of, Norman, Okla.	W. Seifert	R. E. Thornton
Oregon Agri. Coll., Corvallis, Ore.	W. D. Olson	C. T. Hurd
Pennsylvania State College, State College, Pa.	H. F. Pearson	J. H. Warner
Pennsylvania, Univ. of, Philadelphia, Pa.	E. M. Heidelbaugh	J. B. Clothier, Jr.
Pittsburgh, Univ. of, Pittsburgh, Pa.	C. A. Anderson	A. F. Robert
Purdue Univ., Lafayette, Ind.	N. C. Pearcy	F. R. Finehout
Rensselaer Poly. Inst., Troy, N. Y.	W. J. Williams	L. S. Inskip
Rose Poly. Inst., Terre Haute, Ind.	F. M. Stone	C. B. Wilson
Rutgers College, New Brunswick, N. J.	H. Goldsmith	T. B. Brown
Southern California, Univ. of, Los Angeles, Cal.	R. H. Cockfield	E. B. Heath
Stanford Univ., Stanford University, Cal.	H. E. Becker	V. Marquis
Swarthmore Coll., Swarthmore, Pa.	S. T. McAllister	E. Palmer
Syracuse Univ., Syracuse, N. Y.	E. A. Ryan	A. P. Fugill
Texas A. & M. Coll., College Station, Tex.	H. A. Dougherty	G. A. Hollowell
Texas, Univ. of, Austin, Tex.	C. H. Marshall	F. J. Domingues
Virginia Military Inst., Lexington, Va.	W. P. Venable	R. P. Martin
Virginia Poly. Inst., Blacksburg, Va.	D. P. Minichan	T. F. Cofer
Virginia, Univ. of, University, Va.	M. H. Morgan	N. W. Brown
Washington, Sate Coll. of, Pullman, Wash.	E. Johnson	O. J. Ball
Washington Univ., St. Louis, Mo.	F. W. Schramm	E. H. Burgess
